The transverse spinous processes constitute the junction of each pedicle and the lamina on each side of a vertebra. They project laterally and posteriorly and form points of attachments for muscles and ligaments. The posterior spinous process is formed by the fusion of the posterior lamina and serves as an attachment site for muscles and ligaments.

The cervical spine includes the first seven bones of the vertebral column and its supporting structures. In addition to protecting the cervical spinal cord, the cervical spine supports the weight of the head and permits a high degree of mobility in multiple planes. The atlas (C1) and axis (C2) are uniquely suited to allow for rotational movement of the skull **FIGURE 12-17**.

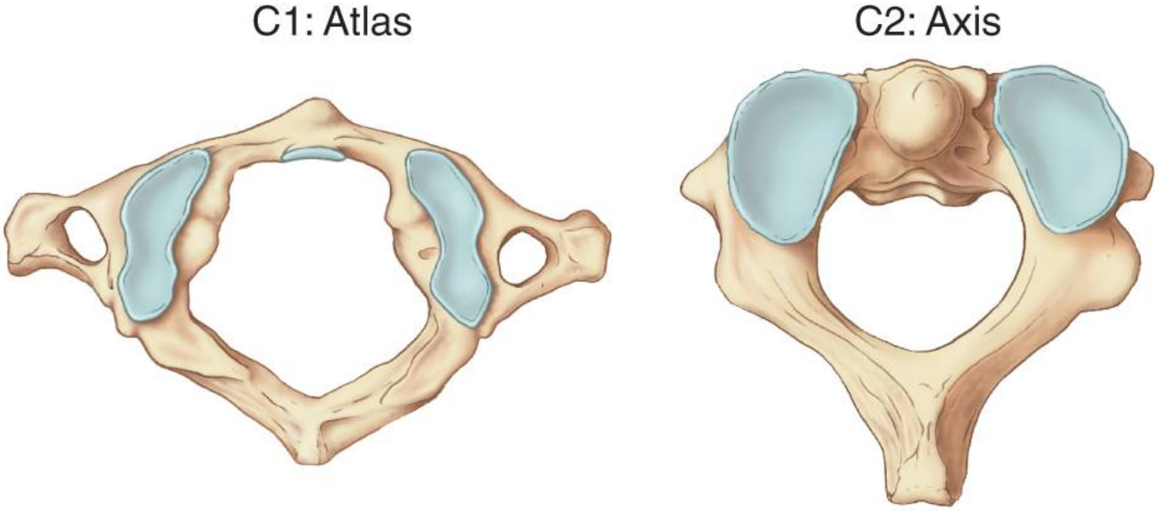

FIGURE 12-17 Superior view of the structure of the atlas and axis.

© Jones & Bartlett Learning.

The thoracic spine usually consists of 12 vertebrae in addition to the supporting muscles and ligaments found in the vertebral column; the thoracic spine is further stabilized by the rib attachments. The spinous processes in this section of the spine are slightly larger, reflecting their role as attachment points for the muscles that hold the upper body erect and assist with the movement of the thoracic cavity during respiration. In patients with more than five lumbar vertebrae, there will be fewer than 12 thoracic vertebrae. Although this may seem insignificant, for the purposes of radiographic interpretation, thoracic and lumbar bodies are usually counted together rather than separately.

The lumbar spine, which includes the five largest bones in the vertebral column, is integral in carrying a large portion of the upper body weight. It is especially susceptible to injury because of this weight-bearing capacity.

The sacrum is composed of five fused vertebrae that form the posterior plate of the pelvis. The coccyx is made up of three to five small fused vertebrae. Coccyx injuries, although often extremely painful, are typically clinically insignificant.

Each vertebra is separated and cushioned by intervertebral disks that limit bone wear and act as shock absorbers. As the body ages, these disks lose water content and become thinner, causing the height loss associated with aging. Stress on the vertebral column may cause a disk to herniate into the spinal canal, resulting in a spinal cord or nerve root injury **FIGURE 12-18**.

Although the vertebrae must be able to stabilize the spinal cord, the muscles, tendons, and ligaments that connect the vertebrae do allow the vertebral column a degree of flexion and extension. The vertebral column can sustain normal flexion and extension of 60% to 70% without stressing the spinal cord. Flexion or extension beyond those limits may damage structural ligaments and allow excess vertebral movement that could expose the spinal cord to injury.

Spinal Cord

The spinal cord transmits nerve impulses between the brain and the rest of the body. Located at the base of the brain, it represents the continuation of the CNS. This bundle of nerve fibers leaves the skull through a large opening at its base called the **foramen magnum**. The large size of the foramen magnum relative to other foramina makes it a common location for brain herniation.

The spinal cord extends from the base of the skull to L2; here it separates into the **cauda equina**, a collection of individual nerve roots. Thirty-one pairs of spinal nerves arise from the different segments of the spinal cord; each pair is named according to its corresponding segment.

A cross section of the spinal cord **FIGURE 12-19** reveals a butterfly-shaped central core of gray matter that is composed of neural cell bodies and synapses. This gray matter is divided into posterior (dorsal) horns, which carry sensory input, and anterior (ventral) horns, which innervate the motor nerve of that segment. Surrounding the gray matter on each side are three columns of peripheral white matter composed of myelinated ascending and descending fiber pathways. Messages are relayed to and from the brain through these spinal tracts.

Description

The brainstem connects the spinal cord to the remainder of the brain. All but two of the 12 cranial nerves exit from the brainstem. Specific groups of nerves are named based on their source of origin and point of termination. Ascending tracts carry information to the brain, and descending tracts carry information to the rest of the body **TABLE 12-4**.

TABLE 12-4 Major Spinal Tracts

Spinal Tract	Function

Spinal Tract	**Function**
Anterior	
Anterior spinothalamic tracts (ascending)	Carry sensation of crude touch and pressure sensation to the brain
Lateral spinothalamic tracts (ascending)	Carry pain and temperature information
Spinocerebellar tracts (ascending)	Coordinate impulses necessary for muscular movements by carrying impulses from muscles in the legs and trunk to the cerebellum
Corticospinal tracts (descending)	Voluntary motor commands
Reticulospinal tracts (descending)	Muscle tone and sweat gland activity
Rubrospinal tracts (descending)	Muscle tone
Posterior	
Fasciculus gracilis and cuneatus	**Proprioception**, vibration, light touch, deep pressure, **two-point discrimination**, and **stereognosis**

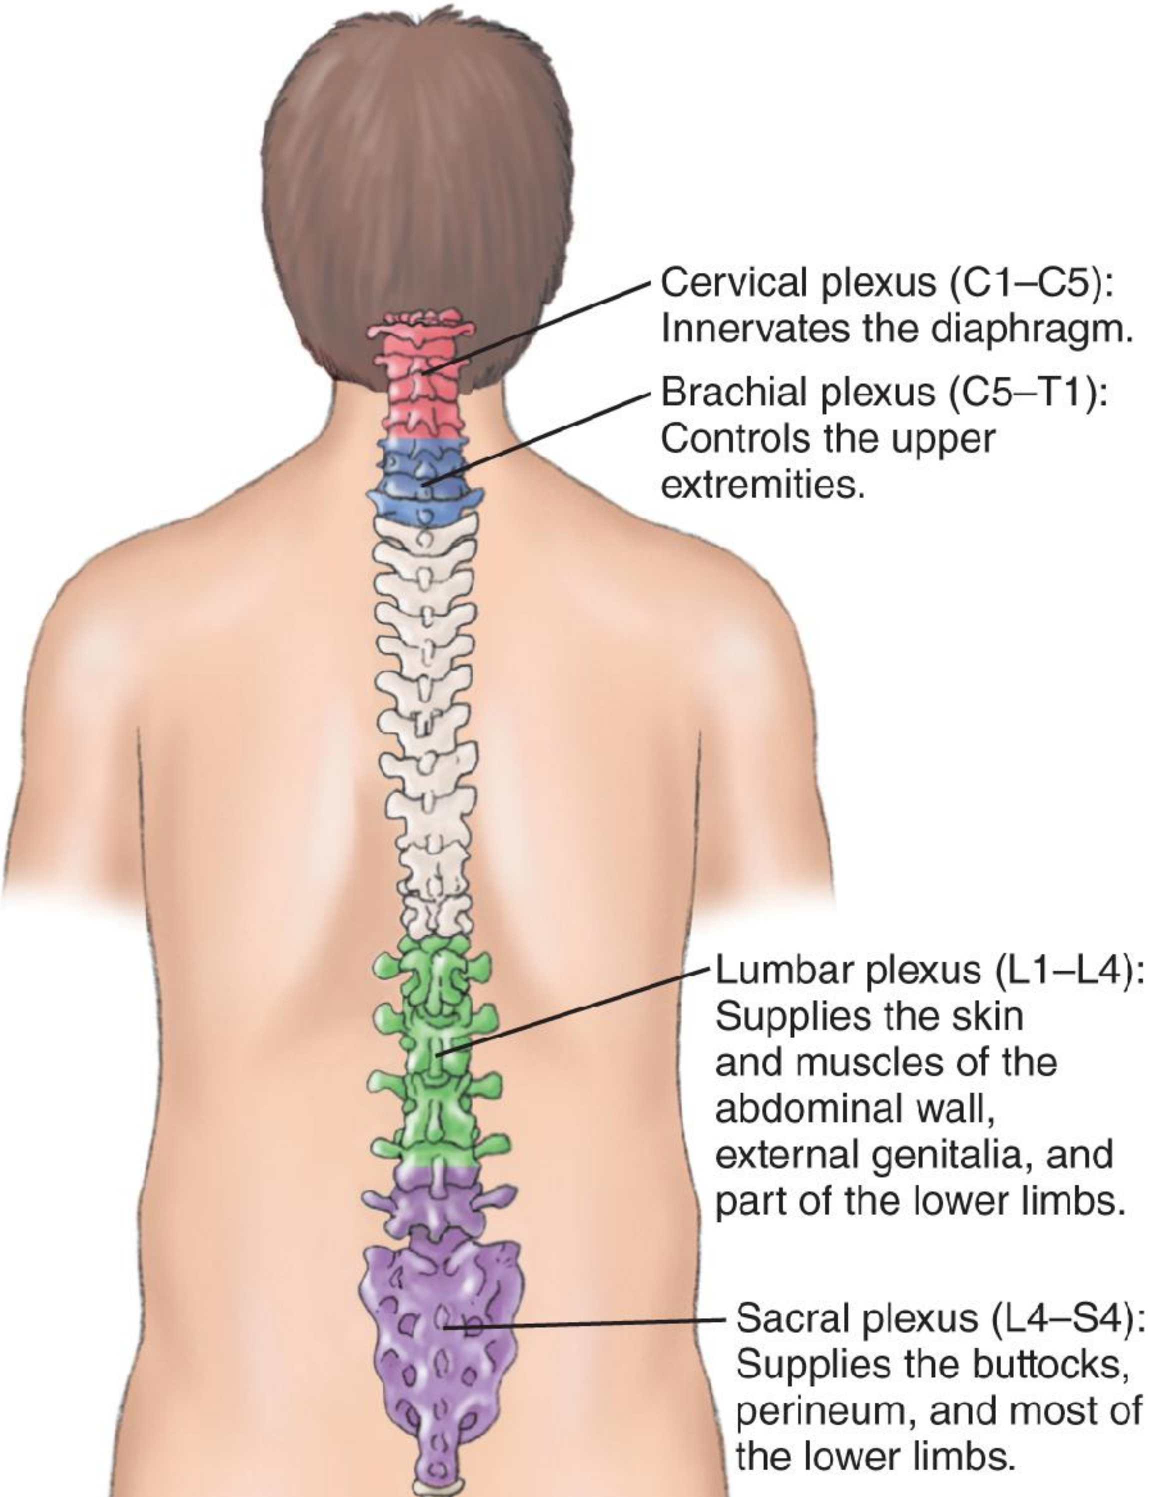
Peripheral Nervous System

Spinal Nerves

The 31 pairs of spinal nerves emerge from each side of the spinal cord and are named for the vertebral region and level from which they arise. The eight cervical roots perform different functions in the scalp, neck, shoulders, and arms. The 12 thoracic nerve roots have varying functions: The upper thoracic nerves supply muscles of the chest that help in breathing and coughing, whereas the lower thoracic nerves provide abdominal muscle control and are part of the sympathetic nervous system. The five lumbar nerve roots supply hip flexors and leg muscles, as well as provide sensation to the anterior legs. The five sacral nerves provide for bowel and bladder control, sexual function, and sensation in the posterior legs and rectum. The coccyx has a single nerve root.

Nerve roots occasionally converge in a cluster called a **plexus** that permits peripheral nerve roots to rejoin and function as a group **FIGURE 12-20**. For example, the cervical plexus includes C1 through C5; the phrenic nerve (C3 through C5) arises from this plexus and innervates the diaphragm. The brachial plexus (C5 through T1) joins nerves controlling the upper extremities; the main nerves arising from this plexus are the axillary, median, musculocutaneous, radial, and ulnar nerves. The lumbar plexus (L1 through L4) supplies the skin and muscles of the abdominal wall, external genitalia, and part of the lower limbs. The sacral plexus (L4 through S4) gives rise to the pudendal and sciatic nerves and supplies the buttocks, perineum, and most of the lower limbs.



Cervical plexus (C1–C5):
Innervates the diaphragm.
Brachial plexus (C5–T1):
Controls the upper extremities.
Lumbar plexus (L1–L4):
Supplies the skin and muscles of the abdominal wall, external genitalia, and part of the lower limbs.
Sacral plexus (L4–S4):
Supplies the buttocks, perineum, and most of the lower limbs.

FIGURE 12-20 Nerve roots converge in plexuses, allowing them to function as a group.

Description

Sympathetic Nervous System

The brain's hypothalamus controls the sympathetic nervous system. Information from the brain is transmitted through the brainstem and the cervical spinal cord, then exits at the thoracic and lumbar levels of the spine to reach the target structures. The thoracolumbar system provides sympathetic stimulation to the periphery largely through alpha and beta receptors. Alpha receptor stimulation induces contraction of smooth muscles in blood vessels and bronchioles. Beta receptors respond to stimulation by relaxing smooth muscles in blood vessels and bronchioles, and have chronotropic and inotropic effects on myocardial cells.

An SCI at or above the level of T6 may disrupt the flow of sympathetic communication. Loss of sympathetic stimulation can disrupt homeostasis and leave the body poorly equipped to deal with changes in its environment. Stimulation of sympathetic nerves without parasympathetic input can cause sympathetic overdrive, resulting in autonomic dysreflexia.

Parasympathetic Nervous System

The parasympathetic nervous system includes fibers arising from the brainstem and upper spinal cord that carry signals to organs of the abdomen, heart, lungs, and the skin above the waist. The vagus nerve (or 10th cranial nerve) travels from its origins outside of the medulla to the heart via the carotid arteries; thus, vagal tone remains intact following a spine injury. When the sympathetic nerves are stimulated and produce autonomic dysreflexia, the parasympathetic nerves attempt to control the rapidly increasing BP by slowing the heart rate. Parasympathetic nerves that supply the reproductive organs, pelvis, and legs begin at the sacral level (S2 through S4). The parasympathetic nervous system is also responsible for stimulating salivary gland secretions and peristalsis, micturition (urination), and sexual arousal (erection). Disruption of the lower parasympathetic nerves in the sacrum results in the loss of bowel/bladder tone and sexual function.

Axonal Transport

The intracellular transport of protein and organelle materials is essential for all mammalian cells, especially the neurons. Most neuron cell bodies have dendrites on one end and an axon on the opposite end. Because most neuronal proteins are synthesized in the cell body, mechanisms are required to direct their transport along the axon or along the dendrite. Additionally, the distance over which materials have to be moved in the nervous system far exceeds the distances in other cell types; the length of a human motor neuron can span more than 1 m. Finally, even within an individual axon, materials being transported must be targeted to specific compartments.

The feature of neurons that supports the delivery of cellular components to the appropriate site of action is a long-range microtubule-based transport system. This system is composed of two key elements: molecular motors, which drive the transport of cellular components, and microtubules, which direct cellular components to the correct site. The type of molecular motor present determines the direction of transport, either away from the cell body and toward the synapse or toward the cell body.

Axonal transport is commonly divided into fast and slow axonal transport based on the speed of the bulk cargo movement. Cellular components such as vesicles and mitochondria move at fast axonal transport speeds, whereas cytoskeleton components move at slow axonal transport speeds.

When transport of materials becomes disrupted, disease can result. Indeed, axonal and cell body accumulations of organelles and other proteins are hallmark pathologies for many human neurodegenerative diseases, such as Alzheimer and related diseases, Parkinson disease, and amyotrophic lateral sclerosis.

Local anesthetics are medications that cause reversible local anesthesia and loss of nociception (pain sensation). They can also be used on specific nerve pathways (nerve block) to produce analgesia and paralysis. Local anesthetics belong to one of two drug classes, aminoamide or aminoester local anesthetics, which differ in terms of the chemical linkage (amide linkage or ester linkage) between the lipophilic part and the intermediate chain of the molecule. Local anesthetics act mainly by inhibiting sodium influx through sodium-specific ion channels in the neuronal cell membrane. When this occurs, an action potential cannot be generated and signal conduction is inhibited.

Neurologic Examination

Critical patients with neurologic complications present a variety of examination and management challenges during care and transport. Examination of the patient with neurologic dysfunction is the essential starting point for the entire patient care process.

Some specific neurologic tests may or may not be performed in the critical care transport environment. With interfacility transports, many of these tests will have been done as part of the initial assessment at the hospital. In some cases, the CCTP may perform these tests if the initial assessment was shortened by time pressure or if the CCTP has time during transport, but some may not be possible to carry out in cramped quarters. Which evaluations are performed depends on the patient's condition; if they are needed, the CCTP will perform them as appropriate. Regardless of whether the CCTP actually performs all possible exams, transport team members must know how to interpret these findings and alter their care based on the results.

Mental and Emotional Status

The mental/emotional component of the neurologic examination assesses the patient's ability to understand and interact with the environment. Specific areas tested in this component include level of consciousness; general behavior; and thought processes, including memory, attention and concentration, abstract thought, and judgment. Not every component of the examination will be relevant in all critical care situations and, therefore, may not be tested. Nevertheless, the CCTP should understand how all components are integrated and how they influence decision making for patient care.

Assessment of the level of consciousness (LOC) is an extremely important component of the neurologic examination. The CCTP should assess the LOC of all patients, considering each patient's ability to perform elements of the assessment and modifying assessment techniques as necessary. For example, intubated patients who are otherwise awake and aware may gesture or write answers to questions instead of verbalizing them.

Arousal and awareness are the most important qualitative markers in assessing LOC. They should be evaluated and documented repeatedly. *Arousal*, or the absence thereof, is the most basic measure of cognitive function. The evaluation of arousal is essentially an assessment of the patient's RAS and its connection with the thalamus and the cerebral cortex. Arousal may be described using either the AVPU scale **TABLE 12-5** or the Glasgow Coma Scale (GCS).

TABLE 12-5 AVPU Scale

Awake: eyes open spontaneously

Verbal: arouses to stimulation by voice

Painful: purposeful movement to a painful stimulus such as a pectoral pinch

Unresponsive: not responsive to any stimuli

© Jones & Bartlett Learning.

In most critical care settings, where time for gathering data may be limited, the GCS is commonly used to document and trend a patient's level of arousal. This scale evaluates three parameters: eye opening, verbalization, and movement. The best response for each category is recorded. A minimum score of 3 indicates a completely unresponsive patient, whereas a score of 15 indicates the patient is awake and alert. Generally, a GCS score of 7 or less indicates a coma. The GCS is discussed in greater detail in Chapter 11, *Trauma*.

Awareness denotes the content of consciousness, which is a higher-level function than arousal. It is described by terms such as disoriented, lethargic, or obtunded **TABLE 12-6**. In evaluating the patient's awareness, the CCTP should assess orientation to person, place, and time **TABLE 12-7**.

TABLE 12-6 Terms Used to Describe a Patient’s Awareness

Confusion: inability to think rapidly and clearly
Disorientation: confusion in reference to time, followed by place, and then self
Lethargy: limited spontaneous movement or speech; easy arousal with normal speech or touch; may not be oriented to person, place, or time
Obtundation: mild to moderate reduction in arousal with limited responses to the environment; falls asleep unless stimulated verbally or tactilely; answers questions with minimal response
Stupor: a condition of deep sleep or unresponsiveness from which the person may be aroused or caused to open eyes only by vigorous and repeated stimulation; response is often grabbing at or withdrawal from stimulus
Coma: no verbal response to the external environment or to any stimuli; noxious stimuli such as deep pain may or may not yield motor movement
Light coma: associated with purposeful movement on stimulation
Coma: associated with nonpurposeful movement only on stimulation
Deep coma: associated with unresponsiveness or no response to any stimulus

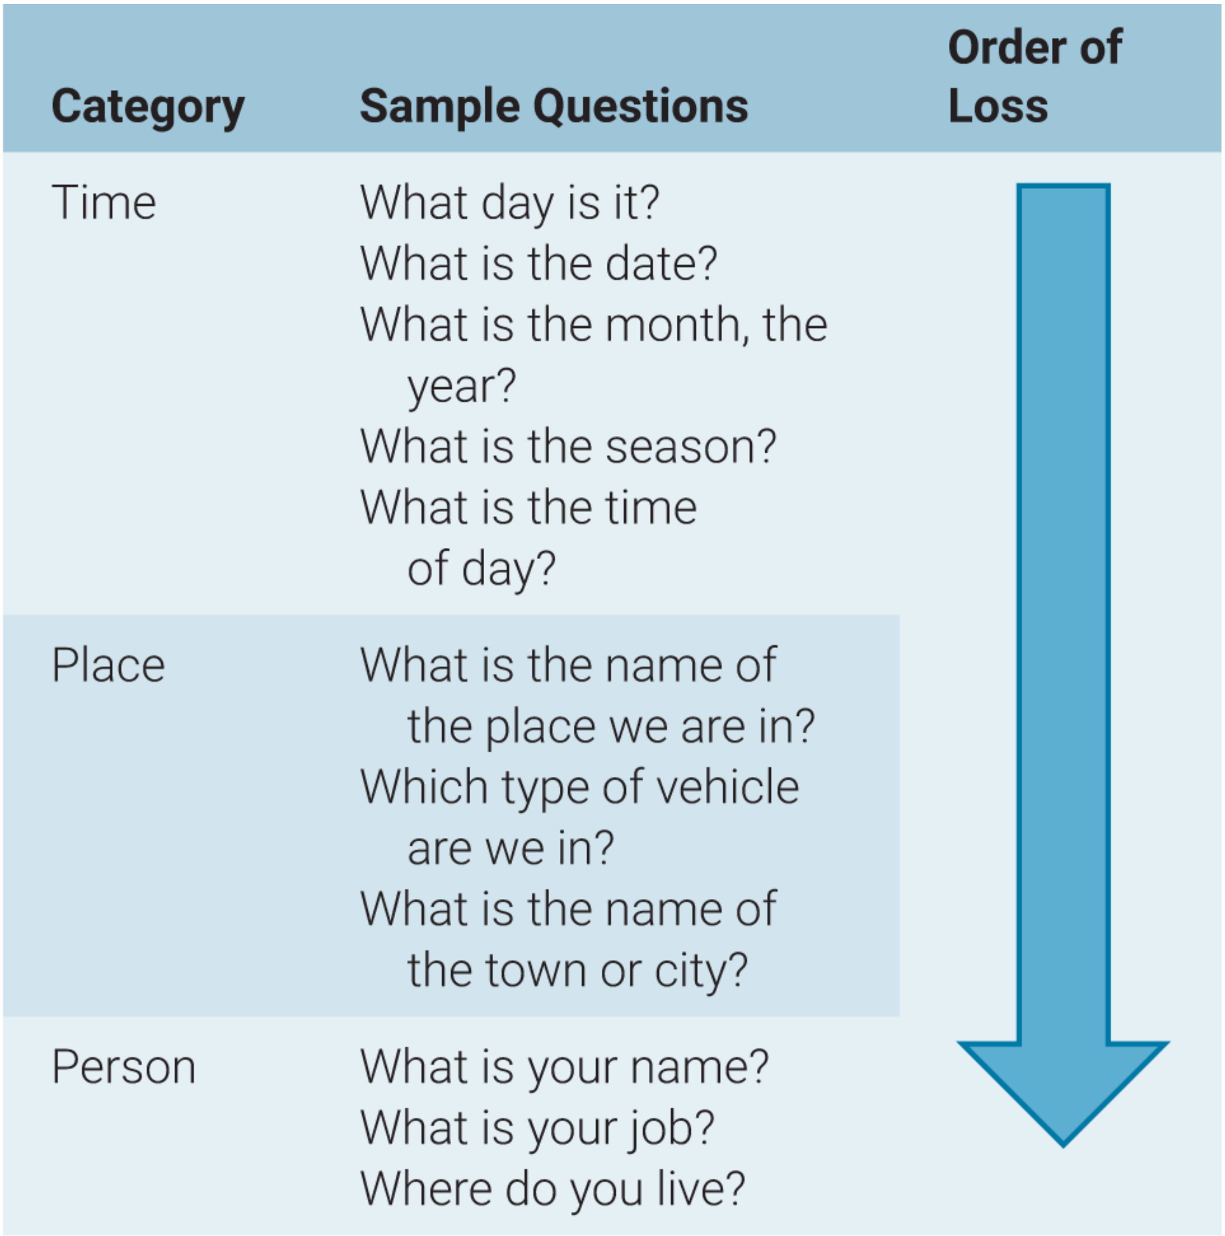
TABLE 12-7 Questions Pertaining to Patient Orientation



Category	Sample Questions	Order of Loss
Time	What day is it? What is the date? What is the month, the year? What is the season? What is the time of day?	↓
Place	What is the name of the place we are in? Which type of vehicle are we in? What is the name of the town or city?	
Person	What is your name? What is your job? Where do you live?	

© Jones & Bartlett Learning.

Description

Providers assess awareness by asking the patient to provide appropriate answers to a variety of questions. Findings may be documented as alert and oriented (A&O × 3, A&O 2/3, or A&O 1/3) or as awake, alert, and oriented (AAO × 3). The three aspects of awareness, or orientation, disappear in the order of time, then place, then person (self), as the patient becomes more disoriented. Changes in the patient's answers that indicate increasing confusion and disorientation may, therefore, be an early sign of neurologic dysfunction.

Simple observation is the primary tool used to assess the patient's behavior. General behavior is best assessed by observing gestures, facial expressions, mood, affect, and posture. During this component of the examination, family members or close friends may be able to help establish whether the patient's responses are normal or abnormal. A variety of neurologic pathologies—including pain, hypoxia, anxiety, and expanding intracranial lesions—may initially manifest through changes in general behavior.

Most critical care patients will not be able to undergo lengthy tests to assess their cognitive functioning. The **Mini-Mental State Examination** **TABLE 12-8** provides a simple, easily applied test of higher cognitive functions. It consists of a series of questions that test orientation, registration, attention and calculation, recall, and language. The highest possible score is 30 points; a score of less than 24 indicates cognitive dysfunction.

TABLE 12-8 Mini-Mental State Examination Components

Parameter	Task	Possible Points[a]
Orientation	Assign 1 point for correct answers to each of the following questions: • What is the time? Date? Day of the week? Month? Year? • What is the name of this country? State? County? Town? Hospital?	5 5
Registration	Name three objects arbitrarily. Assign 1 point for each object the patient repeats, in the correct order that you named them, on the first attempt. Encourage the patient, even with prompting, to repeat all three, so you can test recall later.	3

Parameter	Task	Possible Points[a]
Attention and calculation	Ask the patient to subtract 7 from 100, and then 7 from the result, and so forth through five iterations. Assign 1 point for each correct calculation.	5
Recall	Ask the patient to state the three objects listed during the registration test, assigning 1 point for each object recalled.	3
Language	Indicate two objects (a pencil and a watch). Assign 1 point for each object correctly named. Assign 1 point if the patient correctly repeats the following phrase: “No ifs, ands, or buts.” Have the patient perform a three-stage task. Assign 1 point for each stage the patient performs successfully. For example, you could state, “With the index finger of your right hand, touch the tip of your nose and then your left ear.” On a blank piece of paper, write, “Close your eyes” and ask the patient to obey what is written. Assign 1 point if the patient closes their eyes. Ask the patient to write a sentence. Assign 1 point if the sentence makes sense and contains a subject and a verb. Ask the patient to draw two pentagons. (You can explain that a pentagon has five sides.) A portion of the two pentagons should intersect. For example:  Assign 1 point if the patient’s drawing matches the description.	2 1 3 1 1 1

Parameter	**Task**	**Possible Points**[a]
Total		**30**

[a]Scores of less than 24 indicate cognitive dysfunction. Speech must be intact for the test to be valid.

© Jones & Bartlett Learning.

Speech Function

Abnormalities of speech may need to be considered early on in the neurologic examination, because they may interfere with the CCTP's ability to accurately assess other, higher-level functions. Abnormalities of speech can reflect dysfunction in any component or process of communication. They include the following:

- Deafness: Profound hearing loss or complete inability to hear
- **Aphasia**: Any loss or impairment of language function (expressive or receptive) as a result of brain damage
- **Dysphonia**: Difficulty producing intelligible speech caused by physical impairment at the level of the larynx
- **Dysarthria**: Difficulty articulating words caused by neurologic impairment affecting the vocal apparatus

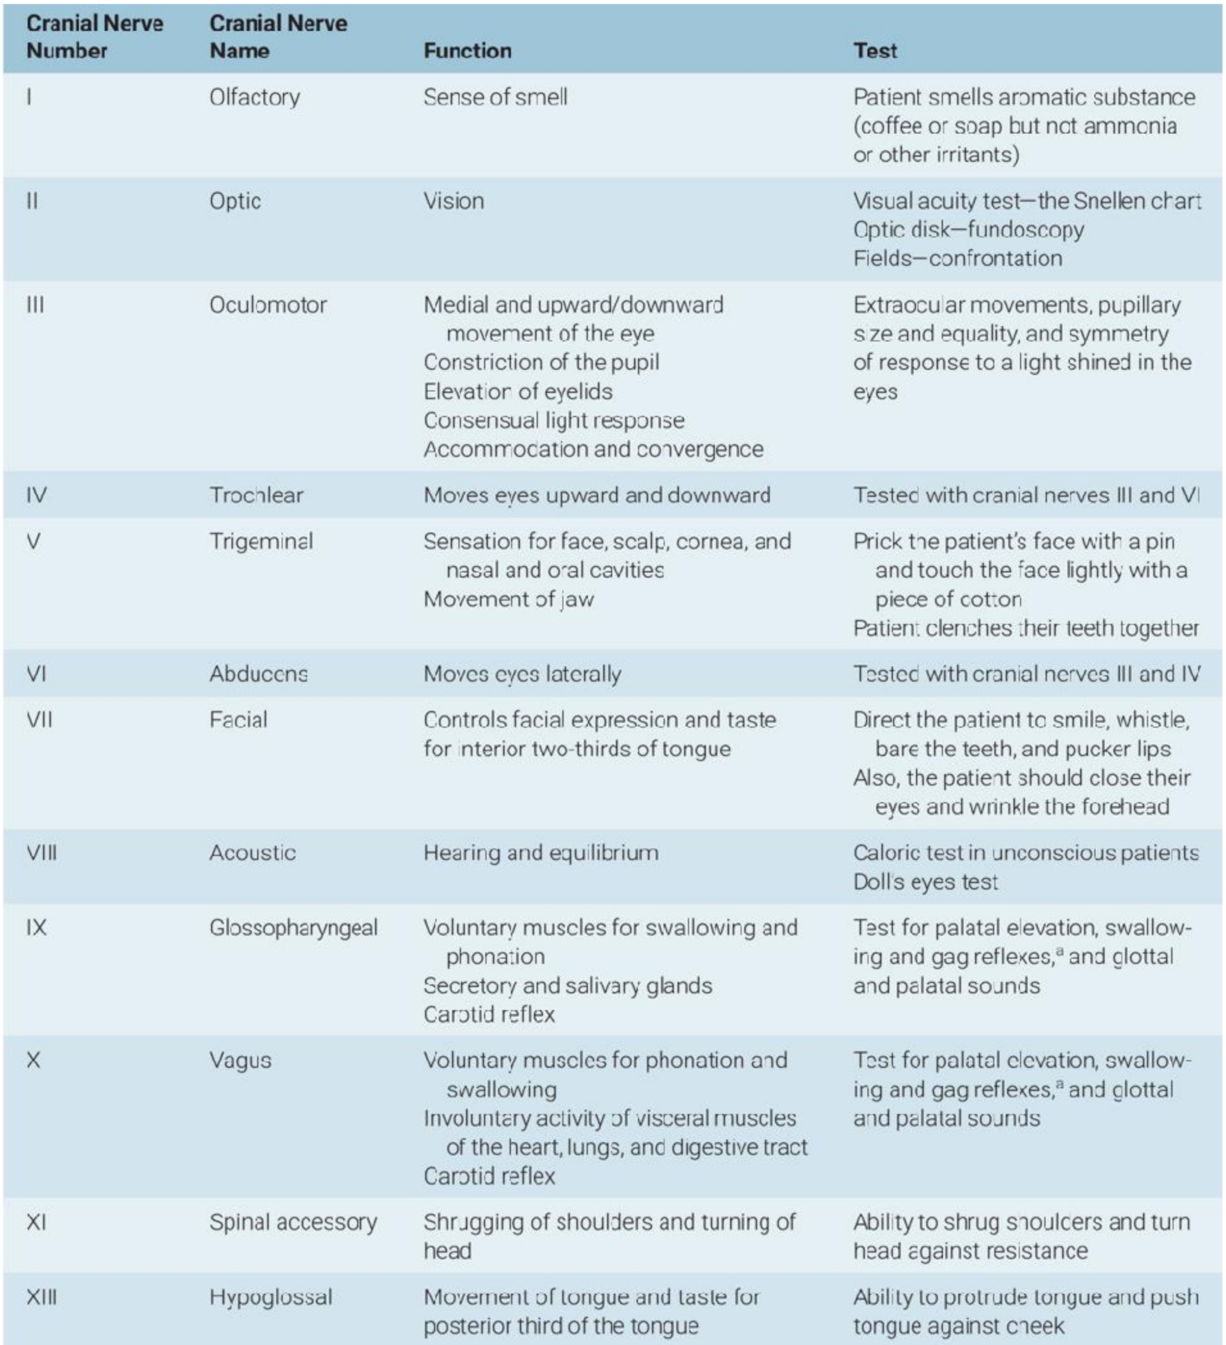
Aphasia is generally the focus of the CCTP's assessment of speech function because it is more commonly associated with an acute process. Sounds are recognized as language in the Wernicke area, which is connected to the concept area, where the meaning of the words becomes understood. The concept area is connected to the Broca area, where speech output is generated. The Wernicke area is also directly connected to the Broca area via the arcuate fasciculus. Because the arcuate fasciculus connects the speech comprehension area (Wernicke area) to the speech production area (Broca area), damage to this area impairs the patient's ability to repeat words and phrases. These areas are found in the dominant hemisphere of each person’s brain (left dominant is most common). It is important to realize that patients who are aphasic, or unable to speak normally, may still be hearing and understanding everything being said around them.

Assessment of Cranial Nerves

Assessment of the cranial nerves, which are located between the midbrain and the pons, provides invaluable information on pressure changes within the cranium and its effects on the brainstem in particular. Many of the cranial nerve tests require patient participation, so they may not be feasible in some critically ill or injured patients. Cranial nerve dysfunction may result from several pathologies, including lesions to the nerve; lesions in the nucleus, the communicating pathways to and from the cortex, the diencephalon, the cerebellum, or other parts of the brainstem; or generalized problems involving the nerve or muscle.

Knowledge of all cranial nerves (ie, the areas that they serve, the expected response to testing, and indications of abnormal response) is necessary to complete a thorough neurologic examination. Nevertheless, certain nerves are more commonly tested in patients who are critically ill or injured—namely, the optic (CN II), oculomotor (CN III), trochlear (CN IV), trigeminal (CN V), abducens (CN VI), facial (CN VII), acoustic (CN VIII), glossopharyngeal (CN IX), vagus (CN X), and hypoglossal (CN XII) nerves. **TABLE 12-9** provides an overview of the cranial nerves, their functions, and methods of testing.

TABLE 12-9 **Cranial Nerves**



Cranial Nerve Number	Cranial Nerve Name	Function	Test
I	Olfactory	Sense of smell	Patient smells aromatic substance (coffee or soap but not ammonia or other irritants)
II	Optic	Vision	Visual acuity test—the Snellen chart Optic disk—fundoscopy Fields—confrontation
III	Oculomotor	Medial and upward/downward movement of the eye Constriction of the pupil Elevation of eyelids Consensual light response Accommodation and convergence	Extraocular movements, pupillary size and equality, and symmetry of response to a light shined in the eyes
IV	Trochlear	Moves eyes upward and downward	Tested with cranial nerves III and VI
V	Trigeminal	Sensation for face, scalp, cornea, and nasal and oral cavities Movement of jaw	Prick the patient's face with a pin and touch the face lightly with a piece of cotton Patient clenches their teeth together
VI	Abducens	Moves eyes laterally	Tested with cranial nerves III and IV
VII	Facial	Controls facial expression and taste for interior two-thirds of tongue	Direct the patient to smile, whistle, bare the teeth, and pucker lips Also, the patient should close their eyes and wrinkle the forehead
VIII	Acoustic	Hearing and equilibrium	Caloric test in unconscious patients Doll's eyes test
IX	Glossopharyngeal	Voluntary muscles for swallowing and phonation Secretory and salivary glands Carotid reflex	Test for palatal elevation, swallowing and gag reflexes,[a] and glottal and palatal sounds
X	Vagus	Voluntary muscles for phonation and swallowing Involuntary activity of visceral muscles of the heart, lungs, and digestive tract Carotid reflex	Test for palatal elevation, swallowing and gag reflexes,[a] and glottal and palatal sounds
XI	Spinal accessory	Shrugging of shoulders and turning of head	Ability to shrug shoulders and turn head against resistance
XIII	Hypoglossal	Movement of tongue and taste for posterior third of the tongue	Ability to protrude tongue and push tongue against cheek

[a] Ten percent of the normal population lacks a gag reflex.

© Jones & Bartlett Learning.

Description

Owing to the nature of the environment in which the CCTP works, most patients encountered will be critically ill or injured. Consequently, it may be necessary to perform rapid exams that test the function of the most important cranial nerves simultaneously. **TABLE 12-10** outlines such nerve groups and their exam results.

TABLE 12-10 Cranial Nerves and Their Exam Results

Cranial Nerve Group	Specific Test	Significance
III, IV, VI	Extraocular movements	Dysconjugate gaze indicates compression or injury of nerve; eyes are unable to turn together in the same direction
V, VII, IX, X, XII	Swallowing	Potential for aspiration
III, VI, VIII	Oculocephalic reflex (doll's eyes)	Brainstem dysfunction
III, VI, VIII	Oculovestibular reflex (caloric test)	Brainstem dysfunction
IX, X	Gag reflex	Loss of protective reflex caused by brainstem dysfunction or nerve injury
V, VII	Corneal reflex	Loss of protective reflex caused by brainstem compression or nerve injury

Data from Kinney MR, Brooks-Brunn JA, Molter N, et al. *AACN Clinical Reference for Critical Care Nursing*. St Louis, MO: Mosby; 1999.

Olfactory Nerve

The CCTP should assess cranial nerve I, which is responsible for olfaction, in patients in whom head trauma has occurred, when pathology at the base of the skull is suspected, and in patients who exhibit an altered mental status. Use familiar odors such as coffee, vanilla, soap, and lemon oil to conduct the exam. *Never* use irritant substances such as ammonia or vinegar as olfactory stimulants.

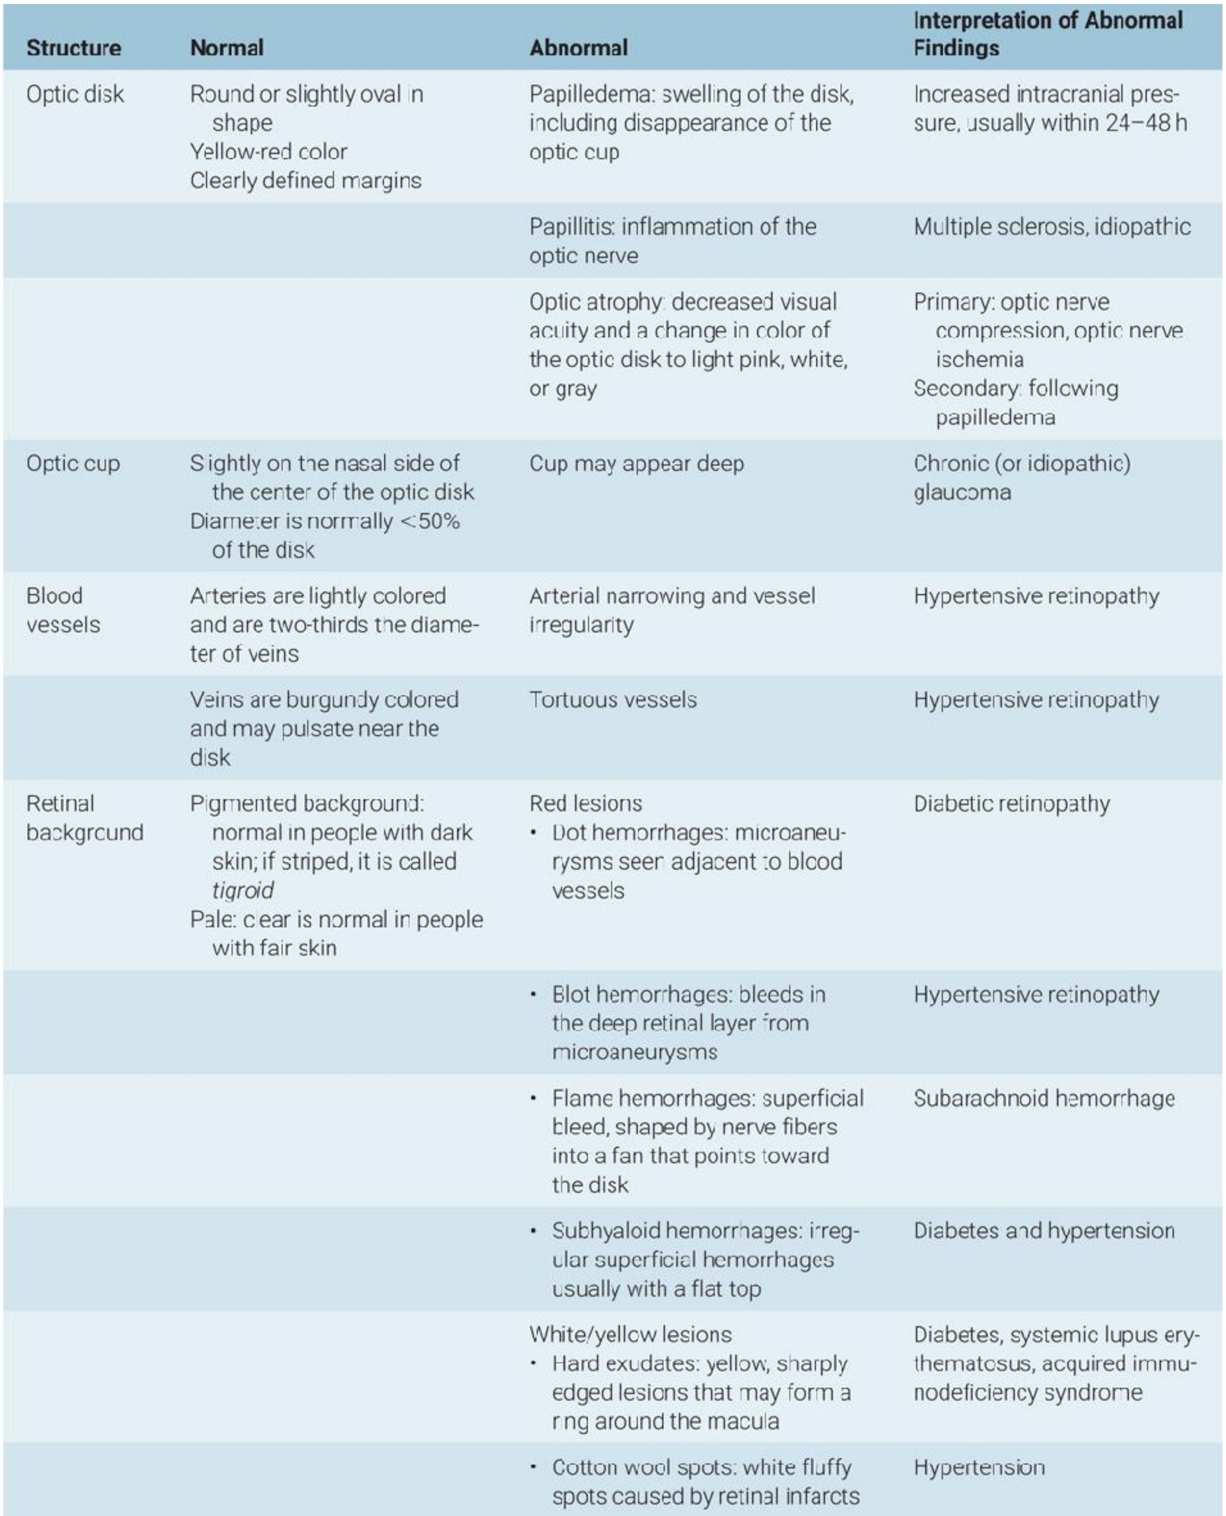
One interesting phenomenon that is occasionally observed is **Foster Kennedy syndrome**, which involves the olfactory nerve and is caused by a tumor or abscess at the base of the frontal lobe. Signs and symptoms of this syndrome include ipsilateral blindness and anosmia, ipsilateral atrophy of the olfactory and optic nerves, and contralateral papilledema.

Optic Nerve

The optic nerve (CN II) arises from cells in the retina and then passes into the orbit, where it is enclosed in meningeal sheaths. After the fibers have passed through the optic chiasm, this nerve's name changes to the optic tract. The fibers from the nasal half of the retina decussate (intersect to form an "X") within the optic chiasm; those from the lateral (temporal) half do not.

Evaluate each eye individually to assess the optic nerve. The tests should include evaluation of visual acuity, visual fields, and the fundi (via fundoscopy). **TABLE 12-11** describes the assessment parameters.

TABLE 12-11 **Assessment Parameters of the Eye**



Structure	Normal	Abnormal	Interpretation of Abnormal Findings
Optic disk	Round or slightly oval in shape Yellow-red color Clearly defined margins	Papilledema: swelling of the disk, including disappearance of the optic cup	Increased intracranial pressure, usually within 24–48 h
		Papillitis: inflammation of the optic nerve	Multiple sclerosis, idiopathic
		Optic atrophy: decreased visual acuity and a change in color of the optic disk to light pink, white, or gray	Primary: optic nerve compression, optic nerve ischemia Secondary: following papilledema
Optic cup	Slightly on the nasal side of the center of the optic disk Diameter is normally <50% of the disk	Cup may appear deep	Chronic (or idiopathic) glaucoma
Blood vessels	Arteries are lightly colored and are two-thirds the diameter of veins	Arterial narrowing and vessel irregularity	Hypertensive retinopathy
	Veins are burgundy colored and may pulsate near the disk	Tortuous vessels	Hypertensive retinopathy
Retinal background	Pigmented background: normal in people with dark skin; if striped, it is called *tigroid* Pale: clear is normal in people with fair skin	Red lesions • Dot hemorrhages: microaneurysms seen adjacent to blood vessels	Diabetic retinopathy
		• Blot hemorrhages: bleeds in the deep retinal layer from microaneurysms	Hypertensive retinopathy
		• Flame hemorrhages: superficial bleed, shaped by nerve fibers into a fan that points toward the disk	Subarachnoid hemorrhage
		• Subhyaloid hemorrhages: irregular superficial hemorrhages usually with a flat top	Diabetes and hypertension
		White/yellow lesions • Hard exudates: yellow, sharply edged lesions that may form a ring around the macula	Diabetes, systemic lupus erythematosus, acquired immunodeficiency syndrome
		• Cotton wool spots: white fluffy spots caused by retinal infarcts	Hypertension

Description

To formally evaluate visual acuity, use a Snellen chart **FIGURE 12-21** to check each eye individually. With the patient at a distance of 20 feet (6 m) from the chart, ask them to read the line with the smallest letters they can decipher. The number beside each line on the chart is the distance at which a person with normal vision can read the letters. This number is the denominator when recording the vision.

Examination of the visual fields provides invaluable information that can often enable the CCTP to determine the location of a lesion on the visual pathway. A normal visual field extends 60° to the nasal side, 100° on the temporal side, and 130° vertically. The confrontation test is used to evaluate the visual fields. In this test, the CCTP faces the patient at a distance of 2 feet (0.5 m), and then asks the patient to cover one eye lightly and look at the CCTP's eye directly opposite. The CCTP should then present a stimulus in each of the four quadrants—upper and lower nasal and upper and lower temporal—of the visual field. Acceptable stimuli include finger movement, rapid finger counting, and hand comparison. The CCTP should assess for the presence of a *scotoma*, or spot, which is an abnormal deficit of the visual field surrounded by normal vision. The *blind spot*, which is normal, represents the location of the optic disk within the visual field, because the optic disk does not have the rods, cones, or ganglion cells necessary for vision.

The **fundus** of each eye includes the optic disk, macula, and blood vessels on the back wall of the internal eyeball; it should be examined using the ophthalmoscope **FIGURE 12-23**. During the examination, the patient should look at a distant object, and the CCTP should attempt to observe the optic disk, the blood vessels, and the retinal background. With the ophthalmoscope dial set on zero, locate the pupillary red reflex (the point at which the retinal reflex is seen glowing pink in the pupil) from a distance of about 2 or 3 feet (0.5 or 1 m). Slowly approach the patient's eye as if viewing the eye through a keyhole. At the same time, dial the plus or minus lenses, as needed, on the ophthalmoscope to focus on the patient's retina. The **optic disk** is located by directing the ophthalmoscope toward the nasal side of the patient's retina. The most prominent structure visible, it represents the termination of the optic nerve.

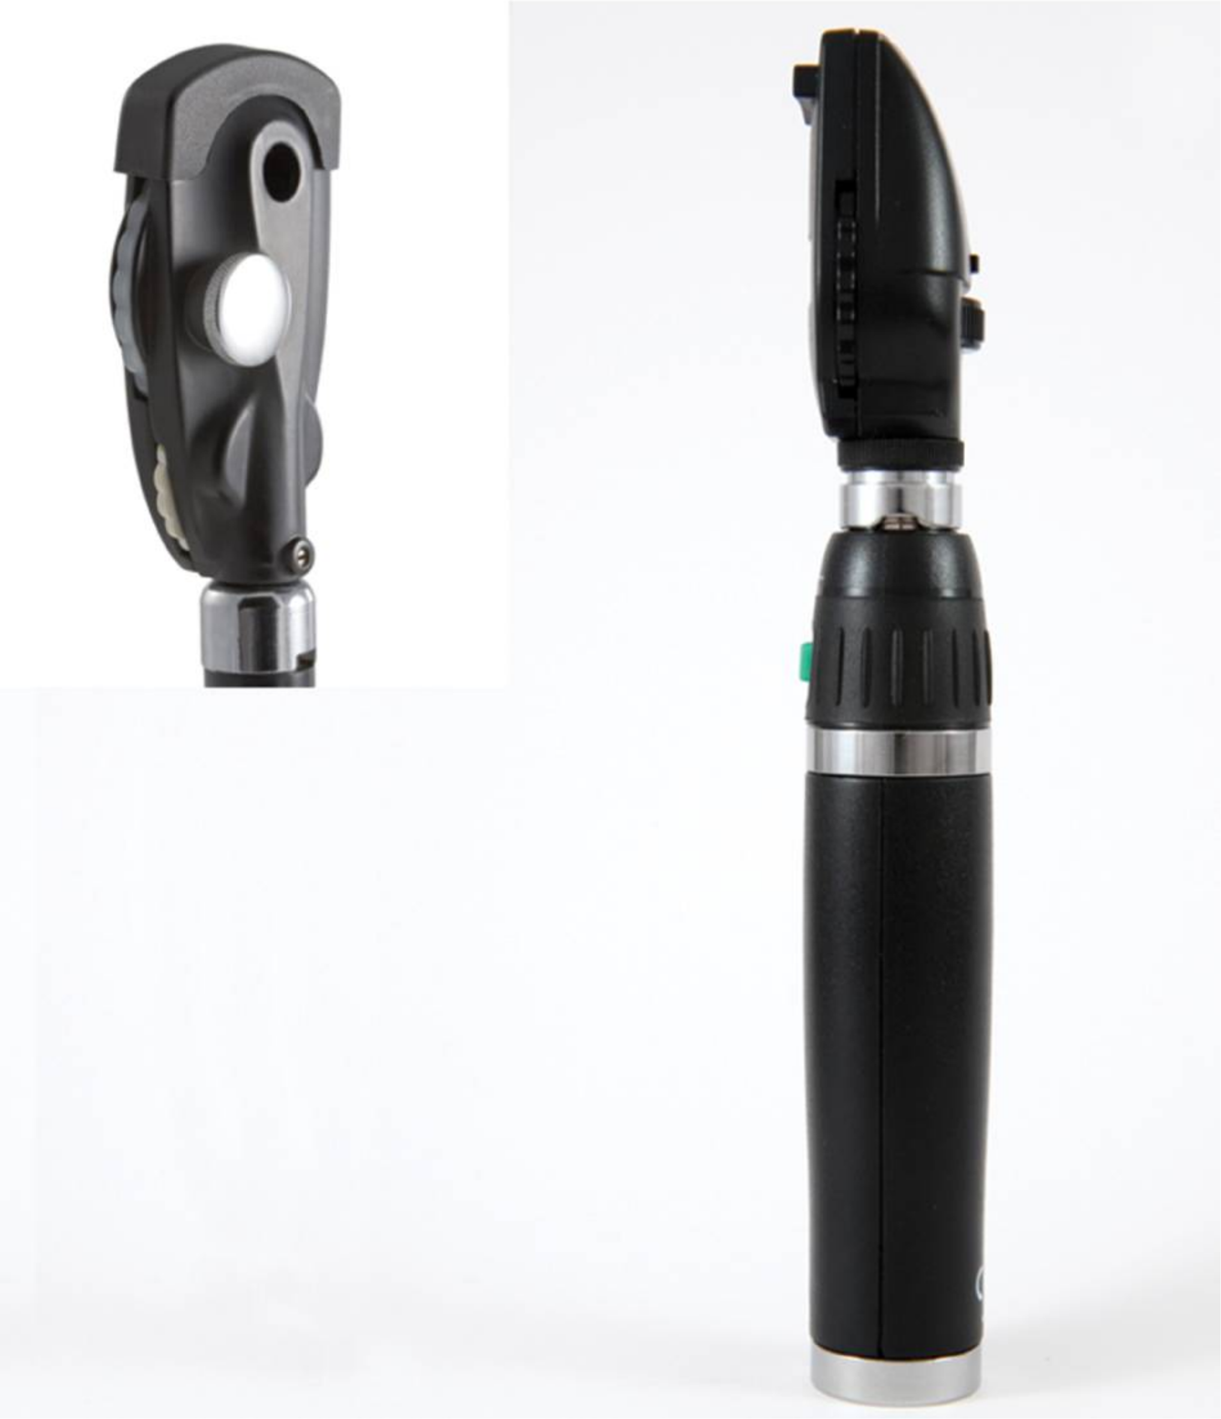

FIGURE 12-23 An ophthalmoscope.

Ocular, Trochlear, Trigeminal, and Abducens Nerves

The oculomotor, trochlear, and abducens nerves (CN III, IV, and VI, respectively) are usually examined as a group because they act together in producing eye movement and controlling ocular muscles to ensure that the eyes remain parallel throughout their range of motion. The CCTP should closely observe two parameters in relation to these nerves: the position of the eyeball and the position of the upper eyelid. The eyeball's position should be observed from a frontal and lateral view as well as from a cephalad view. The upper eyelid should be assessed while having the patient look straight ahead, and the CCTP should look for evidence of **ptosis** (drooping).

To test eye movement, the CCTP asks the patient to follow the CCTP's finger in upgaze and downgaze and from side to side; these areas of movement are commonly called the six cardinal fields of gaze. Eye movements can be divided into four types, each controlled by a different part of the brain **TABLE 12-12**. The brainstem is responsible for integrating inputs from the frontal and occipital lobes and the cerebellum and vestibular nuclei so that both eyes move together in the same direction, called **conjugate movement**. If the patient exhibits a lack of symmetric movement between the two visual axes, **dysconjugate movement** is said to be present. **Diplopia**, or double vision, may occur if the patient is unable to move the eyeball in one particular direction.

TABLE 12-12 Eye Movements

Type of Eye Movement	Definition	Site of Control
Saccadic (command)	Rapid movement from one point of fixation to another	Frontal lobe
Pursuit	Slow eye movement used to maintain fixation on a moving object	Occipital lobe

Type of Eye Movement	Definition	Site of Control
Vestibular-positional	Eye movements that compensate for movement of the head/neck to maintain fixation	Cerebellar vestibular nuclei
Convergence	Movements that maintain fixation as an object is brought close to the face	Midbrain

© Jones & Bartlett Learning.

In conducting a neurologic examination on an unconscious patient, the oculocephalic reflex (doll's eye test) and the oculovestibular reflex (caloric test) may be evaluated for reflex movement of the eyeball (see the section on assessment of cranial nerve VIII for this procedure). The presence of these reflexes indicates that the brainstem is intact.

During the assessment of cranial nerves III, IV, and VI, assess for the following dysfunctions:

- Gaze abnormalities **TABLE 12-13**
- Nystagmus—an involuntary rhythmic movement of the eyes that may be horizontal, vertical, or mixed direction, with fast and slow components to the movement **TABLE 12-14**
- Abnormalities of the pupils in terms of size, shape, equality, and reflexes **TABLE 12-15**

TABLE 12-13 Gaze Abnormalities

Type of Gaze	Description	Causes
Normal gaze	Eye movements are smooth and conjugate	N/A

Type of Gaze	Description	Causes
Horizontal gaze	Deviation of both eyes toward the same side	Destructive hemispheric lesion: both eyes deviate *toward* the side of the lesion Irritative hemispheric lesion (eg, hemorrhage): both eyes deviate *away* from the side of irritation, but later the conjugate gaze becomes paralyzed
Vertical gaze	Deviation of both eyes upward	Upper brainstem lesion
Medial-longitudinal fasciculus	Dysconjugate gaze	Lesion between the pons and the midbrain
Skewed deviation	One eye looks downward and the other looks upward	Lesion in the pons on the same side as the eye that is directed downward
Roving-eye movements	Spontaneous, slow, random deviation	Seen in comatose patients with intact brainstem oculomotor function
Ocular bobbing	Episodic, intermittent, usually conjugate, downward, brisk eye movement followed by a return to the resting position by a “bobbing action”	Severe destructive lower pontine lesions

© Jones & Bartlett Learning.

TABLE 12-14 Nystagmus Types

Type of Nystagmus	Description	Cause(s)
Retraction nystagmus	Irregular jerks of the eyes backward into the orbit, initiated by an upward gaze	Midbrain tegmental damage

Type of Nystagmus	Description	Cause(s)
Convergence nystagmus	Slow, spontaneous, drifting, ocular divergence with a final quick, convergent jerk	Midbrain lesion
See-saw nystagmus	A rapid, pendular, dysconjugate see-saw movement accompanied by severe visual field deficits and loss of visual acuity	Lesion around optic chiasm
Downbeat nystagmus	Irregular jerks initiated by a downward gaze	Lower medullary lesion
Optokinetic nystagmus	A test in which a striped drum is spun in front of the eyes, normally evoking nystagmus in the opposite direction of the spin	Present in most patients
Vestibular nystagmus	Mixed nystagmus that can be horizontal, rotational, or both	Vestibular disease
Toxic nystagmus	Nystagmus occurring while the head is in a specific position, caused by certain drugs or alcohol	Induced by treatment with certain drugs, such as phenytoin, barbiturates, and bromides; also caused by alcohol ingestion

© Jones & Bartlett Learning.

TABLE 12-15 Pupillary Exam Results

Size	2–6 mm (average, 3.5 mm)
Shape	Round
	Patients who have had previous cataract surgery may have the shape of a keyhole
Equality	Diameters are equal
	Be aware of anisocoria, a nonpathologic unequal pupil found in 15% of the population

The oculomotor nerve (CN III) innervates the superior, medial, and inferior rectus muscles; the inferior oblique muscle; the constrictor of the pupil; the ciliary body; and the levator of the eyelid. A complete lesion of the oculomotor nerve results in paralysis of the ipsilateral muscles innervated by the nerve as well as ptosis, pupillary dilation, and inability to look upward, downward, or inward. Oculomotor nerve (CN III) palsy is commonly caused by uncal herniation resulting from an expanding intracranial mass; it is most often seen as a unilateral dilated, or “blown,” pupil.

The trochlear nerve (CN IV) innervates the superior oblique muscle. When the fourth nerve is damaged, the affected ipsilateral eye is higher than the normal opposite eye, and it cannot be turned downward when the eye is rotated inward. The position of the globe is higher relative to the position of the other globe because the superior oblique muscle normally depresses the eyeball. When this muscle is paralyzed, the size of the eyeball will not be depressed normally relative to the other eye. Thus, it is *higher* than the other eye.

The abducens nerve (CN VI) controls the ipsilateral lateral rectus muscle, which makes the eye look outward (laterally). Defects in abduction (from a lesion of the sixth cranial nerve, for example) give the patient a *cross-eyed* appearance. The normal eye is oriented straight ahead; by comparison, the affected eye is rotated slightly inward (medially) owing to the unopposed action of the medial rectus muscle on that side.

The trigeminal nerve (CN V) has both motor and sensory functions. In sensory testing, its innervation includes the face up to the vertex of the scalp, but spares the angle of the mandible. The sensation from the oral and nasal cavities is transmitted through the trigeminal nerve, although these areas are not usually included in the routine neurologic examination.

Pain and temperature should be tested in the three divisions of the fifth cranial nerve: ophthalmic, maxillary, and mandibular. The ophthalmic division innervates the scalp as far back as the vertex of the skull, forehead, cornea, conjunctiva, and skin of the side and tip of the nose. Corneal sensation is tested by gently touching the corneas with a cotton tip or tissue paper while the patient looks in the other direction. This maneuver exercises the afferent limb of the corneal reflex. The normal response is a rapid, partial, or complete blinking movement of the eyelid elicited by the efferent limb of the corneal reflex via the facial nerve.

The second trigeminal division, the maxillary nerve, conducts stimuli from the skin of the cheek, far lateral aspect of the nose, upper teeth, and jaw. The third division, the mandibular nerve, carries sensory and motor impulses. Tests of the sensory distribution address the skin of the lower jaw, pinna of the ear, lower teeth and gums, and the side of the tongue.

The motor fibers supply the muscles of mastication: the temporal, masseter, and pterygoid muscles. The temporal and masseter muscles are examined by having the patient close the jaw together while the CCTP palpates these muscles. The *jaw-jerk reflex* is elicited by a gentle tap on the chin, with resultant closure of the jaw by the masticatory muscles and is considered an abnormal finding.

Facial Nerve

The facial nerve (CN VII) is a complex nerve with motor, sensory, and parasympathetic fibers. Its motor portion innervates the muscles of facial expression and is tested by instructing the patient to wrinkle the forehead, close the eyelids tightly, smile or grimace to show the teeth, and whistle. Two types of facial motor weakness are possible: one with involvement of the upper motor neuron (corticonuclear/corticobulbar pathways), and the other with involvement of the lower motor neurons (*peripheral* seventh nerve palsy). *Central* (upper) motor facial palsy is characterized by the inability to retract the corner of the mouth, whereas forehead function and eyelid closure remain largely unaffected. Lesions in the facial nucleus or the nerve proper will cause paralysis of one-half of the entire face, with inability to wrinkle the forehead or to close the eyelids and lips on the affected side.

The sensory portions of the seventh nerve originate from the taste buds in the anterior two-thirds of the tongue and from the posterior wall of the external ear canal. Although this test is rarely performed in the field, taste is examined using sugar, salt, or quinine solutions. The patient is instructed to protrude the tongue; then the test substance is applied with a cotton-tipped applicator on one side of the tongue. The patient must identify the test substance before drawing the tongue back into the mouth. The facial nerve also carries parasympathetic fibers to the maxillary and lacrimal glands.

Vestibulocochlear Nerve

The eighth cranial nerve is made up of two divisions: (1) the cochlear division, which affects the sense of hearing, and (2) the vestibular division, which affects the sense of balance.

The vestibular division of the acoustic nerve is assessed by using rotational and caloric stimuli to produce changes in the endolymph current in the semicircular canals. Both types of stimuli are also used to determine the brainstem function of unconscious patients. Typically, patients with vestibular dysfunction complain of vertigo, nausea and vomiting, and difficulty with balance, especially with movement of the head.

The **caloric test**, or Bárány test, is commonly used to assess vestibular function; it should not be performed on any patient with a ruptured tympanic membrane. This assessment involves raising and lowering of the temperature in the external auditory canal, which induces convection currents in the endolymph of the semicircular canals and stimulates the vestibular nerve endings. With the patient lying down and the head elevated 30° such that the lateral semicircular canal is vertical, instill cool water (86°F [30°C]), usually about 250 mL, into one ear over 40 seconds. If the patient is conscious, direct them to look forward while the water is being instilled. Repeat this step in the other ear with warm water (111°F [44°C]). Then observe the direction of nystagmus. **TABLE 12-16** identifies the normal and abnormal responses to the caloric test.

TABLE 12-16 Caloric Test Responses

Conscious patient	Cold: nystagmus away from stimulated ear
	Warm: nystagmus toward stimulated ear
	Remember the mnemonic COWS (cold–opposite/warm–same)
Unconscious patient	Cold: nystagmus toward stimulated ear
	Warm: nystagmus away from stimulated ear

© Jones & Bartlett Learning.

The **doll's eye test**, or oculocephalic reflex test, is performed on the unconscious patient by rapidly rotating the head from side to side and observing the eye movement **FIGURE 12-24**. This procedure is contraindicated if neck or cervical spine injury is suspected. If the reflex is intact or doll's eyes are present (indicating adequate brainstem function between CN III, VI, and VIII), the eyes will deviate opposite the movement of the head. The absence of doll's eyes occurs when the eyes move in the same direction of the head as it is turned; this abnormal response indicates severe brainstem dysfunction.

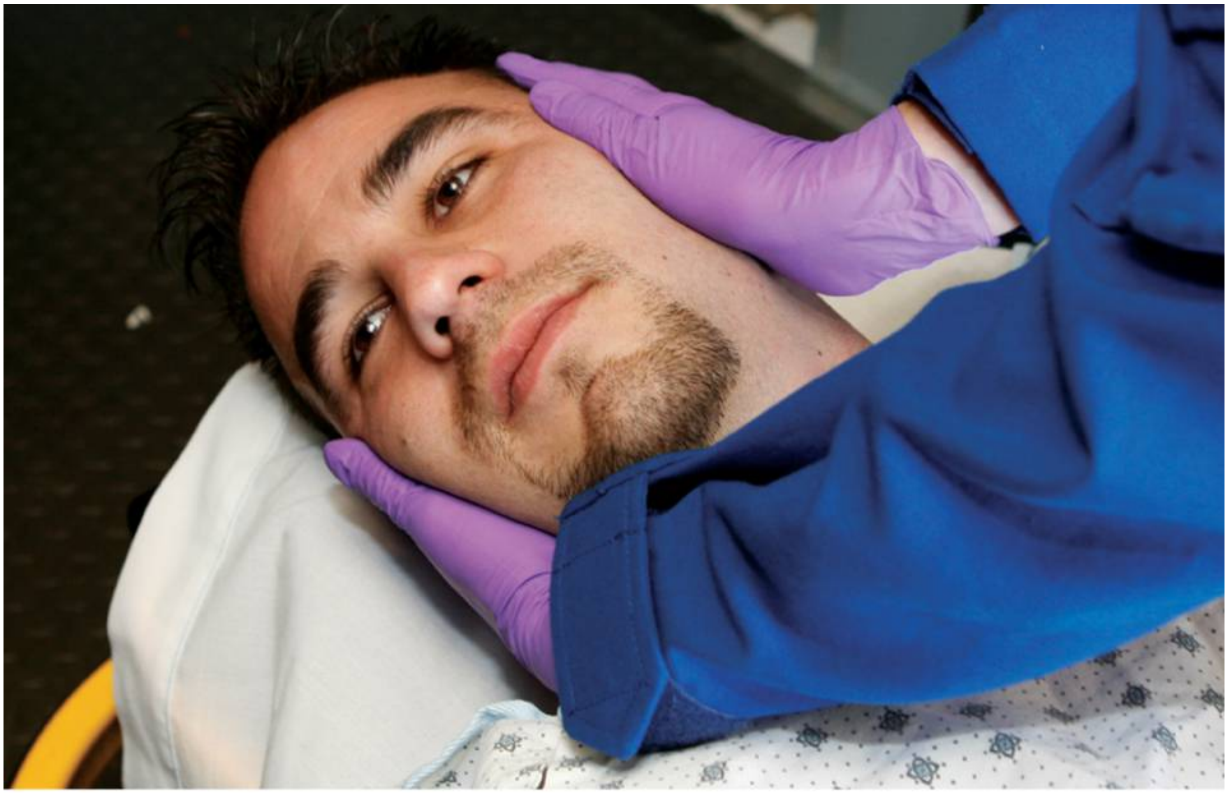

FIGURE 12-24 The doll's eye test, also known as the oculocephalic reflex test.

© Jones & Bartlett Learning.

Glossopharyngeal and Vagus Nerves

The glossopharyngeal and vagus nerves (CN IX and X, respectively) are usually tested together owing to their co-innervation of the pharynx. The glossopharyngeal nerve supplies sensory components to the pharynx, tonsils, soft palate, and posterior third of the tongue. It also supplies motor fibers to the muscle that elevates the pharynx. The vagus nerve is responsible for sensation to the pharynx and larynx; motor function of the soft palate, pharynx, and larynx; innervation of the thoracic and abdominal visceral organs; and sensory input from the heart, lungs, and digestive tract.

To test these nerves **FIGURE 12-25**, direct the patient to open their mouth and say, "Ah." Note the upward movement of the soft palate and any deviation of the uvula. As part of this assessment, you may stimulate the gag reflex (using a tongue depressor or cotton swab), which is also mediated by cranial nerves IX and X. Note that 10% of the population does not have a gag reflex.

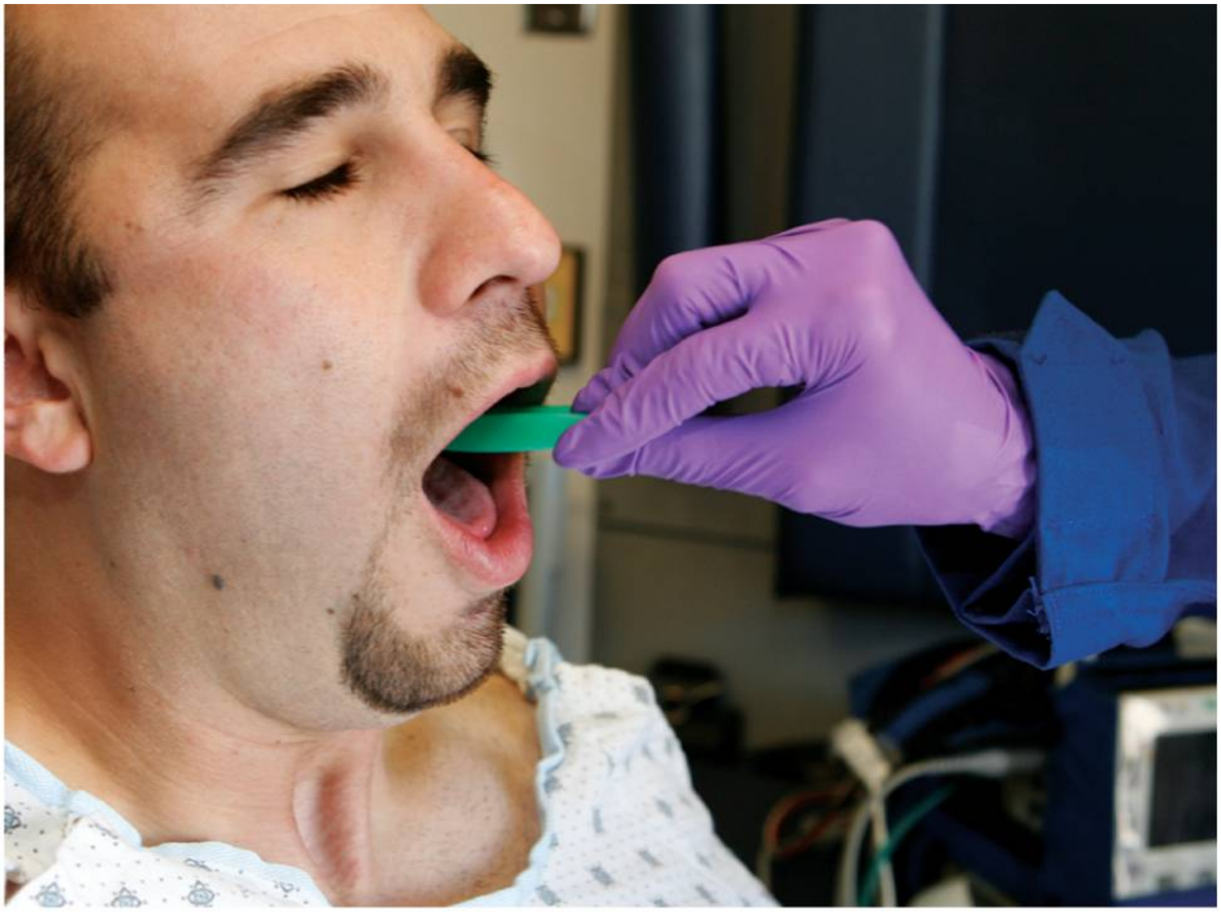

FIGURE 12-25 The test for cranial nerve IX, the glossopharyngeal nerve, evaluates palatal elevation, swallowing and gag reflexes, and glottal and palatal sounds.

© Jones & Bartlett Learning.

Spinal Accessory Nerve

The spinal accessory nerve (CN XI) is tested in two segments. First, the CCTP palpates the trapezius muscle and evaluates its strength while the patient shrugs their shoulders against resistance. Second, the patient turns their head to one side and pushes their chin against the examiner's hand; the CCTP should then palpate the sternocleidomastoid for tone and strength. This test should not be performed on patients with a suspected injury to the base of the skull or the upper neck.

Hypoglossal Nerve

The hypoglossal nerve (CN XII) innervates the musculature of the tongue. To test this nerve, the CCTP observes the tongue for fasciculations and atrophy, tests for muscle strength by having the patient push the tongue against the inside wall of the cheek, and checks for tongue protrusion. Tongue protrusion is straight when the two hypoglossal nerves are working together; when only one branch is working, however, the tongue will deviate toward the injured side. Neck trauma, tumor, or brainstem lesions usually cause unilateral weakness. In contrast, bilateral weakness typically results from degenerative neurologic diseases.

Assessment of Motor Function

The motor examination includes a consideration of muscle tone and strength. This exam proceeds from the upper limbs, to the neck and trunk, and finally to the lower extremities. During this examination, the CCTP should compare the symmetry of each side of the body.

The assessment of motor function evaluates how both the voluntary and involuntary motor pathways are functioning. The voluntary motor pathway is a descending pathway that originates in the precentral gyrus of the frontal lobe and ends at all levels of the spinal cord (suprasegmental level). The descending neuron synapses with motor neurons of the spinal cord (segmental level), and final motor output is achieved at the muscle level (myoneural junction). Voluntary muscle control involves the orchestrated effort of the skeletal structures, muscles, and involuntary motor pathways that control posture, balance, and reflexive activities.

To assess the patient’s voluntary motor pathway, the CCTP should palpate the muscles through the normal range of motion. Abnormalities are characterized as follows:

- Spasticity or undue resistance of the muscles owing to passive lengthening because of injury to the corticospinal system
- Rigidity or a more constant state of resistance that involves the extrapyramidal motor system
- Flaccidity or a decreased muscle tone (hypotonia)

To assess muscle strength, the CCTP puts the patient's muscles of the major joints through their normal range of motion. Strength should also be assessed against gravity and finally against resistance. Muscle strength is rated using a scale of 0 to 5 **TABLE 12-17**. To record the data from this exam, the CCTP should draw a stick figure and place values at various points along the figure to indicate the assessed motor response.

TABLE 12-17 Muscle Strength Grading Scale

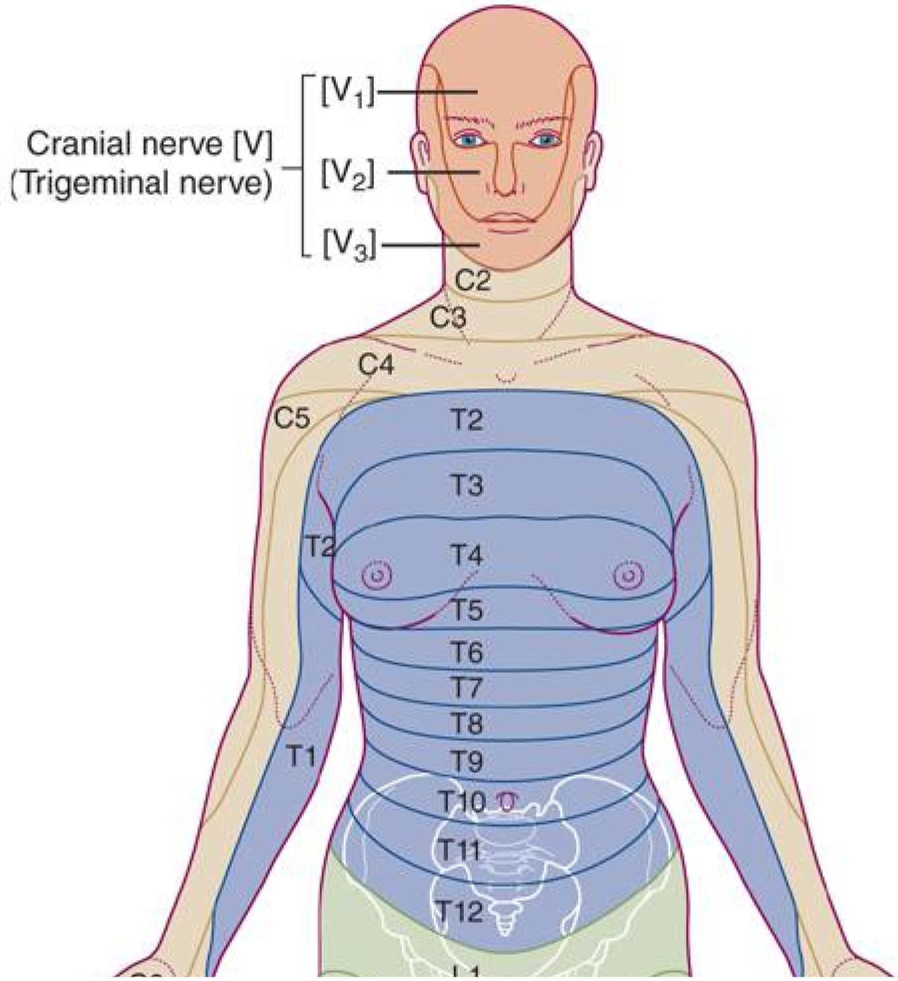
Grade	Description
5	Normal; full strength against resistance
4	Active movement; minimal weakness against resistance
3	Active movement; barely able to overcome gravity and does not overcome active resistance
2	Active movement; does not overcome gravity
1	Slight trace of muscle contraction
0	No muscle contraction

© Jones & Bartlett Learning.

Assessment of Sensory Function

Evaluation of the sensory system seeks to determine the patient's ability to perceive various types of sensations with the eyes closed. Sensation arises from specialized receptors in the body that are designed to recognize and transmit stimuli to the CNS (usually the cerebrum or brainstem), where processing takes place and an appropriate response can be initiated. To reach these sites, the sensory impulses travel along specialized tracts in the nervous system.

Sensory examination assesses the integrity of both the receptors and the tracts of conduction. It is not useful for all patients, however, as altered levels of consciousness or preexisting conditions may interfere with the conduct of a proper examination or may produce abnormalities unrelated to the present illness or injury. The CCTP should be comfortable using a dermatome chart **FIGURE 12-26** to locate sensory areas supplied by a single spinal nerve and should be especially familiar with certain key dermatomes, such as C4, C7, T2, T10, L5, S1, and S5.



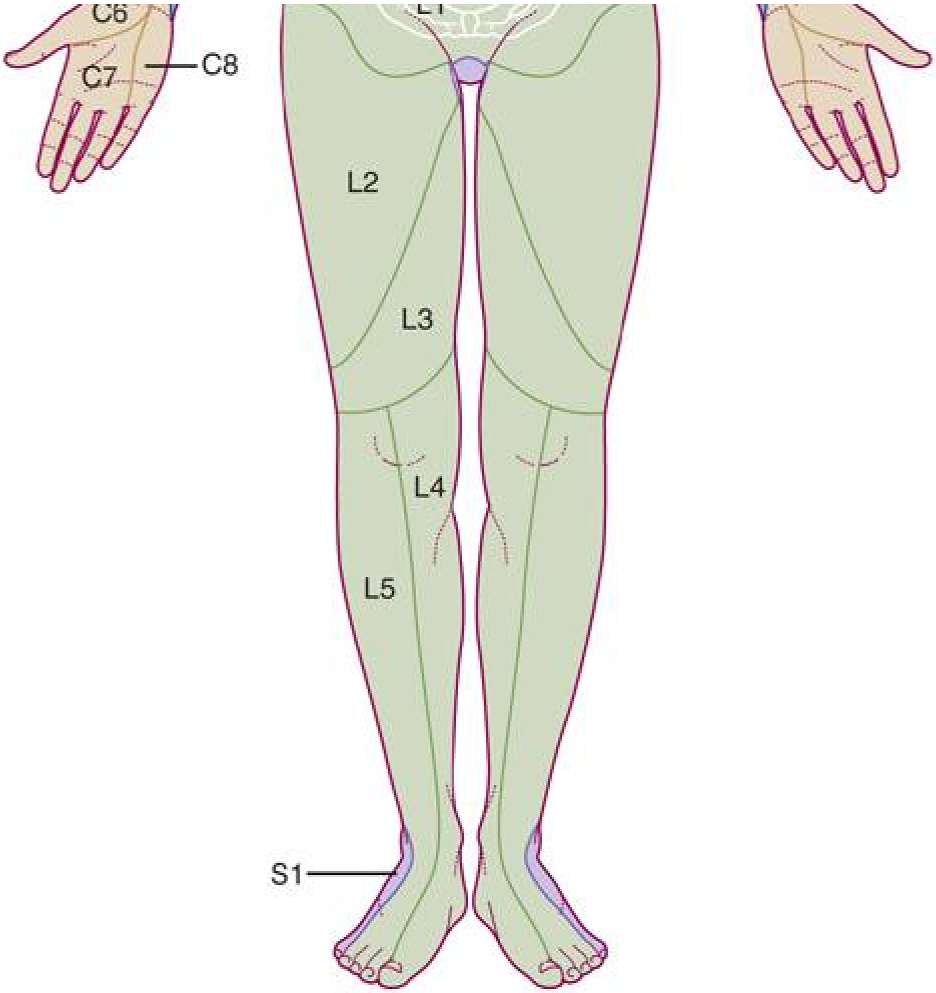


FIGURE 12-26 Dermatomes of the human body.

© Jones & Bartlett Learning.

Description

As part of a detailed assessment of sensory function, the CCTP should examine and document the patient's perception of pain, temperature, and touch. These methods of testing compare symmetric areas on both sides of the body and evaluate distal and proximal areas of the arms and legs for pain, temperature, and touch sensation. The stimuli should be scattered to sample most dermatomes and major peripheral nerves. During this assessment, the patient's eyes should remain closed.

To test the patient's perception of pain, ask the patient to close their eyes, then randomly apply both sharp (using a disposable pin) and blunt stimuli, and note the patient's response. Always begin in areas of known altered sensation and move toward areas of normal sensation to find the edges.

Assess touch using a fine wisp of cotton or an alcohol pad. Instruct the patient to close their eyes during the exam, and then stroke their skin with the cotton or alcohol pad symmetrically on alternating sides of the body. This test measures anesthesia or hyperesthesia.

Reflex Testing

Examination of deep tendon reflexes gives information about the integrity of the spinal nerves and may indicate brainstem or spinal cord lesions. A tendon reflex results from the stimulation of a stretch-sensitive afferent nerve from a neuromuscular spindle, which, via a single synapse, stimulates a motor (efferent) nerve, leading to a muscle contraction. Tendon reflexes are increased in upper motor neuron lesions and decreased in lower motor neuron lesions **TABLE 12-18**. The following scale should be used to grade reflexes:

- 0 = absent
- 1+ = reduced or hypoactive
- 2+ = normal
- 3+ = increased or hyperactive
- 4+ = clonus

TABLE 12-18 Reflex Locations

Reflex	Nerve	Root
Biceps	Musculocutaneous	C5, C6
Brachioradialis	Radial	C5, C6
Triceps	Radial	C7

Reflex	Nerve	Root
Finger	Median and ulnar	C8
Knee	Femoral	L3-L4
Ankle	Tibial	S1-S2

© Jones & Bartlett Learning.

Pathologic Reflexes

The following list includes the most common pathologic reflexes, all of which indicate pyramidal tract disease. The Babinski reflex (Babinski sign) is perhaps the most important of the pathologic reflexes.

- **Plantar reflex.** The provider rapidly strokes the lateral aspect of the sole of the foot with a blunt object, such as the back of a pen, from the heel to the ball of the foot. A normal plantar response will lead to toe flexion and is considered a negative test. An extensor (or up-going toe) response is the Babinski sign, a positive (abnormal) test result. Note that infants will usually demonstrate an extensor response as a primitive reflex.
- **Oppenheim sign.** The provider strokes the anterior medial tibial muscle. An extensor response is a positive finding.
- **Gordon sign.** The provider firmly squeezes the gastrocnemius muscle. An extensor response is a positive finding.
- **Hoffmann sign.** The provider flicks the distal phalanx of the index or middle finger. A sudden clawing of the fingers and thumb is a positive finding.

Grasp Reflex

To test the grasp reflex, the CCTP asks the patient to grasp the CCTP’s index finger. The CCTP then asks the patient to let go of the finger as they pull their hand away from the patient. A normal response is present if the patient is able to let go. An abnormal response consists of the involuntary flexion of the fingers, causing an uncontrollable grasp of the CCTP's hand **FIGURE 12-27**. Such a positive grasp reflex indicates a frontal lobe lesion.

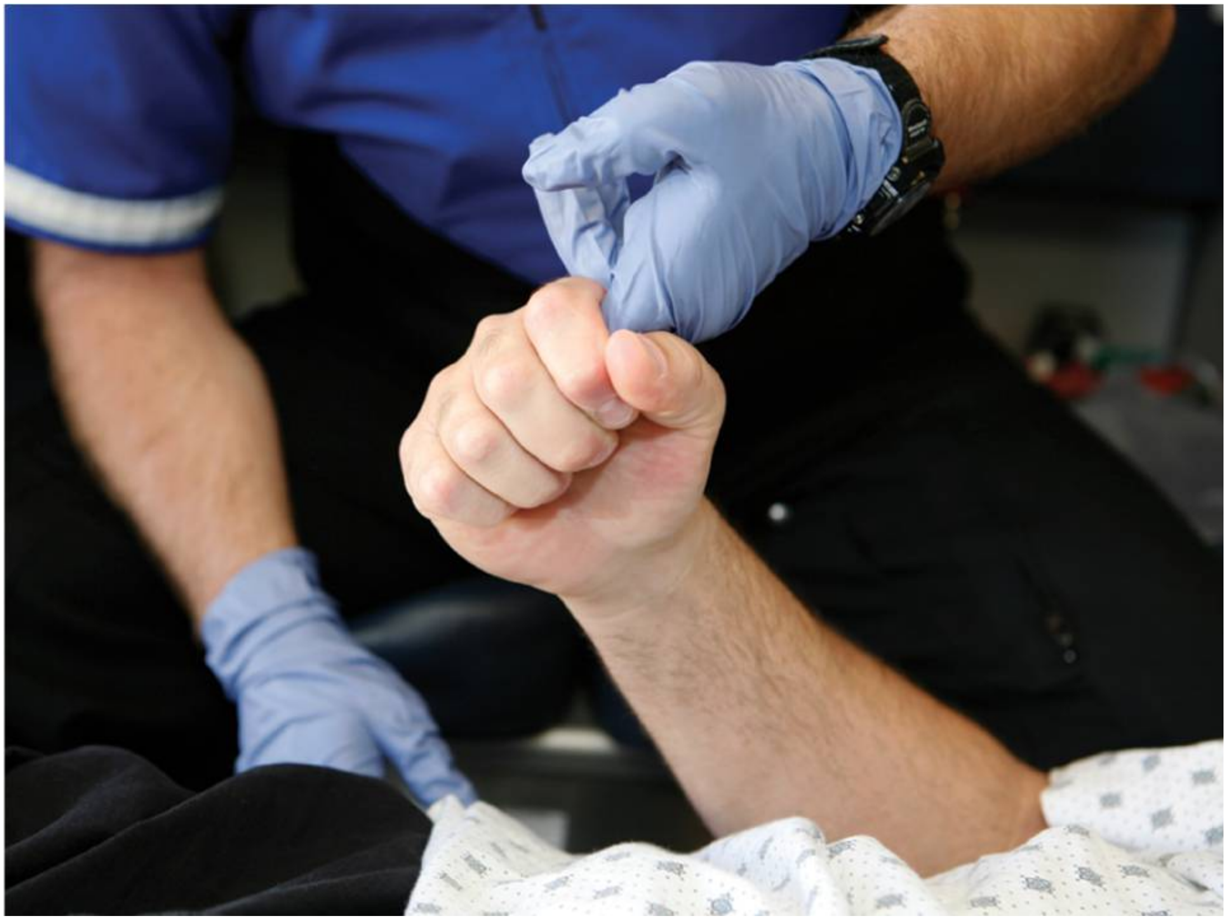

FIGURE 12-27 Grasp reflex.

© Jones & Bartlett Learning.

Superficial Reflexes

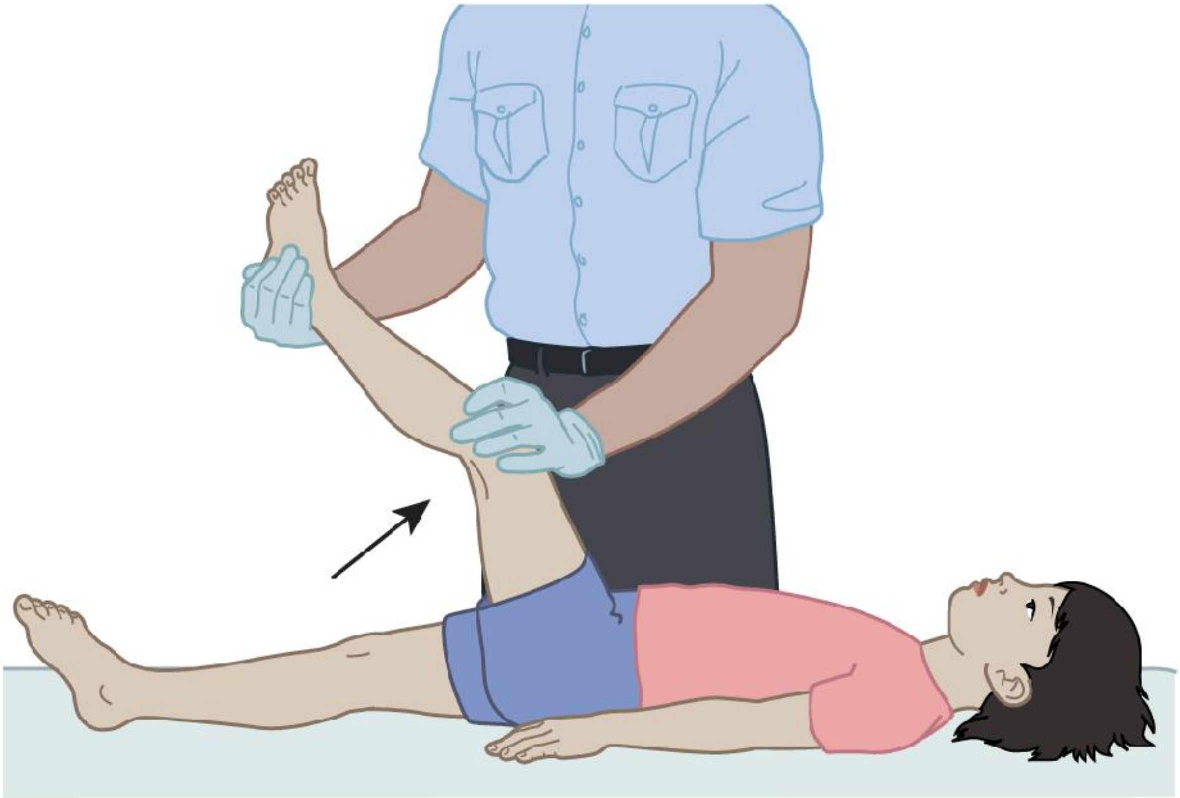
To assess the cremasteric reflex in men, the CCTP strokes downward on the inner aspect of the upper thigh and observes movement of the testicle in the scrotum. This test may be done on neonatal or pediatric patients during transport but is not likely to be done on adults. Cremasteric contraction elevates the testicle on the stimulated side. This exam tests the integrity of afferent (femoral nerve L1, L2) and efferent (L1, L2) fibers. Absence of the reflex may indicate a lesion in the reflex arc or a pyramidal lesion above L1, or it may be nonpathologic.

Evaluation of Meningeal Irritation

Meningeal irritation may result from infections caused by bacteria, viruses, fungi, parasites, or toxins. Infections may be classified as acute, subacute, or chronic. Each type of causative agent results in a different pathophysiology, clinical manifestation, and treatment.

In this condition, the causative agent acts as an irritant, causing an inflammatory reaction around the meninges found in the arachnoid space, the CSF, and the ventricles, and resulting in hyperemia and increased permeability of the meningeal vessels. Eventually, this reaction causes neutrophils to migrate into the subarachnoid space. The exudates formed as a result of this process thicken the CSF and interfere with its normal flow around the brain and spinal cord. In particular, these exudates can obstruct the arachnoid villi and produce hydrocephalus. The purulent exudates increase rapidly, causing increased inflammation, especially around the base of the brain but also extending into the cranial sheaths, spinal nerves, and perivascular spaces of the brain’s cortex. The meningeal cells become edematous. Over time, the combination of purulent exudates and cell edema results in increased ICP.

The clinical manifestations of meningeal irritation can be grouped into meningeal, infectious, and neurologic signs. The meningeal signs include generalized throbbing headache progressing in severity, progressive photophobia, nuchal rigidity, Kernig sign, and Brudzinski sign **FIGURE 12-28**.



A

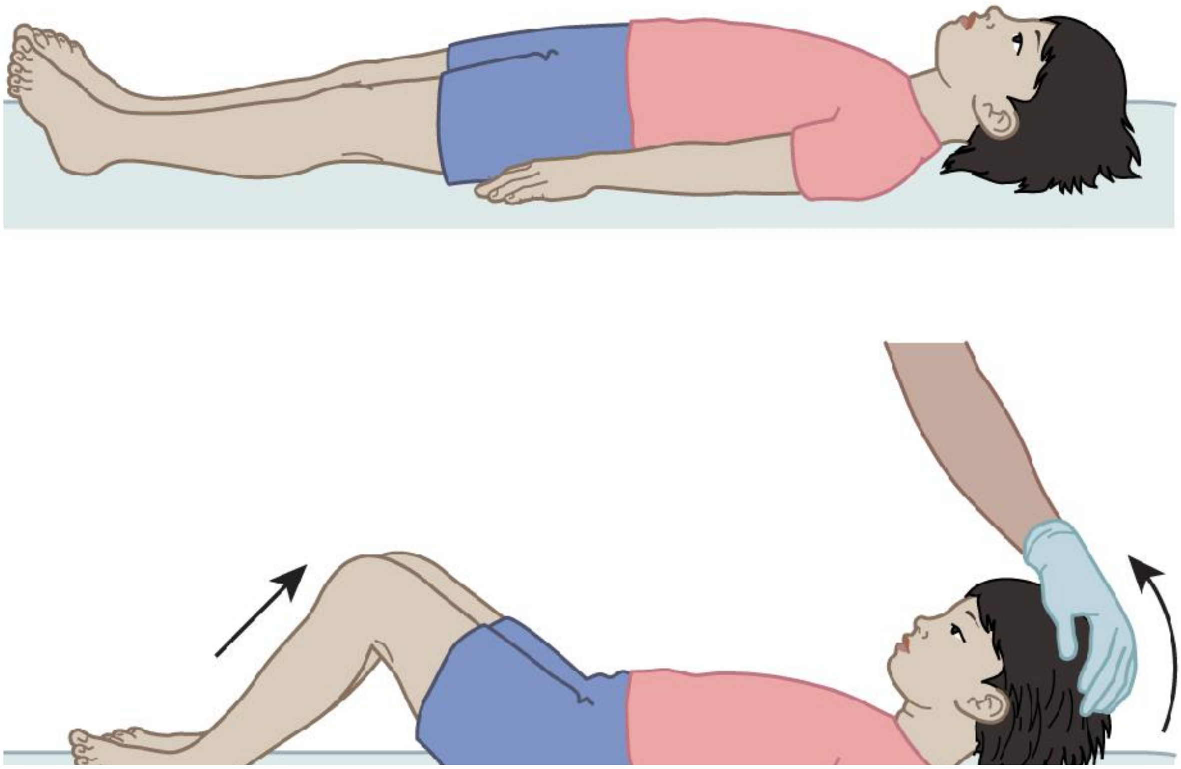


FIGURE 12-28 A. Kernig sign. Meningeal irritation results in the inability to straighten the leg with the hips flexed. **B.** Brudzinski sign. Meningeal irritation results in an involuntary flexion of the knees when the head is flexed toward the chest.

© Jones & Bartlett Learning.

Description

To test for **nuchal rigidity**, while the patient is lying flat, the CCTP places their hand behind the patient's head and gently flexes the head forward until the chin touches the chest, if possible. Marked resistance to head movement in any direction is suggestive of meningeal irritation. This test should not be performed if cervical spine injury is suspected.

Lhermitte Phenomenon

In the **Lhermitte phenomenon**, forward flexion of the neck produces an electric shock feeling, usually running down the back. The presence of this sensation indicates cervical pathology.

Vital Signs

As part of the neurologic examination, the CCTP should obtain vital signs. The centers for control of vital functions are found within the brainstem **TABLE 12-19** **FIGURE 12-29**. Thus, any changes in vital signs, which may be subtle, can provide invaluable information concerning the critical care patient's overall neurologic status. Such changes may include those related to breathing **TABLE 12-20** or cardiac function **TABLE 12-21**.

TABLE 12-19 **Control Center Location and Function**

System	Location	Function
Cardiovascular System		
Cardiac center	Medulla	Regulates rate and force of contraction
Vasomotor center	Medulla	Regulates blood pressure
Respiratory System		
Dorsal respiratory group	Medulla	Initiates inspiration; sets the basic rhythm of respiration
Ventral respiratory group	Medulla	Almost inactive except when increased ventilatory effort is needed
Apneustic center	Pons	Exact function is unclear; sends signals to the dorsal respiratory group to prevent apnea (especially in injury)
Pneumotaxic center	Pons	Modifies inspiration rate
Temperature Regulation		
Anterior hypothalamus (response to heat)	Hypothalamus	Activates cutaneous vasodilation, sweating, increased respiration, anorexia, apathy, and inertia
Posterior hypothalamus (response to cold)	Hypothalamus	Activates shivering, hunger, increased catecholamine release, cutaneous vasoconstriction, horripilation (bristling of hairs on the skin)

Description

TABLE 12-20 **Breathing Patterns**

Breathing Pattern	Location of Injury
Normal	Response to external stressor—not associated with central nervous system dysfunction

Breathing Pattern	Location of Injury
Posthyperventilation apnea	Associated with diffuse bilateral metabolic or structural disease of the cerebrum
Cheyne-Stokes respirations	Bilateral dysfunction of deep cerebrum, diencephalonic structures (thalamus and/or hypothalamus), or basal ganglia
Central neurogenic hyperventilation	Dysfunction of midbrain or upper pons
Apneustic breathing	Respiratory control mechanisms located at the pontine level
Cluster breathing	Dysfunction of lower pontine and upper medullary areas
Ataxic (Biot) breathing	Dysfunction of medullary control centers
Agonal gasps	Failing medullary control centers

Data from McCance K, Huether S. *Pathophysiology: The Biologic Basis for Disease in Adults and Children*. St Louis, MO: Mosby; 2002.

TABLE 12-21 Cardiovascular Variances

Cardiovascular Variance	Probable Causes
Bradycardia	Increasing ICP
	SCI involving the sympathetic pathways
Tachycardia	Shock
	The end stage of a neurologic injury
Arrhythmias	Increasing ICP
	Other intracranial pathologic conditions

Abbreviations: ICP, intracranial pressure; SCI, spinal cord injury

© Jones & Bartlett Learning.

Blood Pressure

The effect on BP most often seen as a result of neurologic injury is hypertension (an increase in BP), especially in the case of rising ICP. As cerebral perfusion decreases, ICP increases; in response, the body attempts to maintain adequate perfusion by increasing BP. Hypertension is commonly seen in conjunction with bradycardia and an abnormal respiratory pattern—a trio of symptoms collectively known as the **Cushing triad**.

Cerebral injury rarely causes hypotension except in the last stages of injury. The CCTP should, however, take all steps necessary to ensure that the patient does not become hypotensive (systolic blood pressure [SBP] less than 90 mm Hg): Even one episode can be associated with high mortality owing to its detrimental effects on cerebral perfusion.

Pulse pressure is also a valuable tool in the evaluation of neurologic injury. The CCTP may observe widening of the pulse pressure (to greater than 40 mm Hg) in the presence of increasing ICP (discussed later).

Body Temperature

Monitor the patient’s body temperature closely for changes. Alterations in body temperature, either hypothermia or hyperthermia, are possible in the presence of neurologic injury, especially if the hypothalamus is involved.

Neurogenic fever (NF), or fever in a patient with traumatic brain injury (TBI) not associated with an infection, was once thought to be relatively uncommon; more recent data, however, suggest that it may occur in as many as one-third of all patients with severe TBI. This condition is likely due to disruption of the hypothalamic temperature set-point, resulting in an abnormally increased body temperature. NF tends to respond poorly to antipyretic agents and may not be associated with the same degree of diaphoresis seen with other causes of fever. When it is suspected, an exhaustive workup is necessary to rule out infectious causes of the fever, as the diagnosis is made by first excluding all infectious possibilities.

Nutritional supplementation should be adjusted in patients with fever to address their increased catabolic demands, particularly in cases of prolonged, sustained fever. Every 1.8°F (1°C) increase in body temperature raises the metabolic rate by 13%, and this additional stress on a critically ill patient can significantly increase morbidity.

Neurologic Diagnostics

This section discusses the neurologic diagnostic tools with which the CCTP should be familiar.

Computed tomography (CT) scanning provides a mathematically reconstructed cross-sectional view of the body, including the brain, and is performed on almost every patient with abnormal neurologic findings. The image is obtained by passing intersecting x-ray beams through the area of interest and measuring the density of substances through which the x-ray beams pass. As the density of a substance increases, its image appears more white. As the density of a substance decreases, its image appears more black. In a normal CT scan of the head, bone appears white, blood appears off-white, brain tissue appears shaded gray, CSF appears off-black, and air appears black.

A CT scan can be performed with or without the use of an intravenous (IV) contrast medium. Noncontrast CT is typically undertaken to examine the intracranial area for evidence of intracranial hemorrhage, cerebral edema, or displacement of structures. **Computed tomography angiography (CTA)** adds the injection of an IV contrast agent into the patient moments before CT scanning. This variant allows for enhancement of vascular areas and better detection of vascular lesions. Patients receiving contrast should be monitored during infusion of the dye and for 10 to 20 minutes after the infusion for evidence of anaphylactic reaction. Patients should also be monitored for evidence of acute tubular necrosis.

The role of CTA has expanded recently, with this technology being used to diagnose large-vessel occlusion (LVO) that may be amenable to neurointerventional procedures. Several large randomized controlled trials—most notably, the MRClean and EXTEND-IA studies

—have demonstrated the benefits of neurointerventional treatment with cerebral angiography after IV administration of tissue plasminogen activator (tPA). As a result of these recent advances, most stroke imaging protocols now include a brain CTA after IV administration of tPA based on a negative noncontrast CT. CCTPs will likely be increasingly called upon to transfer patients who have experienced stroke from a primary stroke center to a comprehensive stroke center for neurovascular procedures when CTA demonstrates the patient has a clot amenable to treatment with this regimen.

Magnetic resonance imaging (MRI) produces images with greater detail than does CT and has become the standard diagnostic study for many conditions. A non–iodine-containing contrast medium is usually administered as an IV infusion before performing the procedure. The patient is then placed in a large magnetic field and radiofrequency waves that cause resonance of protons are introduced. A computer uses this resonance to create an image of internal structures and tissues.

Cerebral angiography allows for visualization of the lumens of vessels to provide information about those vessels' patency, size, irregularities, or occlusion. It is typically used in the diagnosis and treatment of cerebral aneurysm, arteriovenous malformation (AVM), and carotid artery disease. In this procedure, a catheter is inserted into the patient's femoral artery, threaded through the aorta, and enters into the origin of cerebral circulation. Once the catheter is in place, a radiopaque contrast medium is injected, facilitating visualization of circulation with the use of serial radiologic imaging. Neurointerventional treatments administered through the catheter can include embolization, clot lysis, and placement and removal of stents or coils. Potential complications associated with this procedure include contrast medium hypersensitivity and renal dysfunction.

Transcranial Doppler (TCD) ultrasonography allows monitoring of cerebral blood flow velocity through thinner areas of the skull; specifically, temporal bone (transtemporal), the eye (transorbital), and the foramen magnum (transoccipital). Blood flow velocities can be measured in the anterior, middle, or posterior cerebral arteries and the vertebral and basilar arteries depending on the angle of the

Doppler ultrasound probe. This imaging procedure is commonly used in patients following rupture of an intracranial aneurysm to assess for vasospasm, a problem commonly observed following rupture of a cerebral vessel. It can also be performed to identify intracranial lesions following a stroke and to detect cerebral blood flow changes associated with increased ICP.

Electroencephalography (EEG) involves the recording of electrical impulses generated by the brain to localize abnormal electrical activity. This technology is commonly used as a bedside test in patients with suspected seizure activity, cerebral infarct, metabolic encephalopathies, altered consciousness, infectious disease, and some types of head injuries, and to confirm brain death. Continuous EEG monitoring is often employed in critical care units for patients with known or suspected seizure activity or those at high risk of deterioration.

With this technology, electrodes placed on the patient's head allow electrical impulses to be transferred to a recording unit. Five types of waves are most commonly seen: delta, theta, alpha, beta, and gamma.

- *Delta bands* are normally observed in adults during sleep, and are also normal in infants. Pathologic causes of these waveforms include various types of lesions (including subcortical, diffuse, and deep midline lesions), as well as metabolic encephalopathy and hydrocephalus.
- *Theta bands* are normally associated with young children, drowsy older children, and drowsy adults, and are sometimes seen during meditation. Pathologic causes are similar to those for delta bands (focal subcortical lesions, deep midline disorders, metabolic encephalopathy, and some kinds of hydrocephalus).
- *Alpha bands* are normal when relaxing or closing the eyes, but are also associated with coma.
- *Beta bands* are normal when a person is active, working, or anxious. They may also appear following use of benzodiazepines.

- *Gamma bands* are normal and are associated with performing cognitive motor functions.

An EEG finding of intermittent slowing with triphasic wave morphology is associated with metabolic encephalopathy. Continuous generalized slowing in the delta or theta range indicates the presence of anoxic damage. Other abnormal EEG findings that are suggestive of a poor prognosis include the combination of alpha waves that do not change with stimulation and a coma state (alpha coma), occasional generalized bursts of activity with intermittent inactivity (burst suppression), generalized spikes at fixed intervals of 1 to 2 Hz, and no activity (electrocerebral silence).

Lumbar puncture is typically performed by entering the subarachnoid space in the lumbar region of the vertebral column with a needle to obtain diagnostic information or to provide a therapeutic intervention. CSF samples can be taken and evaluated for the presence of subarachnoid blood (subarachnoid hemorrhage) or infection, or sent for laboratory analysis (refer to Table 12-1 on CSF composition). The most common complication of this procedure is headache.

Laboratory Assessment

Laboratory studies, other than routine blood studies, biopsy, and CSF analysis, have not traditionally been used in the diagnosis and management of neurologic emergencies. For most patients, a complete blood count (CBC), basic chemistry panel, coagulation study, and cardiac biomarkers should be obtained.

The CBC serves as a baseline study and may reveal a cause of stroke, such as polycythemia or thrombocytosis, or provide evidence of a concurrent illness, such as anemia. The chemistry panel also serves as a baseline study and may reveal the origin of coma, such as hypoglycemia, or provide evidence of concurrent illness, such as renal insufficiency. Coagulation studies may reveal coagulopathy and are useful when the administration of fibrinolytics or anticoagulants is being considered. Cardiac biomarkers are important because of the association of cerebral vascular disease and coronary artery disease. Finally, a toxicology screening may be useful in selected patients in whom a harmful drug or chemical is the suspected cause of an altered level of consciousness, other abnormal neurologic finding, or vital sign anomalies, such as tachycardia or hypertension. See Chapter 21, *Toxicologic Emergencies*, for more information.

Traumatic Brain Injury

Although the rigid cranial vault protects it, the brain may be damaged when high forces impact the skull. Current understanding of the pathophysiology of TBI emphasizes the importance, or role, of two types of injury. Primary (direct) injury occurs as a result of traumatic forces that cause physical or functional disruption of brain tissue. Secondary (indirect) processes occur after injury and cause brain dysfunction or cellular damage (eg, hypoxia and ischemia). Secondary injuries (ie, physiologic derangements) occur rather frequently in the period following primary injury, but often cannot be recorded by standard monitoring equipment. Failure to identify the presence of these injuries may lead to a poor outcome.

Primary Brain Injury

The head is only one part of a collision in an accident; the brain is the other component involved. Primary brain injury can result from two mechanisms: contact phenomena injuries and acceleration-deceleration injuries.

Contact phenomena injuries occur as the direct result of trauma to the head; they include all local effects such as scalp laceration, skull fracture, hematoma, and intracerebral hemorrhage. For years, clinicians believed that contact phenomena injuries were the major factors causing damage in TBI. Subsequent research, however, has shown that the brain itself is often damaged by abrupt changes in velocity, which may cause strains, compression, tension, and shearing injuries to cerebral tissue. Sudden changes in velocity (acceleration-deceleration) cause the brain to move across its bony interior, resulting in damage. When the head is subjected to **translational force**, the head's center of gravity moves along a linear path; when it is subjected to **rotational force**, the head moves around its center of gravity. Rotational injuries result when forces cause the brain to twist within the cranial cavity, resulting in stretching or tearing of neurons in the white matter as well as tearing of the blood vessels that secure the brain to the skull.

Areas of the brain associated with rough portions of the skull (ie, the frontal and temporal lobes) have higher incidences of injury compared with areas with smoother surfaces, such as the occipital lobe. The term **contrecoup injury** is used to describe a situation in which an impact occurs on one side of the head, causing the brain to move within the cranial vault and forcibly contact the opposite side of the skull, resulting in damage on that side of the brain. This phenomenon is also referred to as transitional injury, because forces can be transferred to the opposite side of the brain **FIGURE 12-30**.

Most of the current literature cites work by Ommaya and his centripetal theory as the best model to explain the lesions observed after head injury. Ommaya's research simulated acceleration-deceleration injuries and found that certain types of brain injuries can be reproduced without any contact force acting on the head. Additionally, his research showed that the higher the magnitude of the injuring forces, the deeper the functional and structural damage that occurred to brain structures. As forces increase, the brainstem eventually becomes involved. Even without direct involvement of the brainstem, however, interruption of afferent nerve impulses may be sufficient to produce prolonged loss of consciousness.

Secondary Brain Injury

Secondary brain injury involves the more delayed mechanisms of brain damage. These physiologic derangements, if left uncorrected, will adversely affect brain function integrity. Secondary brain injuries may be classified as insults of either systemic or intracranial origin **TABLE 12-22**.

TABLE 12-22 Causes of Secondary Insult to the Brain

Systemic Origin	Intracranial Origin
Hypoxia	Hematoma
Hypercarbia	Swelling, vasospasm
Arterial hypotension	Raised intracranial pressure
Severe hypocarbia	Infection
Fever	Epilepsy
Hyponatremia	Hydrocephalus
Anemia	

© Jones & Bartlett Learning.

The pathophysiology of secondary brain injury is well understood. After a brain injury occurs, the normal protective mechanisms may no longer maintain blood flow in the face of falling perfusion pressure, or they may not increase blood flow during hypoxemia. As a consequence, ischemic or hypoxic damage is more likely to occur **FIGURE 12-31**.

Description

Mechanically injured neurons are more susceptible to the effects of hypoxemia and cerebral hypoperfusion. They are also vulnerable to damage by the high concentrations of neurotransmitters (eg, glutamate and aspartate) and toxic metabolites that accumulate in the extracellular environment in the wake of TBI.

Neuronal swelling, edema, and cerebral hyperemia from carbon dioxide retention combine to raise the ICP and lower the **cerebral perfusion pressure (CPP)**. This relationship can be expressed mathematically as **mean arterial pressure (MAP)** minus ICP equals CPP:

$$\text{MAP} - \text{ICP} = \text{CPP}$$

where

$$\text{MAP} = \text{DBP} + \tfrac{1}{3}\,(\text{SBP} - \text{DBP})$$

As an example, suppose a patient has a BP of 190/100 mm Hg. The calculation of MAP would be

$$\text{MAP} = 100 + \tfrac{1}{3}\,(190 - 100)$$

$$= 100 + \tfrac{1}{3}\,(90)$$

$$= 100 + 30$$

$$= 130$$

CPP is the primary determinant of blood flow to injured brain tissue when the injury has impaired the ability of the cerebral circulation to autoregulate in response to fluctuations in systemic BP **FIGURE 12-32**. The situation is exacerbated if the ICP is further raised by the presence of a space-occupying lesion or by swelling, or if the CPP is further reduced by extracranial blood loss. The resulting positive feedback loop rapidly causes irreversible clinical deterioration if cerebral perfusion and oxygenation are not quickly improved.

Abbreviations: BP, blood pressure; ICP, intracranial pressure

Data from McCance K, Huether S. *Pathophysiology: The Biologic Basis for Disease in Adults and Children*. 7th ed. St. Louis, MO: Elsevier Mosby; 2014.

Description

Normal ranges for CPP, MAP, ICP, and end-tidal carbon dioxide ($ETCO_2$) in adults are as follows:

- CPP: 70 to 90 mm Hg; should not go below 70 mm Hg
- MAP: 70 to 110 mm Hg
- ICP: 5 to 15 cm H_2O
- $ETCO_2$: 35 to 45 mm Hg

Specific Neurologic Injuries

Scalp Injuries

Injury to the scalp is oftentimes the first indication that a patient has a brain injury. The forces involved in the primary injury determine the type and extent of scalp injury that may be visible. Common injuries to the scalp include abrasions, contusions, lacerations, and avulsions. Like facial injuries, scalp injuries tend to bleed profusely because of the highly vascular nature of the scalp.

Abrasions involve the top layer of the scalp, which may be rubbed away, as evidenced by minor bleeding. Treatment usually focuses on controlling bleeding and cleaning and dressing the area. It is important to remember that some scalp injuries can occur simultaneously secondary to the mechanism of injury.

When examining an abrasion, the CCTP may also note an underlying contusion. Contusions are scalp bruises with possible accumulation of blood in the subcutaneous layer. Definitive control of bleeding is often best achieved by stapling or suturing significant scalp lacerations. It is also important to rule out more significant (deeper) injuries.

Lacerations can be more serious. In these injuries, the scalp is violently torn, leaving a jagged opening that may extend through multiple layers of tissue and even down to the skull itself. Bleeding may be profuse, and deeper injury to the brain tissue or skull is very likely.

Avulsions result from forceful, partial, or complete tearing away or separation of the scalp tissue, which appears as a flap. The primary concerns with this type of injury are the underlying integrity of the skull and the risk of infection resulting from introduction of contaminants. Treatment should focus on evaluation of the skull for fractures and a thorough cleaning of the tissue under the avulsion.

Skull Fractures

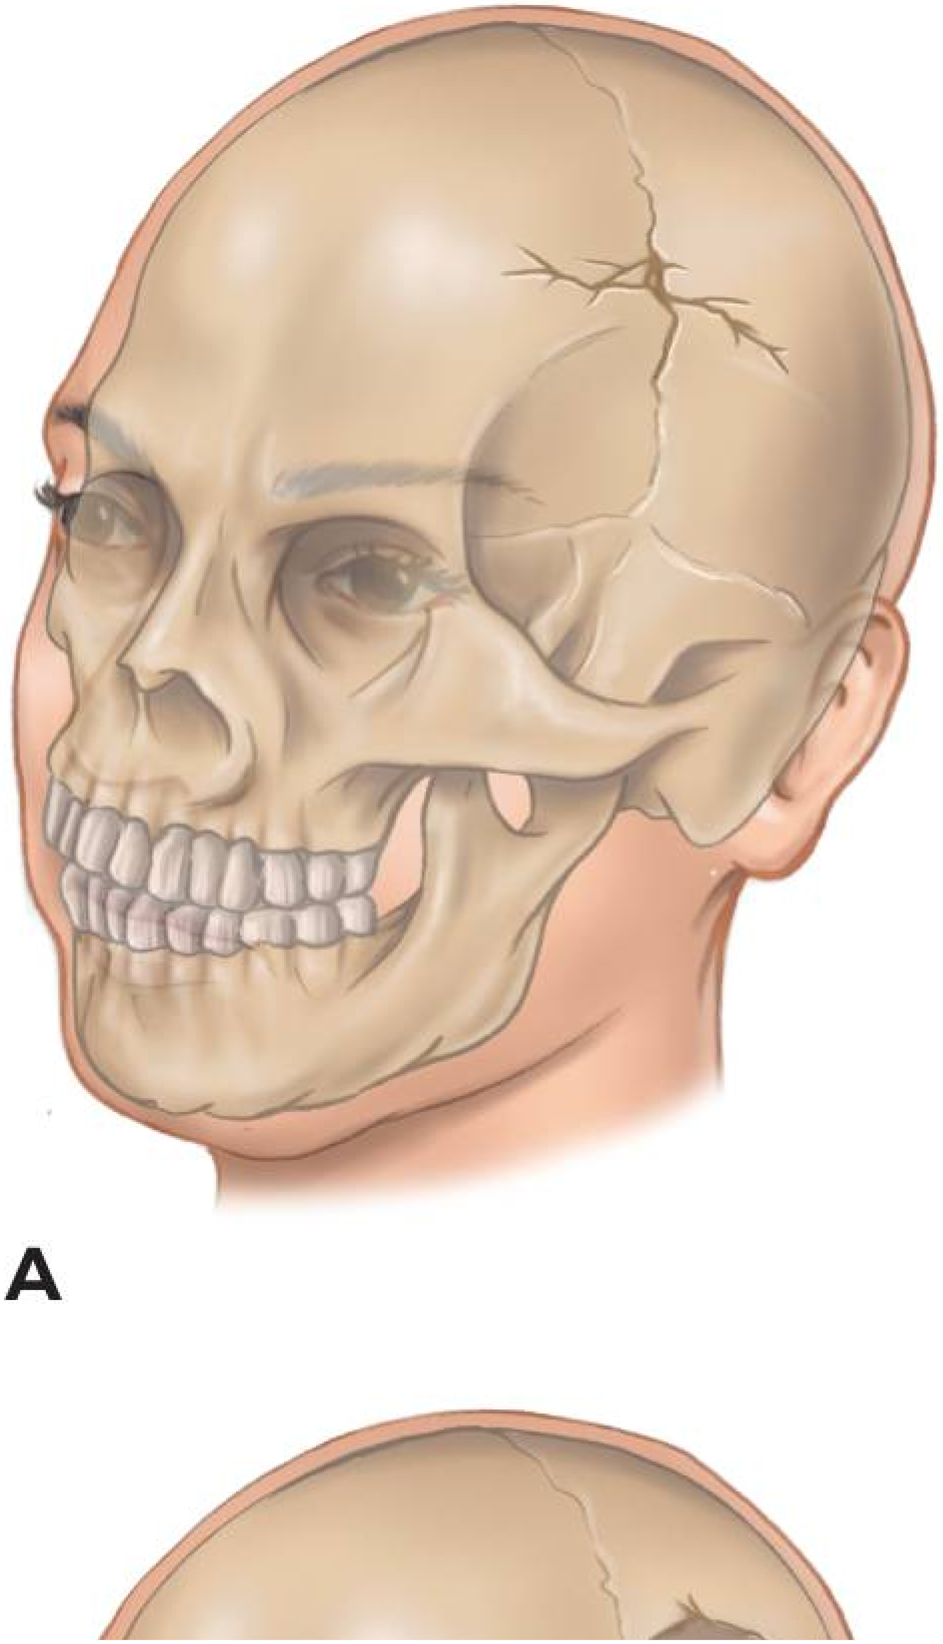
Skull fractures result from a direct, and often high-force, blow to the cranium; they are present in more than 50% of patients with a severe TBI. Any of the bones that make up the skull—the frontal, parietal, temporal, occipital, sphenoid, and ethmoid bones—may be fractured. Between the skull and the dura, large blood vessels can be damaged; if the impact is severe enough, this damage can result in hemorrhaging within the brain.

Although not a part of the cranium, the bones of the face—the maxillary, zygomatic, nasal, lacrimal, and palatine bones; vomer; mandible; and part of the ethmoid and sphenoid bones—may also be fractured. Such fractures may indicate possible underlying brain injury.

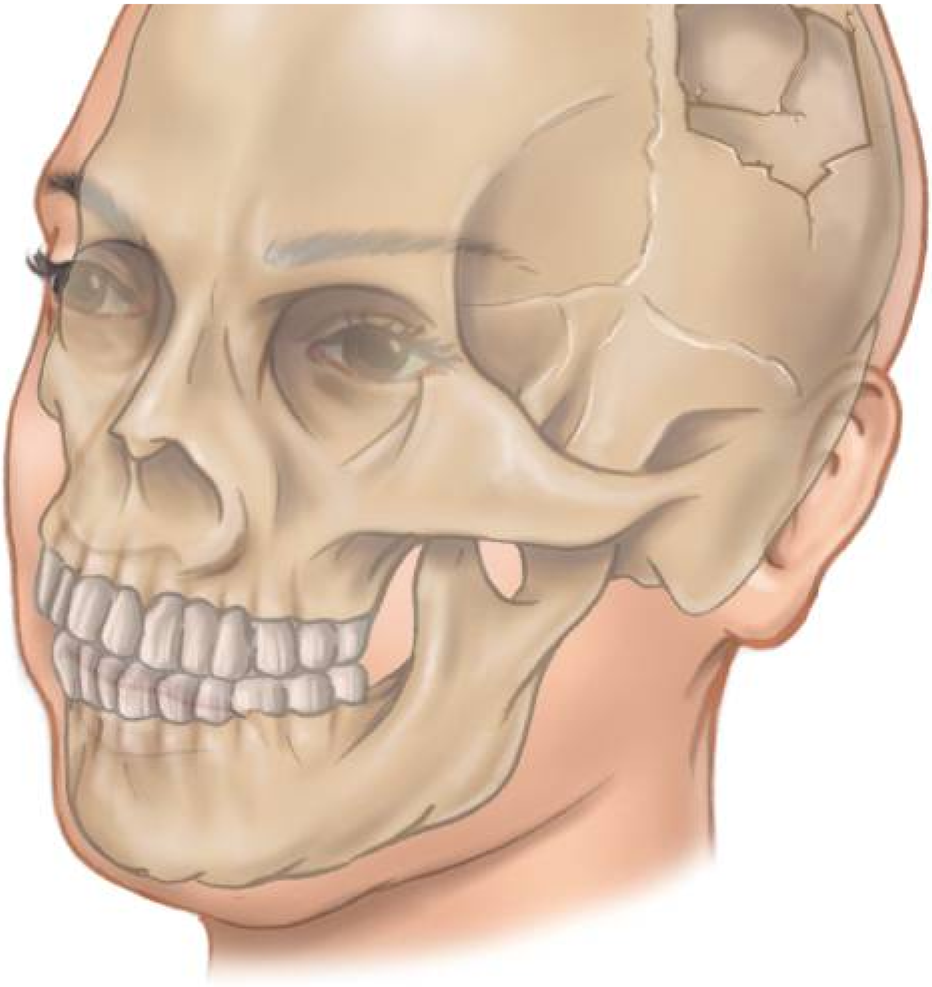
Skull fractures are classified into linear, depressed, comminuted, and basilar types.

Linear Skull Fractures

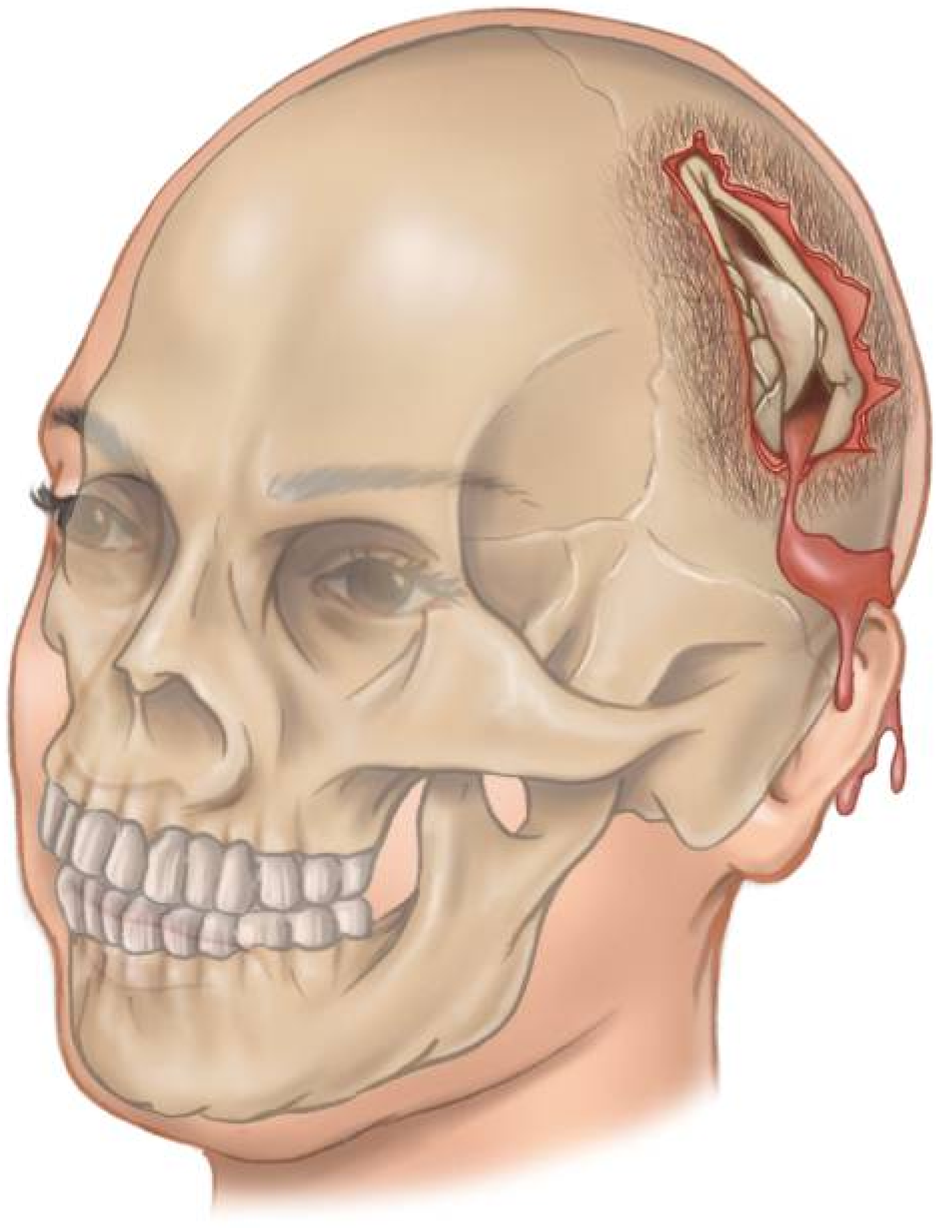
A **linear skull fracture** is characterized by a single fracture line and is often an incidental finding of CT. This kind of fracture occurs when two or more bones of the skull separate at the suture line. Hematomas, soft-tissue swelling, and point tenderness are usually present over the site of impact **FIGURE 12-33A**. A simple closed linear fracture rarely requires any surgical intervention.



A



B



C

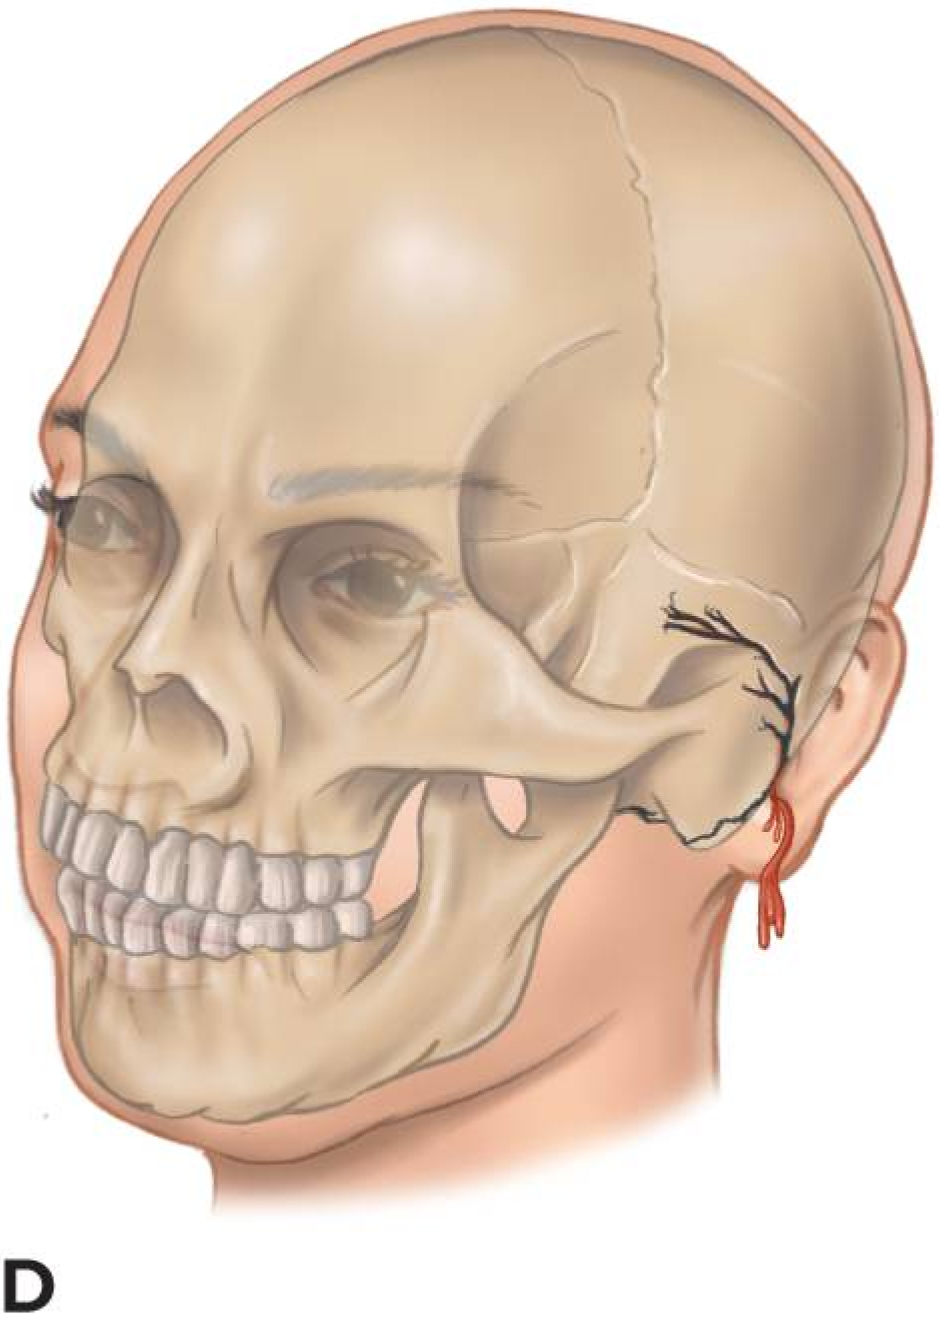


FIGURE 12-33 Types of skull fractures. **A.** Linear. **B.** Depressed. **C.** Open. **D.** Basilar.

© Jones & Bartlett Learning.

Stellate fractures of the skull (and other bones) are also possible. A **linear stellate fracture** comprises multiple linear fractures radiating from the site of impact. These fractures have the potential to do damage depending on the number and depth of the fracture(s).

In contrast, a **diastatic stellate fracture** involves the separation of an epiphysis when it is the center site of impact. Diastatic stellate fractures are prevalent in abused children. Thus, the presence of a diastatic fracture to a long bone in a child should arouse suspicion of possible head trauma or shaken baby syndrome.

Depressed Skull Fractures

In a **depressed skull fracture**, a portion of the skull is depressed, and the scalp and/or dura may or may not be torn **FIGURE 12-33B**. This type of fracture may produce soft-tissue swelling over the site of the trauma; a bony step-off may be palpated as well. Depressed skull fractures may be classified as open or closed, indicating the presence, or lack thereof, of a breach in the dura mater in conjunction with the fracture. An open depressed skull fracture **FIGURE 12-33C** is the more serious of the two injuries.

Three types of depressed skull fractures are distinguished: true, flat, and ping-pong ball fracture. In a **true fracture** (the most common type), the fracture has contact with the cranial vault. A **flat fracture** features a depressed segment without any connection with the cranial vault and is the least common type. A **ping-pong ball fracture** is a pediatric greenstick fracture of the skull. Although these distinctions may be of importance in the hospital setting, during the prehospital phase of the transport, the most important considerations are to identify the existence of a depressed skull fracture, to classify it as open or closed, and to treat it appropriately.

Comminuted Skull Fractures

A fracture in which the skull is splintered or shattered into many pieces is referred to as a **comminuted fracture**. These pieces may then act as projectiles and cause direct injury to the meningeal layers or the brain tissue itself. A great deal of blunt force is required to cause this type of skull fracture.

Basilar Skull Fractures

A **basilar skull fracture** involves fractures along the base of the skull **FIGURE 12-33D**. This area is punctuated by multiple foramina that accommodate the spinal cord, nerves, and blood vessels. Because of the many hollow or open spaces within the skull (eg, the sinuses, eye orbits, nasal cavities, external auditory canals, middle and inner ears), the skull is weaker here and susceptible to basilar fractures. Basilar fractures usually result from a blow to the parietal, temporal, or occipital regions of the skull, with the temporal area being the most commonly affected.

Tearing of the dura mater during a basilar skull fracture may also occur, resulting in a wound between the brain and the external environment. This condition may present with leakage of CSF, which may be combined with blood through the dural tear either into the nasal cavity or via the external auditory canal **FIGURE 12-34**. Openings in the dura mater also provide a conduit for infectious agents to enter the meninges or brain tissue. The **halo test** for leaking CSF is accomplished by collecting escaping fluid from the nose, mouth, or ears, onto a gauze pad. The appearance of a “target” or “halo” symbol consisting of a dark red circle surrounded by a lighter yellow one is considered a positive halo sign **FIGURE 12-35**. The CCTP must exercise caution when using the halo test as the sole diagnostic evaluation of a CSF leak, because other fluids such as lacrimal fluid, nasal fluid, or saliva may cause a similar response.

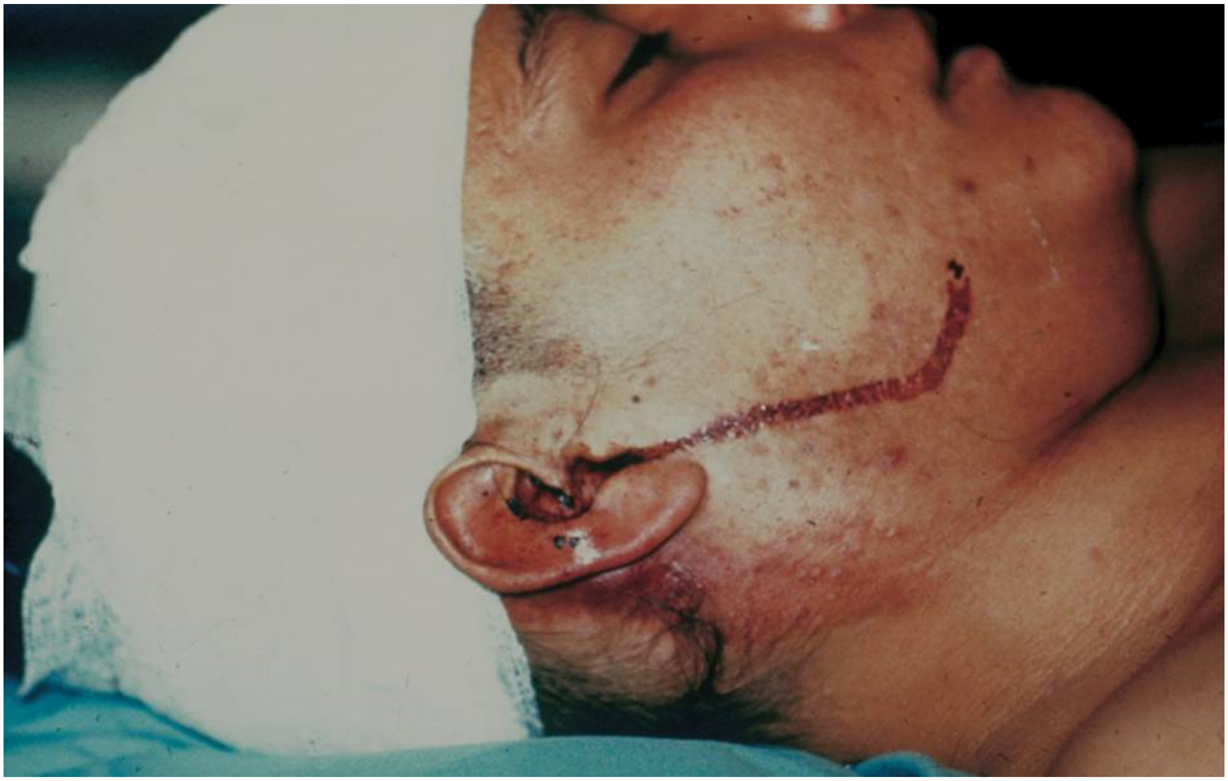

FIGURE 12-34 Blood leaking from the external auditory canal after a head injury may contain cerebrospinal fluid and suggests a basilar skull fracture.

Other clinical signs may be evident depending on the location of the injury. Fractures involving the auditory canal and lower lateral areas of the skull may result in the migration of blood to the mastoid region, posterior and slightly inferior to the ear, resulting in discoloration referred to as retroauricular ecchymosis or **Battle sign** **FIGURE 12-36**. Similarly, orbital fractures and hemorrhaging into the surrounding tissue are known as periorbital ecchymosis or **raccoon eyes** **FIGURE 12-37**. Raccoon eyes and Battle sign may take several hours to develop and become evident after the injury; thus, these signs are not often seen by emergency paramedics during initial evaluation of a head-injured patient at the scene of initial trauma but may be seen by the CCTP during transport and/or subsequent treatment of the patient.

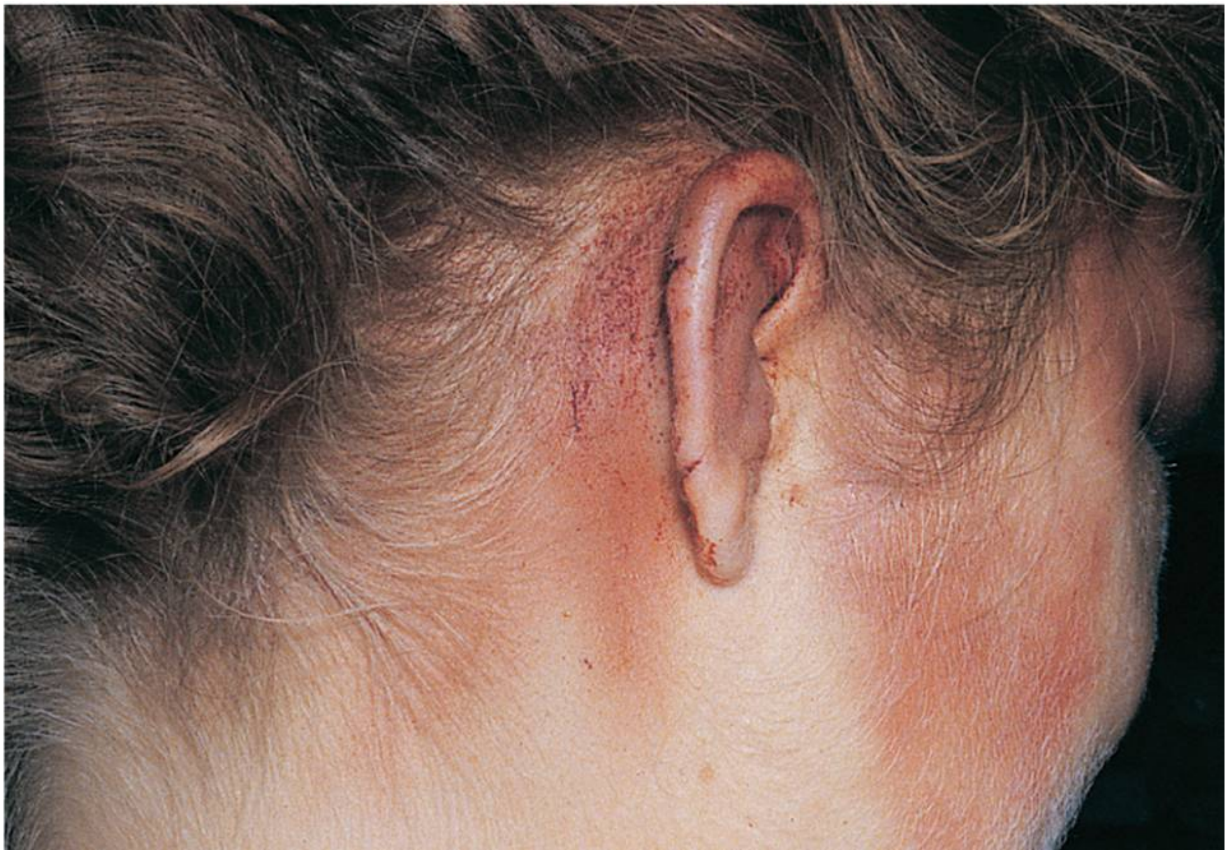

FIGURE 12-36 Battle sign consists of ecchymosis behind the ear or over the mastoid process.

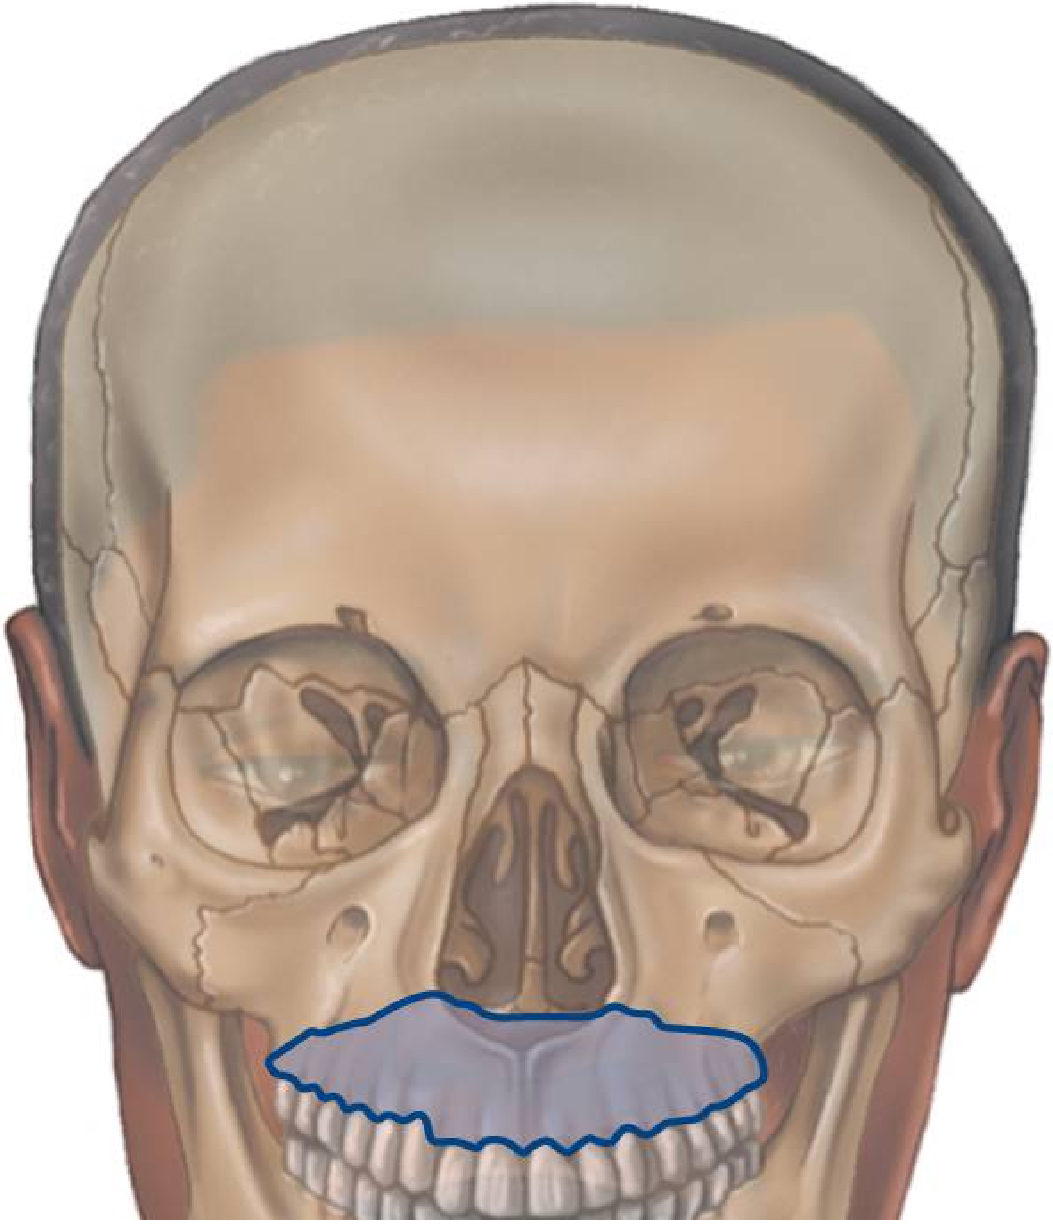
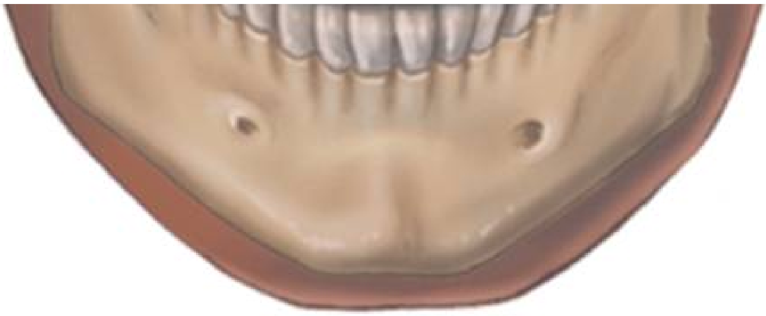
Facial Fractures

As many as 60% of patients with significant facial injuries sustain trauma to other organ systems, including the brain. Unfortunately, many facial injuries have very grotesque presentations accompanied by copious bleeding—characteristics that may potentially distract the CCTP from other, more serious injuries. Fractures of the facial bones are usually very painful and require massive amounts of analgesia to maintain patient comfort. This is especially true with mandible fractures, which can cause life-threatening airway compromise if the patient is in the supine position. Because of the instability of the mandible, the tongue no longer has support and can become lodged in the back of the airway, obstructing this passageway.

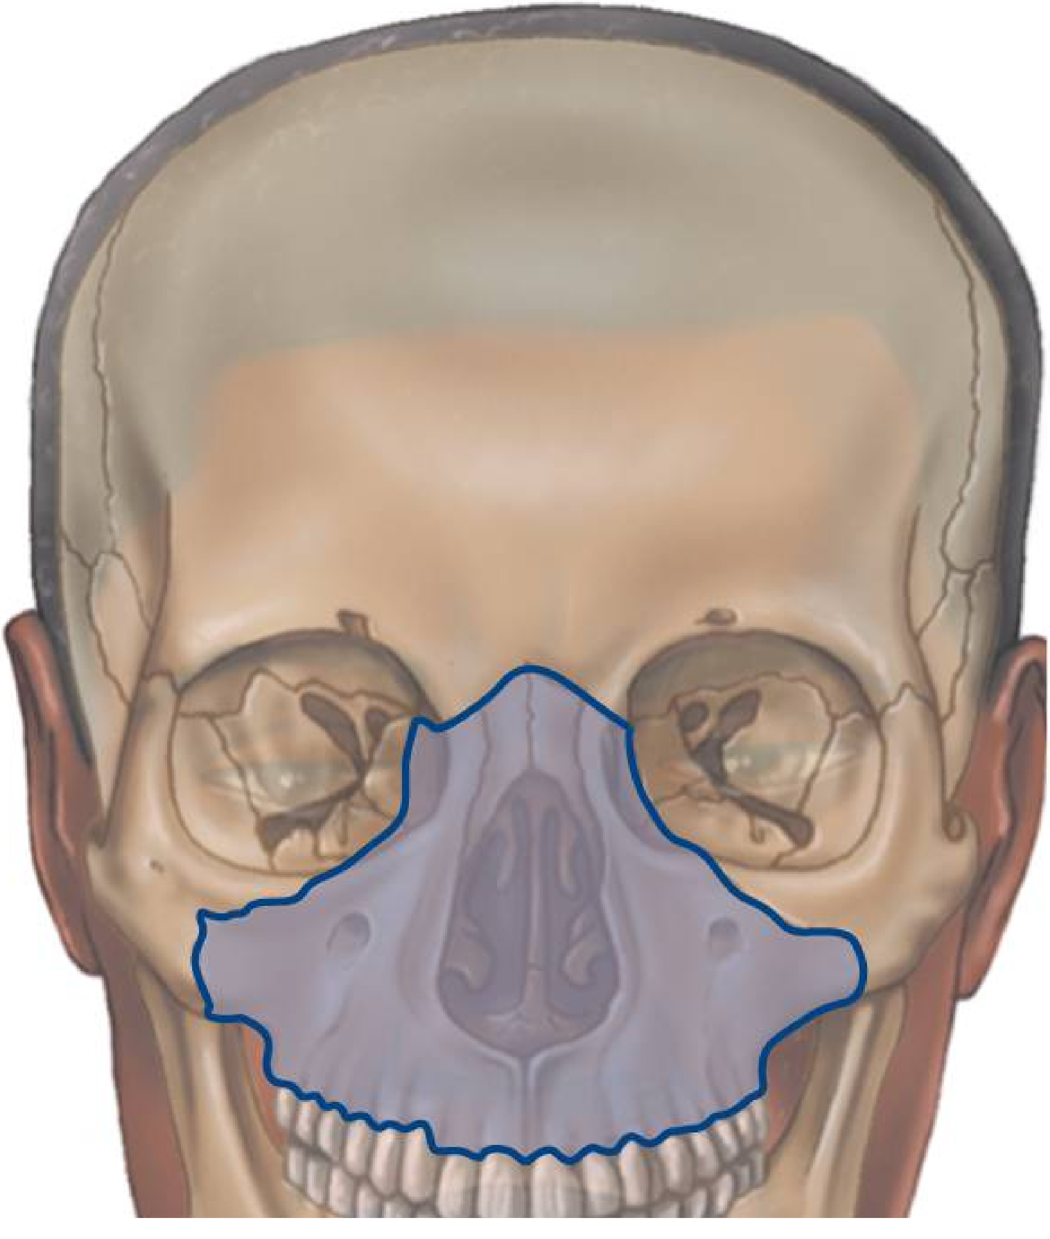
Airway control is the first assessment priority in patients with facial injuries. After securing the airway, the CCTP can assess for the presence of facial fractures by grasping the hard palate and rocking it back and forth. The CCTP should also check for malocclusion and dental trauma, test extraocular muscles to rule out orbital fractures, and look for facial elongation ("monkey face") and periorbital ecchymosis.

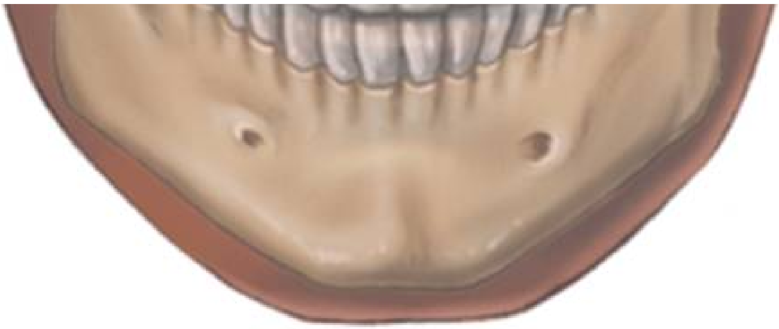
Some of the most serious facial injuries are maxillary fractures, which result from high-energy forces to the face. These fractures are classified using the **Le Fort criteria** **FIGURE 12-38**.



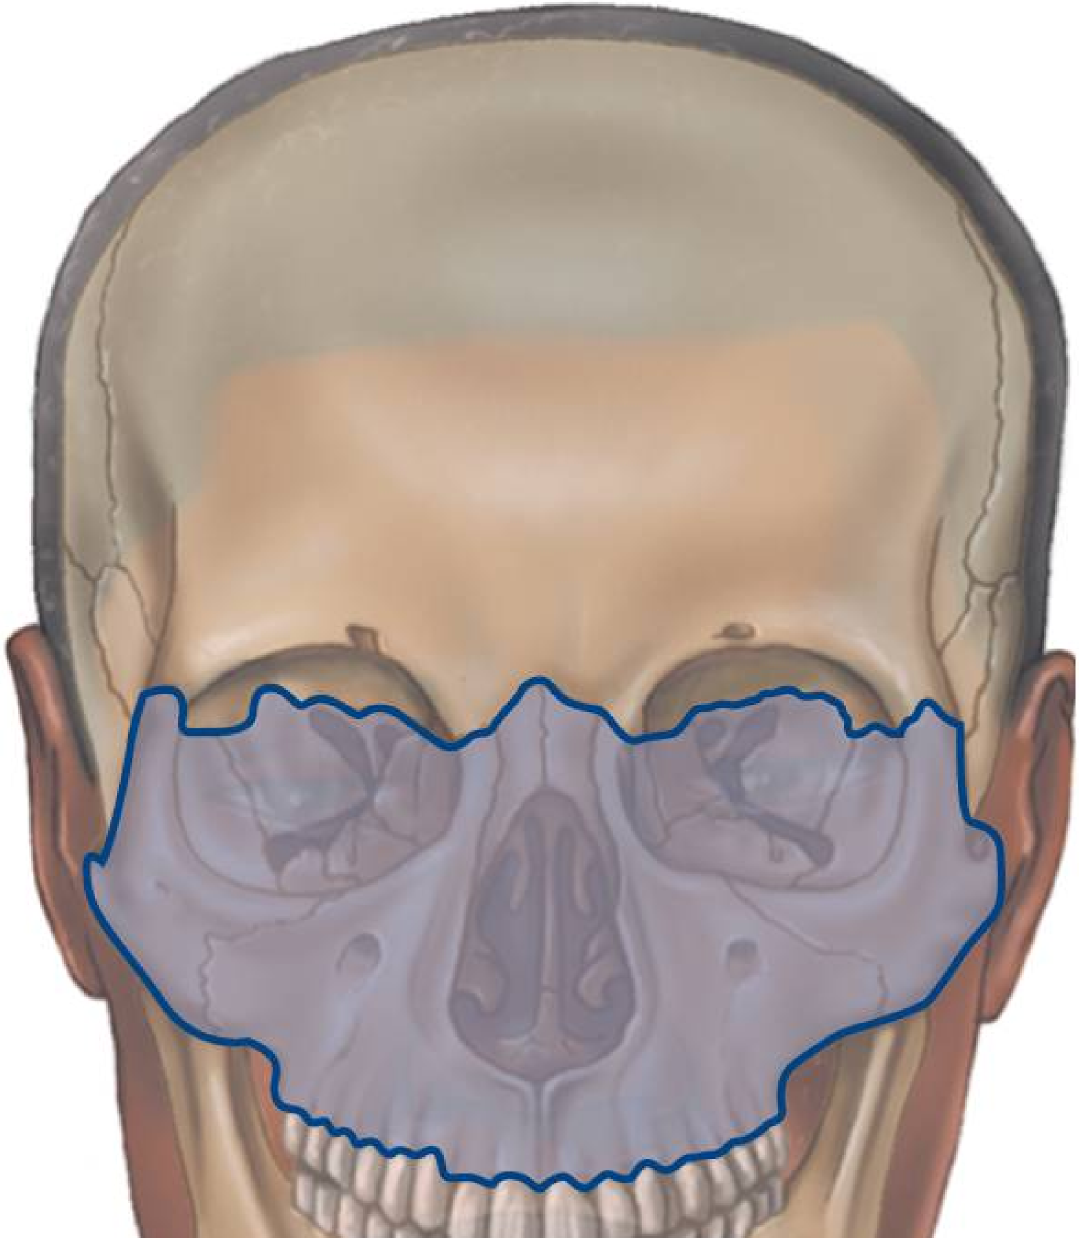


A





B



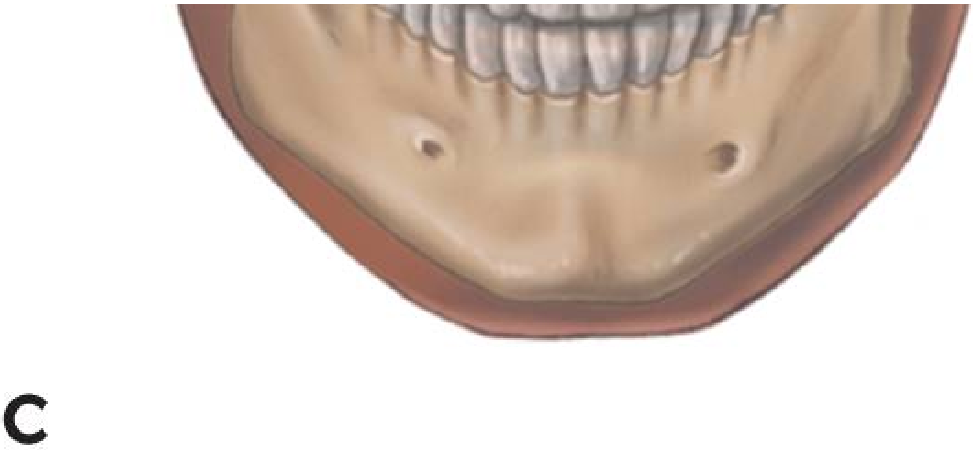


FIGURE 12-38 Le Fort fractures. **A.** Le Fort I. **B.** Le Fort II. **C.** Le Fort III.

© Jones & Bartlett Learning.

- *Le Fort I* is a transverse fracture separating the hard palate from its bony frame. This fracture exhibits slight instability to the maxilla with no associated displacement.
- *Le Fort II* is a fracture involving the central maxilla and palate; it has a pyramidal appearance (the fractured portion is shaped like a pyramid). This fracture extends through both maxilla and the nasal bones.
- *Le Fort III* is effectively a craniofacial disruption, with fractures extending from the frontozygomatic sutures, orbits, and nasoethmoidal regions. This fracture is unstable and is associated with oral and nasal patency problems. It can leave the patient with a “monkey face” appearance, resulting from the protrusion of the face secondary to its instability.
- *Le Fort IV* is essentially a Le Fort III fracture with a concurrent frontal bone fracture.

Le Fort III fractures usually result in leakage of CSF.

Brain Injuries

Injuries to the brain can be either focal or diffuse. Focal lesions are those large enough to be observed directly. In contrast, diffuse injuries are not associated with gross localized and visible lesions, but include concussions and diffuse axonal injuries **TABLE 12-23**.

TABLE 12-23 Brain Injury Types

Focal	Diffuse
Contusion Hematoma Epidural Subdural	Axonal injury
Intracerebral	Hypoxia/ischemia
Swelling	Diffuse vascular
Infarct	Fat embolism
Pressure necrosis	Subarachnoid
Abscess	Meningitis

Focal Injuries

Contusions and Lacerations

A cerebral contusion is a bruising of the brain tissue. Patients with isolated cerebral contusions may exhibit altered mental status, but rarely develop coma. Contusions commonly occur with rapid deceleration injuries and typically appear on the tips of the frontal and temporal lobes, where the skull base has an irregular shape. Contusions appearing on the same side of the impact are known as coup injuries, whereas injuries on the side opposite the impact are known as contrecoup injuries (see Figure 12-30).

Treatment for patients with cerebral contusions is largely supportive; no surgical intervention is usually needed. The patient should be monitored for evidence of increasing ICP resulting from hematoma or edema formation; if either of these conditions occurs, it should be treated aggressively.

Special Populations

Indirect and hemorrhagic brain injuries are much more common in older adults. The brain tends to atrophy with aging, so older patients can tolerate more swelling before herniation occurs, making it easier to tear the bridging veins.

Lacerations that result in penetration of the cranium may cause tearing of the cortical surface of the brain. A major difference between a contusion and a laceration is that the pia mater and arachnoid mater are torn over a laceration but remain intact over a contusion. Treatment for cerebral lacerations is identical to that for cerebral contusions, with the CCTP monitoring for signs of increasing ICP.

Epidural Hematomas

An accumulation of blood between the inner periosteum and the dura mater is known as an **epidural hematoma (EDH)**, also called an extradural hematoma. Most EDHs are arterial in origin, occurring when a blow strikes the temporal region and causes concomitant disruption of the middle meningeal artery. Blood may accumulate quickly in the potential space as the high arterial pressure gradually strips the dura away from the inner surface of the skull, forming an oval-shaped mass that exerts pressure on the underlying brain tissue **FIGURE 12-39**. An EDH can be caused by venous bleeding but is limited by the space between the dura and the skull. As the hematoma enlarges, however, the temporal lobe may be displaced and squeeze over the tentorium.

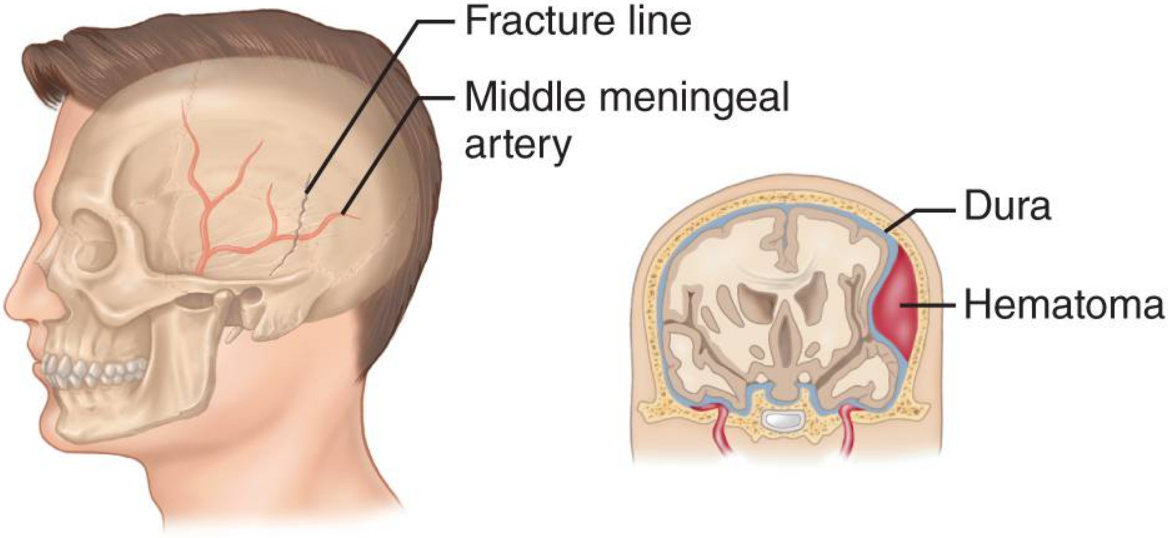

FIGURE 12-39 An epidural hematoma, caused by a blow to the temporal region of the head and concomitant disruption of the middle meningeal artery, with the accumulation of blood between the inner periosteum and the dura mater.

© Jones & Bartlett Learning.

The patient with an EDH may present with a history of a brief period of unconsciousness, followed by a lucid period lasting for minutes to several hours. The lucid period ends with a rapid deterioration of consciousness from drowsiness, to lethargy, and then to coma as a mass effect and herniation develop. If tentorial herniation (herniation of the tentorium of the cerebellum) occurs, the third cranial nerve may become compressed, causing an ipsilateral fixed and dilated pupil **FIGURE 12-40**. Tentorial herniation may also occur on the opposite side, causing either contralateral or bilateral blown pupils (Kernohan notch phenomenon). As ICP continues to rise, the patient may develop bradycardia, Cheyne-Stokes respiratory patterns that progress to brainstem patterns, and brain distortion. Other clinical manifestations may include headache, seizures, hemiparesis or hemiplegia, decorticate or decerebrate posturing **FIGURE 12-41**, respiratory distress, and death. The most common presentation includes vomiting, seizures, unilateral hyperreflexia with a positive Babinski sign, and elevated CSF pressure.

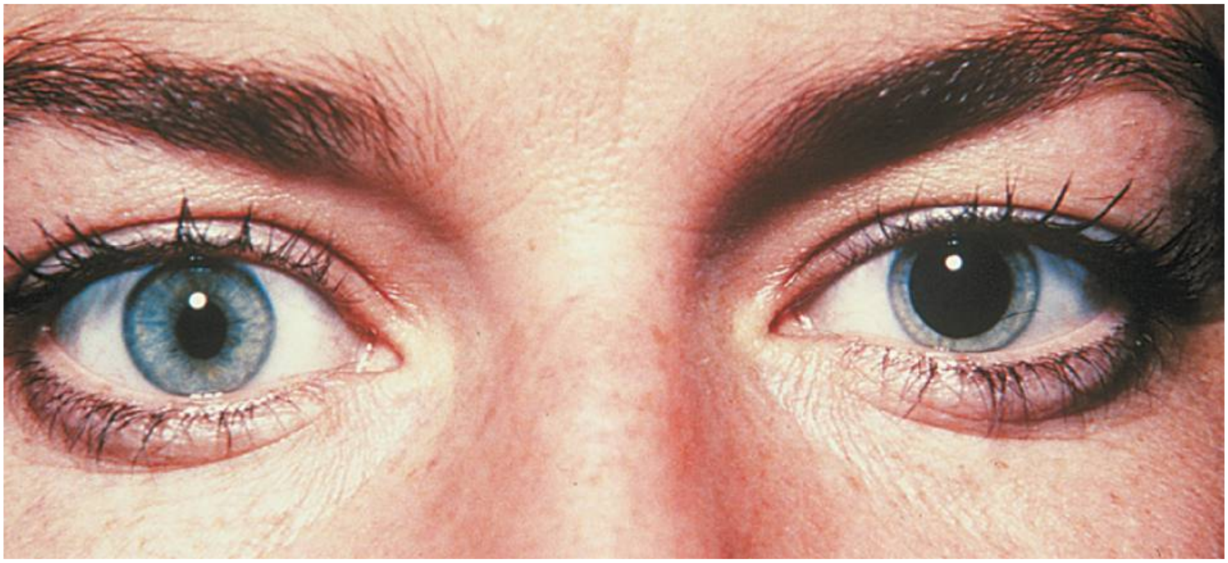

FIGURE 12-40 Ipsilateral fixed and dilated pupil.

© American Academy of Orthopaedic Surgeons.

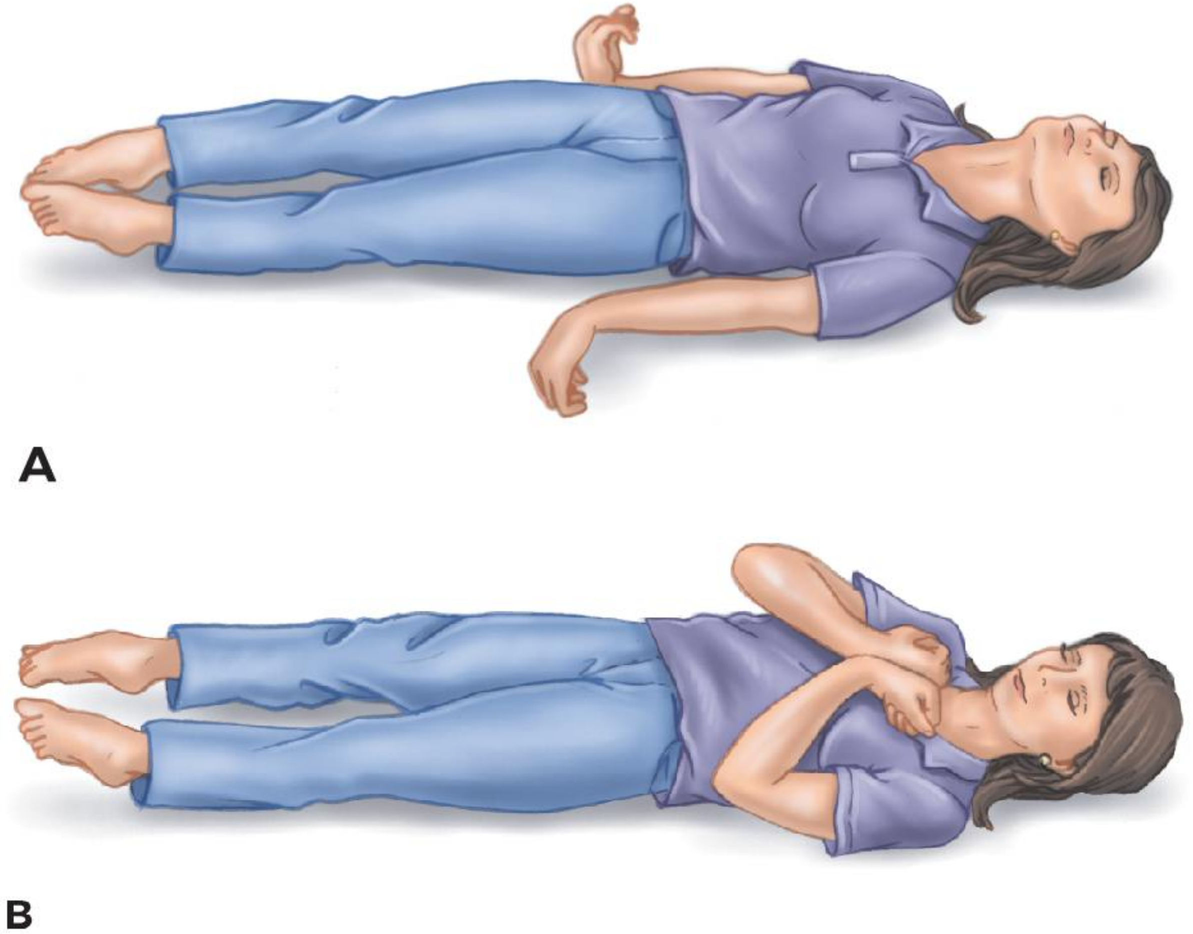

FIGURE 12-41 Posturing indicates significant intracranial pressure. **A.** Decerebrate (extensor) posturing. **B.** Decorticate (flexor) posturing. (Think of the arms being pulled to the core of the body.)

© Jones & Bartlett Learning.

Large hematomas produce a mass effect (ie, act as a space-occupying lesion) and increased ICP. If herniation occurs or will likely occur, the hematoma should be evacuated with a craniotomy. The torn vessel will also be repaired during the craniotomy.

The bleeding with EDH can sometimes be so severe that, in some cases, the brain is actually displaced (midline shift) within the skull. Some medications, such as osmotic diuretics (mannitol), can be given in the early stages of midline shift to slow the progression of this condition until surgical intervention can be obtained.

Mannitol is an osmotic diuretic used to reduce the increased ICP resulting from an increased volume of CSF. It is also used to reduce intraocular pressure. In the case of brain hemorrhage, increases in CSF result from inflammation of brain tissue caused by blood or damage to the subarachnoid villa, which impedes reabsorption of CSF. Mannitol is also useful for patients with cerebral edema not related to a brain bleed. It has little effect in reducing the volume of blood that accumulates owing to the hemorrhage, however. The dosage for adults and children older than 12 years is 1.5 to 2 g/kg in a 15%, 20%, or 25% IV solution given over 30 to 60 minutes via an infusion pump.

Hypertonic saline may also be administered to reduce ICP. Given either by bolus or by continuous infusion, hypertonic saline likely reduces ICP through osmotic effects. Concentrations and volumes administered vary significantly, with concentrations ranging from 1.5% to 23.5% and volumes from 10 to 30 mL/kg.

Brainstem herniation is a primary concern with EDH. It occurs when the expanding blood pushes the brain down the foramen magnum, causing a shearing-type force on the brain. Once this takes place, death is imminent, because this condition is irreversible.

Signs and Symptoms

Epidural Hematoma

- Brief period of unconsciousness, followed by a lucid period lasting for minutes to several hours
- Following the lucid period, rapid deterioration of consciousness (drowsiness to lethargy to coma)
- Ipsilateral fixed and dilated pupil
- Contralateral or bilateral blown pupils (Kernohan notch phenomenon)
- Headache
- Bradycardia
- Cheyne-Stokes respiratory pattern, progressing to brainstem breathing patterns
- Possible seizures
- Hemiparesis
- Hemiplegia

- Decorticate or decerebrate posturing
- Respiratory distress
- Vomiting
- Seizures
- Unilateral hyperreflexia with a positive Babinski sign
- Elevated CSF pressure
- Elevated ICP with brain distortion
- Death

Transport Management

Epidural Hematoma

- Provide rapid transport.
- Consider administering an osmotic diuretic (mannitol).

Subdural Hematomas

High-energy impacts may also result in bleeding that accumulates between the dura and arachnoid mater, known as a **subdural hematoma (SDH)**. SDHs are six times more common than EDHs and have a higher mortality rate. Most SDHs result from a disruption of the bridging veins located over the crest of the brain and their subsequent bleeding. SDHs are categorized based on the time that elapses between the initial injury and the appearance of signs and symptoms as well as the appearance of the blood and fluid composition **FIGURE 12-42**.

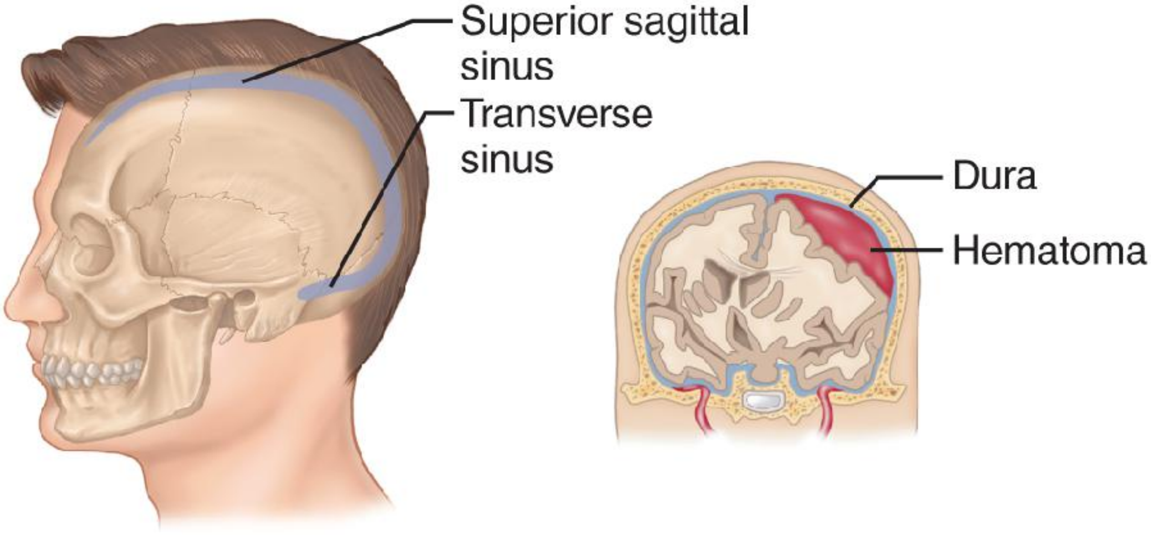

FIGURE 12-42 A subdural hematoma, in which venous bleeding occurs beneath the dura mater but outside the brain.

© Jones & Bartlett Learning.

Acute SDH—that is, SDH in which signs and symptoms appear within 24 hours of the injury—is commonly seen with acceleration-deceleration injuries. With this type of injury, clotted blood may be visible on CT as crescent-shaped collections of blood with high attenuation usually along the cranium. Patients usually present with a gradual or sometimes rapid deterioration in level of consciousness, pupillary changes, and hemiparesis or hemiplegia.

In subacute SDH, signs and symptoms appear between 2 days and 2 weeks after the initial injury because the blood accumulates more slowly. This type of hematoma consists of a mixture of clotted and fluid blood; on CT, it may appear as areas that are isodense, hypodense, or of mixed density depending on the age of the lesion **FIGURE 12-43**. Patients with subacute SDH present with gradual mental status and/or personality changes as well as many of the symptoms for the acute hematoma that evolve as the lesion expands.

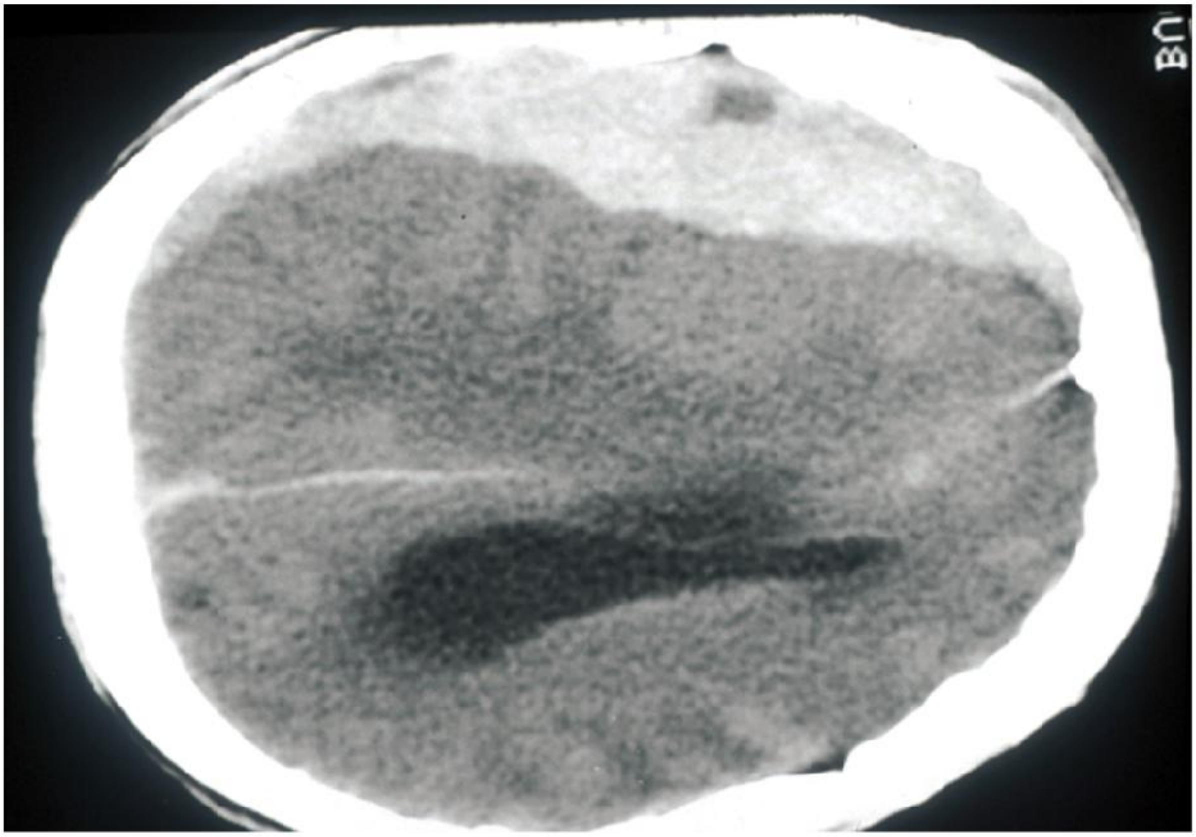

FIGURE 12-43 Computed tomographic scan of an acute subdural hematoma.

© Living Art Enterprises/Science Source.

Chronic SDH manifests as clinical signs and symptoms more than 2 weeks after the injury. This type of hematoma is composed of fluid only. Because the lesion expands very slowly, the patient may experience headache (progressing in severity), slowed cerebral functioning, confusion, drowsiness, and possibly seizures.

Treatment of SDHs depends on the size of the hematoma and the patient's symptoms, and ranges from watchful waiting to surgical intervention. Small SDHs may be observed and allowed to reabsorb without surgery. SDHs accompanied by signs and symptoms of increasing ICP usually require surgical intervention to evacuate the expanding mass and stop the bleeding. A newer, less invasive technology, known as the Subdural Evacuating Port System (SEPS), can be inserted at the bedside through a 5-mm burr hole under local anesthesia to drain chronic and subacute SDHs. The SEPS allows for evacuation of SDHs using a closed system, often avoiding the need for surgical intervention.

Signs and Symptoms

Subdural Hematoma

- Gradual or rapid deterioration in level of consciousness
- Pupillary changes
- Hemiparesis
- Hemiplegia
- Gradual personality changes
- Headache (progressing in severity)
- Slowed cerebral functioning
- Difficulty speaking
- Confusion
- Drowsiness
- Possible seizures

Transport Management

Subdural Hematoma

- Provide supportive care.

Other Types of Brain Hemorrhage

An **intracerebral hemorrhage** results from direct bleeding into the brain parenchyma and can be observed in as many as 15% of patients with brain injuries **FIGURE 12-44**. Many of these hemorrhages occur in the same areas as cerebral contusions, making it appear that the rough internal areas of the cranium are often to blame for these injuries. Intracerebral hemorrhages act as space-occupying lesions, producing headaches, deteriorating levels of consciousness, hemiplegia on the contralateral side, and a dilated ipsilateral pupil. They are discussed in more detail later in this chapter.

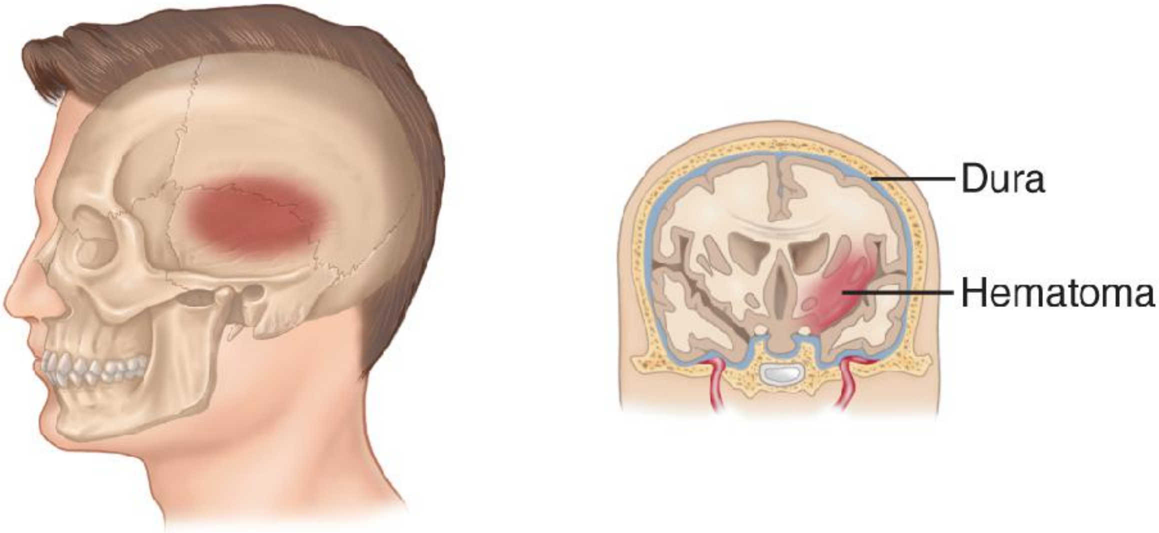

FIGURE 12-44 An intracerebral hemorrhage is a result of direct bleeding into the brain parenchyma.

© Jones & Bartlett Learning.

Patients may also develop a **delayed traumatic intracranial hemorrhage (DTICH)** within the first 3 to 10 days following an injury to the occipital-parietal region via a coup-contrecoup mechanism. Serial CT scans should be performed within the first 72 hours after injury if DTICH is suspected, as part of the effort to decrease the mortality and morbidity that result from such bleeding.

The presentation of a patient with a **subarachnoid hemorrhage (SAH)** depends on the size of the hemorrhage and the coexisting injuries. With this type of injury, bleeding occurs between the arachnoid mater and the dura mater of the brain, resulting in the patient reporting the “worst headache in my life.” Patients with SAH are also more likely to have hypoxia, hypotension, and increased ICP, all of which contribute to secondary brain injury. Signs and symptoms include altered mental status, coma, paralysis, slurred speech, mood changes, and seizures, and appear to be due to increased ICP and meningeal irritation. SAH is discussed in more detail later in this chapter.

Diffuse Injuries

Concussion, also known as **mild TBI**, is a traumatically induced physiologic disruption of brain function that occurs without structural damage. This injury is manifested by at least one of the following signs and symptoms:

- Any loss of consciousness
- Any loss of memory for events immediately before (retrograde) or events immediately after (anterograde) the event that precipitated the injury
- Any alteration in mental status at the time of the injury (eg, feeling dazed, disoriented, irritable, drowsy, giddy, or confused)
- Focal neurologic deficits in which the patient is not unconscious for longer than 30 minutes; after 30 minutes, the patient has a GCS score of 13 to 15

Deep areas of the brain may also be involved in a TBI; such injuries are referred to as **diffuse axonal injury (DAI)**. The mechanism for DAI is usually very rapid acceleration-deceleration forces. In these injuries, shearing forces damage the integrity of the axon at the node of Ranvier, which consequently alters the axoplasmic flow (the flow in the cytoplasm of the axon). Areas especially susceptible to this type of injury, because they contain a significant amount of white matter, include the corpus callosum, the brainstem, and sometimes the cerebellum.

Diffuse axonal injury accounts for approximately 50% of all primary brain injuries and 35% of TBI-related deaths. It is characterized by microscopic findings of wide and asymmetric axonal swelling, which appear within hours of the injury and may persist for much longer, and by focal hemorrhagic lesions. The resulting injury is graded based on pathologic findings:

- **DAI grade 1.** Histologic evidence of axonal damage in the white matter of the cerebral hemispheres, corpus callosum, brainstem, and, less commonly, cerebellum
- **DAI grade 2.** In addition to evidence of axonal injury, lesions in the corpus callosum
- **DAI grade 3.** In addition to the findings seen in grades 1 and 2, lesions in the dorsolateral quadrant of the rostral brainstem

The clinical presentation of DAI includes a sequence of events beginning with immediate unconsciousness (termed *coma* in this context), leading to a longer period of confusion and associated posttraumatic amnesia, and followed by a protracted recovery time. DAI can be clinically classified as mild, moderate, or severe based on the patient's signs and symptoms.

- **Mild DAI.** Coma lasts from 6 to 24 hours, with the patient beginning to obey commands by 24 hours. Death is rare with mild DAI, but cognitive and neurologic deficits are common.
- **Moderate DAI.** Coma lasts longer than 24 hours, but prominent signs of brainstem damage are absent. Patients who survive usually have an incomplete recovery.
- **Severe DAI.** Coma is protracted and associated with prominent signs of brainstem damage (eg, decortication, decerebration, abnormal respiratory pattern). Patients usually die or experience severe disability.

Treatment for all types of DAI is supportive.

Signs and Symptoms

Diffuse Axonal Injury

- Sequence of events:
    - Immediate unconsciousness
    - Longer period of confusion and posttraumatic amnesia
    - Protracted recovery time

- Mild DAI: Coma lasts from 6 to 24 hours, with the patient beginning to obey commands by 24 hours
- Moderate DAI: Coma lasts longer than 24 hours, but prominent signs of brainstem damage are absent
- Severe DAI: Coma is protracted and associated with prominent signs of brainstem damage (decortication, decerebration, and abnormal respiratory pattern)

Transport Management

Diffuse Axonal Injury

Intracranial Pressure

Physiology

In adults, the normal ICP is 5 to 15 mm Hg. ICP is not a static state, but rather may be influenced by multiple factors. A recording of ICP will show two forms of pressure fluctuations: (1) a rise with cardiac systole, owing to the distention of the intracranial arteriolar tree that follows it, and (2) a slower change in pressure with respiration, with ICP falling with each inspiration and rising with each expiration. Straining and compression of the neck veins can also cause a sudden, considerable rise in pressure.

The **Monro-Kellie doctrine** describes the cranium as a rigid box that is filled with a nearly incompressible brain and whose total volume tends to remain constant. This doctrine assumes that the cranium volume includes three compartments: (1) the brain and medulla spinalis, along with the meninges; (2) the blood vessels and blood; and (3) the CSF space. Expansion of any of these three volumes occurs at the expense of the other two elements; intracranial bleeding, cerebral edema, mass formation, or inability to regulate the production and removal of CSF may precipitate such an event.

CSF is secreted constantly within the brain. After circulating, it is absorbed at a rate equal to the rate at which it is produced. CSF circulation is a slow process, with only 500 to 700 mL being circulated each day. At any given time, the cranium contains approximately 75 mL of CSF. Excesses of CSF can be displaced through the foramen magnum into the spinal theca, a sac between C1 and C2. This process may help in cases of cribriform plate damage if the channel for drainage becomes blocked. The spinal dural sheath can accept a quantity of CSF because it does not adhere closely to the canal and is surrounded by a layer of loose areola tissue and a plexus of epidural veins. In addition, during periods of increased ICP, blood flow through venous emissaries increases.

Intracranial circulation of blood is approximately 1,000 L/d, delivered at a pressure of 100 mm Hg. At any given time, the cranium contains approximately 750 mL of blood. Obstruction to venous outflow leads to an increase in the volume of intracranial blood, resulting in increased ICP. As the ICP increases, the cerebral venous pressure increases in parallel so that it remains 2 to 5 mm higher than the ICP, a differential that prevents the collapse of the venous system.

Increased ICP can result from changes in CSF, edema, expansible masses, and changes in vessel size. The ability of the skull contents to compensate for the increased pressure depends on the location and rate of expansion of the lesion and the **brain tissue compliance**—that is, the volume-buffering capacity of the system. (Brain tissue compliance is defined as the change in brain volume resulting from a change in pressure.)

Cerebral Blood Flow

The brain accounts for only 2% of total body weight, yet its blood flow represents 15% of the resting cardiac output and it uses 20% of the total amount of oxygen consumed by the body. Every 24 hours, the brain requires 1,000 L of blood in addition to its normal diet of 71 L of oxygen and 100 g of glucose. The **cerebral blood flow (CBF)** remains constant over a wide range of arterial pressures between 60 mm Hg and 150 mm Hg. With a rise to more than 150 mm Hg, however, blood flow increases. CBF ceases when MAP drops to 20 mm Hg, except in the chronically hypertensive patient, in whom this autoregulation limit appears to be reset. The exact nature of this autoregulation is not known; we know only that many factors, including direct reaction of the cerebral arterial smooth muscle to stretching, various by-products of metabolism, and direct control by nerves surrounding vessels, seem to have a role.

In patients with a normal cerebrovascular system and BP, even moderate alterations of P_{CO_2} (partial pressure of carbon dioxide) are capable of markedly altering CBF. Within the P_{CO_2} range of 30 to 60 mm Hg, there is a 2.5% change in CBF as the P_{CO_2} changes by 1 mm Hg. With a pressure of less than 20 mm Hg or more than 80 mm Hg, there is no further change. As the body ages and with the development of arteriosclerosis, there is a marked decrease in P_{CO_2} influence on CBF.

The effect of P_{O_2} (partial pressure of oxygen) changes is not as obvious as the effect of changes involving carbon dioxide. Moderate variations of oxygen pressure above or below the normal level do not affect CBF. Increased P_{O_2} causes vasoconstriction of nonischemic areas of the brain as well as a reduction in CBF. In contrast, in the ischemic areas of the brain, increasing the P_{O_2} has no effect. Cerebral vasodilation begins with a P_{O_2} of 50 mm Hg, resulting in increasing CBF. By the time the P_{O_2} falls to 30 mm Hg, CBF may have already tripled.

ICP influences the CBF through the CPP, which is the difference between MAP and ICP. An increase in ICP leads to a fall in the CPP. Every effort should be made to maintain the CPP at 70 mm Hg or more during treatment of increased ICP **FIGURE 12-45**.

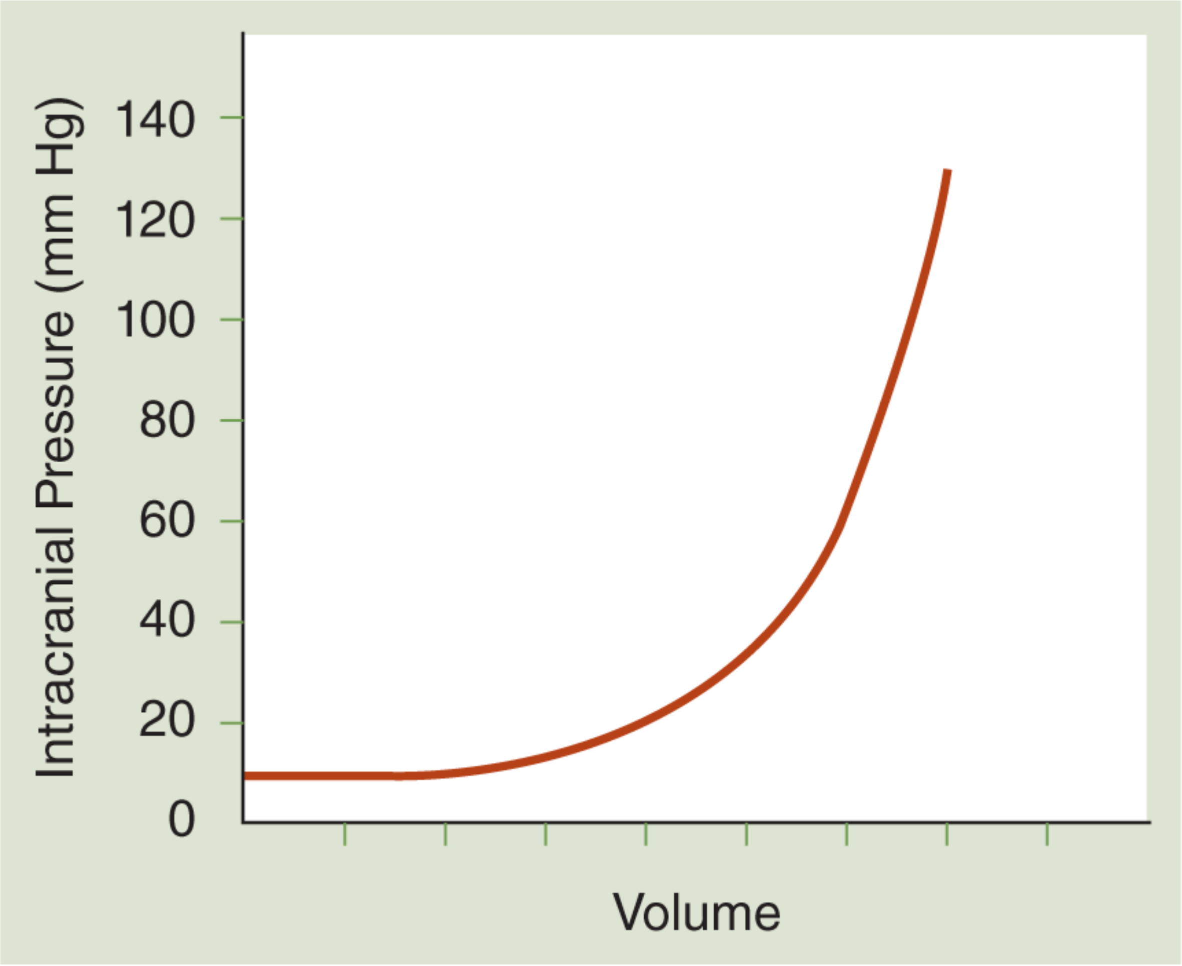

FIGURE 12-45 An intracranial pressure curve.

© Jones & Bartlett Learning.

For the CCTP, the following key points related to CBF are crucial:

- A number of physiologic factors may affect or change CBF. For example, increases in CBF as a result of hypoxia or hypercapnia (increased levels of carbon dioxide in the blood) will cause an increase in ICP once the normal compensating mechanisms have been exhausted.
- Poor airway and ventilatory control contributes to hypoxia, hypercapnia, and hypotension, and will further damage the already critically ill brain.

Cerebral Perfusion Pressure

Cerebral perfusion pressure is responsible for the movement of blood through the brain and is the result of the difference between MAP and ICP (CPP = MAP – ICP). This relationship represents the pressure gradient driving CBF, and hence oxygen and metabolite delivery. The uninjured brain is capable of autoregulating its blood flow to provide a consistent flow of blood, regardless of BP, by altering the resistance of cerebral blood vessels.

After head trauma, however, these homeostatic mechanisms are often lost. As a consequence, a patient with TBI may have increased cerebral vascular resistance, making the brain more susceptible to changes in BP. Those areas of the brain that are ischemic or at risk for ischemia are critically dependent on an adequate CBF and, therefore, CPP.

For the CCTP, the following key points related to CPP are crucial:

- Maintenance of CPP reduces mortality in severe head injury.
- CPP should be maintained between 70 and 90 mm Hg to reduce the risk of poor outcomes for patients with increased ICP.
- Systemic hypotension (SBP less than 90 mm Hg) is associated with a poor prognosis.
- Maintenance of an adequate CPP is the cornerstone of modern brain injury therapy.

After brain injury, and especially in the patient who has sustained multisystem trauma, CBF may be dangerously low, bordering on ischemia. To prevent further neuronal death (secondary brain injury), the flow of well-oxygenated blood must be restored as soon as possible. The optimal level of CPP has not yet been determined, but the CPP target lies within the range of 70 to 90 mm Hg. When CPP is maintained above 70 mm Hg in the absence of cerebral ischemia through the aggressive administration of fluids and pressors, there is a significantly increased risk of acute respiratory distress syndrome.

CPP may be maintained by either raising MAP or lowering ICP. In practice, ICP is usually controlled so that it remains within normal limits (less than 20 mm Hg), and MAP is raised therapeutically to a level greater than 90 mm Hg. Although it is unknown whether ICP control is necessary, given that outcomes from severe TBI related to ICP seem to rely more on its role in determining CPP, it is clear that ICP plays a role in herniation. Current data support initiating treatment when ICP exceeds 20 mm Hg.

Substantial evidence indicates that early hypotension (SBP of less than 90 mm Hg) is associated with increased morbidity and mortality following severe brain injury. Even patients with one episode of hypotension during their intensive care unit (ICU) stay have a significantly poorer prognosis. To ensure that patients remain normovolemic, the CCTP must be vigilant in controlling other sites of hemorrhage while providing adequate oxygenation.

Many patients with TBI, because of the extent of their injuries, will require intensive neurologic monitoring. As previously discussed, CCTPs should perform serial neurologic examinations, especially for patients with TBI. They may also be required to maintain (but not place) invasive neurologic monitoring devices. Each device must be maintained in accordance with the manufacturer's requirements, and each CCTP is responsible for becoming familiar with all aspects of each device prior to using it on a patient. Because of the often subtle, yet devastating effects created by rising ICP, invasive monitoring can be a valuable tool that gives a more detailed picture of the patient's overall neurologic condition.

Pathophysiology of Increased ICP

The brain is encapsulated within the skull and surrounded by CSF generated in the choroid plexus and reassimilated by the subarachnoid villa to balance ICP between 5 and 15 cm H_2O. Because the skull is essentially an immovable structure, any change diminishing its volume will create an increase in ICP. The most common causes of increased ICP are cerebral hemorrhage, tumors, hydrocephalus, and trauma.

Variations in CSF volume result from many causes, including overproduction of CSF, decreased absorption of CSF, and obstructions in cerebral circulation. All of these conditions lead to an increased volume of CSF within the cranial vault and, therefore, to increased pressure on brain tissue.

Brain tissue is the most difficult component within the cranial vault to manipulate without surgical intervention. The parenchyma can respond to increases in ICP, changes in CSF or blood volume, and changes in vessel size (which affect the volumes carried). Minimal volume changes incite the tissue to react with partial collapse of the cisterns, ventricles, and vascular system, which leads to decreased production and increased absorption of CSF.

Increased ICP is defined as a sustained elevation in pressure to more than 20 cm H_2O. During compensation, the ICP rises and plateaus, at which time the increased level of CSF absorption keeps pace with the increase in volume. Intermittent expansion causes only a transient rise in ICP at first. When a sufficient amount of CSF has been absorbed to accommodate the volume, ICP returns to normal. Once compensatory mechanisms are no longer effective, however, pressure increases rapidly, followed by shifting of the brain tissue toward open spaces in the skull. This shift, which results in decreased blood flow to the medulla, is accompanied by dilation of small arteries in the pia mater and some slowing of venous flow, followed by pulsatile venous flow.

The following compensatory mechanisms help maintain ICP:

- Shunting of CSF into the spinal subarachnoid space
- Increased CSF absorption
- Decreased CSF production
- Shunting of venous blood out of the skull

When ICP rises to the level of the arterial pressure, a cascade of events known as Cushing triad begins. Cushing triad comprises progressively increasing SBP, progressively decreasing diastolic blood pressure (DBP; widening pulse pressure), and bradycardia. It is a sign of increased ICP, which occurs as the result of Cushing reflex (a vasopressor response). Vasoconstriction occurs as the body attempts to shift fluid volumes in the cranium, thereby reducing ICP. If ICP continues to rise, brain displacement accelerates, putting pressure on the medulla oblongata by pushing it into the foramen magnum, and in turn resulting in disturbances in breathing, heart rate, and BP. The Cushing triad—hypertension, bradycardia, and respiratory irregularities—is a late sign and often indicates that severe and even irreversible injury has occurred within the cranial cavity. Its identification is important because it suggests severe ischemia in the brain. Possible causes include cerebral hemorrhage, a brain tumor, or brain herniation, which can be fatal.

If ICP increases to the level of systemic arterial pressure, cerebral circulation will be terminated. This situation can be reversed only if arterial pressure rises sufficiently higher than ICP, which restores CBF. If this effort fails, brain death occurs.

The cause of the rise in ICP and the rate at which it occurs are also important. Many patients with benign **intracranial temperature (ICT)** or obstructive hydrocephalus may show few or no ill effects despite their increased ICP, because the brain is normal and autoregulation is intact. Conversely, cerebral blood flow may be compromised even when ICP is relatively low if parenchymal lesions—such as tumors, hematomas, and contusions—cause the brain to shift and disrupt autoregulation. In acute hydrocephalus, a rapid deterioration occurs because there is no time for compensation.

Disruption of brain function secondary to ICP may include the following conditions:

- Reduction in CBF.
- Transtentorial or foramen magnum herniation resulting in selective compression and ischemia of the brainstem.
- Transtentorial herniation with brainstem compression that leads to clinical deterioration even with adequate CBF. A temporal mass may cause uncal herniation without raised ICP. Similarly, a frontal mass can cause axial distortion and impair brainstem perfusion.

Clinical Manifestations of Increased ICP

The clinical features of increased ICP result from the presence of Cushing triad and are indicated by arterial hypertension, bradycardia, and respiratory changes. It has traditionally been thought that the hypertension and bradycardia result from ischemia or pressure on the brainstem. More recently, some sources have suggested that cerebral ischemia might eliminate supratentorial inhibition of brainstem vasopressor centers and that bradycardia occurs independently of the rise in BP.

Respiratory changes depend on the level of brainstem involved. Midbrain involvement results in Cheyne-Stokes respirations. When both the midbrain and the pons are involved, sustained hyperventilation occurs. With upper medulla involvement, rapid and shallow respirations are followed by ataxic breathing in the final stages.

Increased ICP also has pulmonary effects. Pulmonary edema seems to reflect increased sympathetic activity caused by the effects of increased ICP on the hypothalamus, medulla, or cervical spinal cord. This is a direct result of the disruption of the pulmonary capillary integrity and increased left arterial pressures.

ICP Monitoring

The primary goal of ICP monitoring is to improve the ability to maintain adequate CPP and oxygenation. Intracranial hypertension (sustained ICP of 15 mm Hg or greater) results when the brain’s protective mechanisms to shunt CSF to the subarachnoid space or to vasoconstrict cerebral arterioles fail to maintain the ICP at less than 15 mm Hg. Intracranial hypertension compromises the relationship between systemic BP and the resistance that must be overcome to accomplish cerebral perfusion. When CPP falls below 50 mm Hg, secondary brain ischemia, herniation, and ultimately brain death occur. ICP monitoring allows for early detection of intracranial hypertension and subsequent aggressive management of the underlying pathology.

Key points in monitoring ICP are as follows:

- The baseline requirements are oxygen saturation (Sp_{O_2}), electrocardiography (ECG), MAP, $ETCO_2$, central venous pressure, and urine output.
- ICP and BP monitoring are the only way to reliably determine CPP and assess cerebral hypoperfusion in patients with severe brain injury.
- Multimodality monitoring, including jugular venous oxygen saturation (Sj_{O_2}), brain tissue oxygen tension ($P_{br}O_2$), and TCD ultrasonography, should be used when ICP and CPP cannot be maintained by standard methods.

ICP monitoring is a complex task that requires knowledge and understanding of the technical components of fluid-filled monitoring systems, the pathophysiology of the CNS, and the interaction between these systems. Personnel performing the setup, data collection, or maintenance procedures should be appropriately trained and credentialed and should be competent in the following areas:

- The technical setup and operation of the pressure monitoring system
- CNS physiology and pathophysiology
- ICP waveform analysis
- Appropriate response to adverse reactions
- Application of universal precautions

Problems associated with ICP monitoring include its cost, the risk of infection, and the risk of hemorrhage. Effective, ongoing ICP monitoring requires a team effort.

Indications for ICP Monitoring

The primary reason for ICP monitoring is a critical injury or illness involving components of the skull, specifically the brain. In addition, ICP monitoring undoubtedly helps in the management of conditions in which prolonged intracranial hypertension is expected. It is difficult to determine a numerical value for ICP clinically, and direct ICP measurement and monitoring is a helpful tool for selecting the most appropriate therapy and accurately studying the effectiveness of that treatment. ICP monitoring should be employed in all salvageable patients with severe TBI who have a GCS score of less than 8 but greater than 3 after resuscitation and an abnormal CT scan (eg, hematomas, contusions, swelling, herniation, or compressed basal cisterns).

ICP monitoring is also indicated for patients with severe TBI with a normal CT scan if two or more of the following conditions are noted at admission:

- Age older than 40 years
- Unilateral or bilateral motor posturing
- SBP of less 90 mm Hg

When clinical monitoring is not possible, such as during hyperventilation therapy and high-dose barbiturate therapy, ICP monitoring may prove helpful. Preoperative monitoring, for example, assists in assessment of normal-pressure hydrocephalus (NPH) before a shunting procedure takes place. ICP monitoring can provide an additional assessment in the event of suspected brain death because brain perfusion effectively ceases once ICP exceeds DBP.

Other indications for ICP monitoring are debated. Generally, though, the following specific indications may warrant this kind of monitoring:

- Severe TBI
- Intracranial hemorrhage
- Cerebral edema
- Prior craniotomy
- Space-occupying lesions, such as epidural and subdural hematomas, tumors, abscesses, or aneurysms that occlude the CSF pathway

- Patients with Reye syndrome who develop coma, posturing, and abnormal responses to noxious stimuli
- Encephalopathy from lead ingestion, hypertensive crisis, or hepatic failure
- Meningitis/encephalitis resulting in malabsorption of CSF
- GCS score of less than 8 or a positive CT (ie, evidence of a brain hemorrhage or evidence of a condition that will lead to a brain hemorrhage)

Contraindications to ICP Monitoring

The relative contraindications for ICP monitoring are as follows:

- CNS infection
- Coagulation defects
- Coagulopathy
- Scalp infection
- Severe midline shift resulting in ventricular displacement
- Cerebral edema resulting in ventricular collapse

Complications of ICP Monitoring

In general, complications related to ICP monitoring are rare. The greatest concern is ventriculitis (meningitis), although it has not been demonstrated in prospective studies of clinically significant intracranial infections following ICP measurement. Bacterial colonization does occur (5% of cases are ventricular/subarachnoid, and 15% are parenchymal), however, and its incidence increases markedly after five consecutive days of monitoring. Irrigation of ICP devices to restore patency of the ventriculostomy catheter using either an isotonic sodium chloride solution or antibiotic solution significantly increases the risk of colonization. Definitive treatment entails removal of the ICP monitoring bolt.

The risk of hematoma formation associated with ICP monitors varies. Parenchymal catheters have a higher incidence of hematoma than do other monitoring methods. Malfunction of the devices does occur, and readings of more than 50 mm Hg may be inaccurate, with higher rates of obstruction and loss of signal.

Complications of ICP monitoring can be summarized as follows:

- Intracranial infection
- Intracerebral hemorrhage
- Air leakage into the ventricle or subarachnoid space
- CSF leakage
- Over-drainage of CSF, leading to ventricular collapse and herniation
- Occlusion of the catheter with brain tissue or blood
- Inappropriate therapy because of erroneous ICP readings owing to dampened waveforms, electromechanical failure, or operator error (ie, inappropriate leveling)

ICP Monitoring Methods

ICP can be monitored using either noninvasive or invasive techniques. Noninvasive ICP monitoring simply involves assessing for clinical deterioration in the patient’s neurologic status. Signs such as bradycardia, increased BP, and pupillary dilation are reliable signs of rising ICP. Invasive methods, by comparison, provide a quantitative measure of pressure, and some allow for CSF drainage. Although several invasive devices are available **FIGURE 12-46**, the most commonly used are the intraventricular catheter (IVC) and the subarachnoid screw. ICP monitoring devices are placed in the hospital setting—never during transport. It is more common to transport a patient to a facility to have an ICP device inserted than to transport a patient with the device already in place.

Description

Intraventricular Catheters

Intraventricular monitoring is considered the gold standard of ICP monitoring techniques, especially in patients with ventriculomegaly (an enlarged ventricle of the brain). An additional advantage of this method is that it is both diagnostic and therapeutic, with the potential for draining CSF. Insertion of a ventricular catheter is technically difficult and has an associated risk of infection (20%, increasing with the duration of placement) as well as hemorrhage (2%, and even greater in patients with coagulopathy disorders).

Advantages of an IVC are as follows:

- Allows for drainage of CSF to lower ICP
- Allows CSF cultures to be obtained
- Provides increased accuracy in ICP monitoring
- Is accurate and reliable

Risks associated with use of an IVC include the following problems:

- Infection
- Injury to the brain
- Clot formation
- Hemorrhage
- Collapsed ventricle
- Technically difficult (or impossible) placement, especially when ventricular compression is present as a result of trauma or cerebral edema

Placement of a ventricular catheter requires the insertion of a soft catheter through a burr hole into the lateral ventricle. As noted earlier, the catheter allows for both monitoring of ICP and therapeutic drainage of CSF to reduce ICP. IVCs connect to a transducer set, which is never pressurized. Complications associated with the IVC include infection and hemorrhage. The device must also be carefully leveled at the foramen of Monro (halfway between the outer canthus of the eye and the tragus of the ear). Any fluid drained must be monitored for amount, color, and clarity at hourly intervals. The CCTP should avoid manipulating the catheter, and should recalibrate it only if given approval by medical direction and if properly trained in operation of the device in use.

Intraparenchymal Devices

Intraparenchymal devices are inserted directly into the brain parenchyma through a small burr hole and utilize a thin cable with a fiberoptic or electronic transducer at the tip of a thin cable. They carry less risk of infection or hemorrhage (less than 1%) compared to

IVCs, but do not allow for CSF drainage. Moreover, their accuracy has a tendency to “drift” over time, as these devices’ transducers cannot be recalibrated after insertion (although several reliability studies have found only small variations in their accuracy). Their complex design also increases the risk of failure. The most widely used intraparenchymal catheter is the Camino fiberoptic system.

Epidural Catheters

Another ICP monitoring device, the epidural catheter, rests against the dura mater just beneath the skull. It offers two advantages: a decreased rate of infection compared to the IVC and a lower risk that its placement will injure the brain. However, this device is also less accurate than the IVC, and it cannot be used to drain CSF. Measurements from epidural catheters are often inaccurate, as the dura tends to dampen pressure transmitted to the epidural space. Nevertheless, these catheters are often utilized in coagulopathic patients owing to their considerably lower risk of hemorrhage (4%) versus intraventricular devices.

Subarachnoid Screws and Bolts

The subarachnoid screw (or bolt) uses a fluid-filled screw placed adjacent to the dura through a burr hole. A subdural bolt is inserted beneath the dura mater and above the pia mater; a subarachnoid bolt is placed beneath the arachnoid mater and above the pia mater. Placement of either type of device punctures the dura, allowing CSF drainage, although the screw often becomes clogged. Screws or bolts allow ICP monitoring, although their measurements are less accurate than those provided by the more direct ventriculostomy drain.

The most commonly used subarachnoid devices are the Richmond screw, the Becker bolt, the Philly bolt, the Leeds screw, and the Landy screw. The Richmond screw and Becker bolt are used extradurally.

Oftentimes a fiberoptic monitor is inserted through the subarachnoid bolt. Fiberoptic monitoring devices have a pressure sensor at the tip and do not require leveling or zeroing. The fiberoptic cable is fragile, however, and can break if twisted, stretched, or bent.

An alternative to fiberoptic monitoring is to use a fluid-filled catheter connected to an arterial pressure monitoring system. The CCTP should avoid manipulating this catheter, and should recalibrate it only if given approval by medical direction and if properly trained to operate the device in use.

Advantages of subarachnoid screws and bolts include the following:

- Not as invasive as an IVC or epidural catheter
- Lower rate of infection
- Less injury to the brain
- Easier to place

Disadvantages of these devices include the following:

- Less accurate monitoring
- Cannot drain CSF
- Risk of bleeding and brain injury
- Higher rate of infection than with an epidural catheter
- Requires a closed, intact skull
- Tendency to become clogged with debris, rendering readings unreliable

Other ICP Monitoring Devices

A fiberoptic transducer-tipped probe is a catheter with a pressure-sensing device that is placed into the subdural space, brain parenchyma, or ventricle. This non–fluid-filled continuous intact system offers the advantages of a good waveform, reliable and accurate pressure readings, and lack of air bubble formation within the catheter. Disadvantages include the inability to access the ICP unless an IVC setup is used and the inability to zero the unit once it is in place.

Mechanically coupled surface monitoring devices include cardiosearch pneumatic sensors that are used subdurally or extradurally. Electronic devices (the Camino and Galtesh designs) are fully implantable systems and are valuable in the small group of patients who require long-term ICP monitoring for brain tumors, hydrocephalus, or other chronic brain diseases. A Cosmon ICP telesensor can be implanted as part of a shunt system.

The Ommaya reservoir is an alternative that can be implanted for the purpose of administering medications, removing CSF, and obtaining CSF pressure readings. This device is placed directly in the spinal fluid; therefore, any medication given (such as chemotherapy agents) can be injected directly into the CSF. The same medications are much less effective when injected into the bloodstream because they are blocked from entering the brain by the blood–brain barrier. The Ommaya reservoir is most commonly used to treat cancers of the brain and vertebral column.

Alternatively, a fluid-filled catheter that is placed in the subdural space and connected to an arterial pressure monitoring system is a cost-effective solution that adequately serves the purpose of ICP monitoring. The ICP waveform obtained through this system resembles a dampened arterial BP waveform and is considered normal when the pressure is between 0 and 15 mm Hg. In addition, a stopcock within the system allows for therapeutic drainage of CSF and for sampling for infection surveillance.

The Ladd device uses a fiberoptic system to detect distortions in ICP. It can be used in the subdura, on an extradural basis, and even extracutaneously.

ICP Waveform Analysis

While obtaining an average ICP over time is certainly useful for monitoring a patient’s neurologic status, interpretation of the waveform itself provides the clinician with real-time information about brain compliance. This information, in turn, may provide clues about impending deterioration and allow for earlier targeted interventions.

The ICP waveform is typically 1 to 4 mm Hg in amplitude and corresponds to the arterial pulse, reflecting the pressure interaction of the vascular system with the CSF system. A normal ICP waveform contains three peaks: P1, P2, and P3. P1, the “percussion wave,” is the result of the pressure from arterial pulsation being transmitted into the CSF. In a normal ICP waveform, P1 is the largest-amplitude component. P2, the “tidal wave,” represents pressure reflected back from parenchyma. In a normal waveform, P2 has a smaller amplitude than P1. However, as brain compliance decreases, pressure is transmitted through parenchyma less easily, increasing P2. A waveform with P2 greater than P1 reflects decreased intracranial compliance. P3, the “dicrotic wave,” reflects the pressure transmitted through the venous system from aortic valve closure. The end of P2 and the beginning of P3 correspond with the dicrotic notch on an arterial pulse waveform **FIGURE 12-47**.

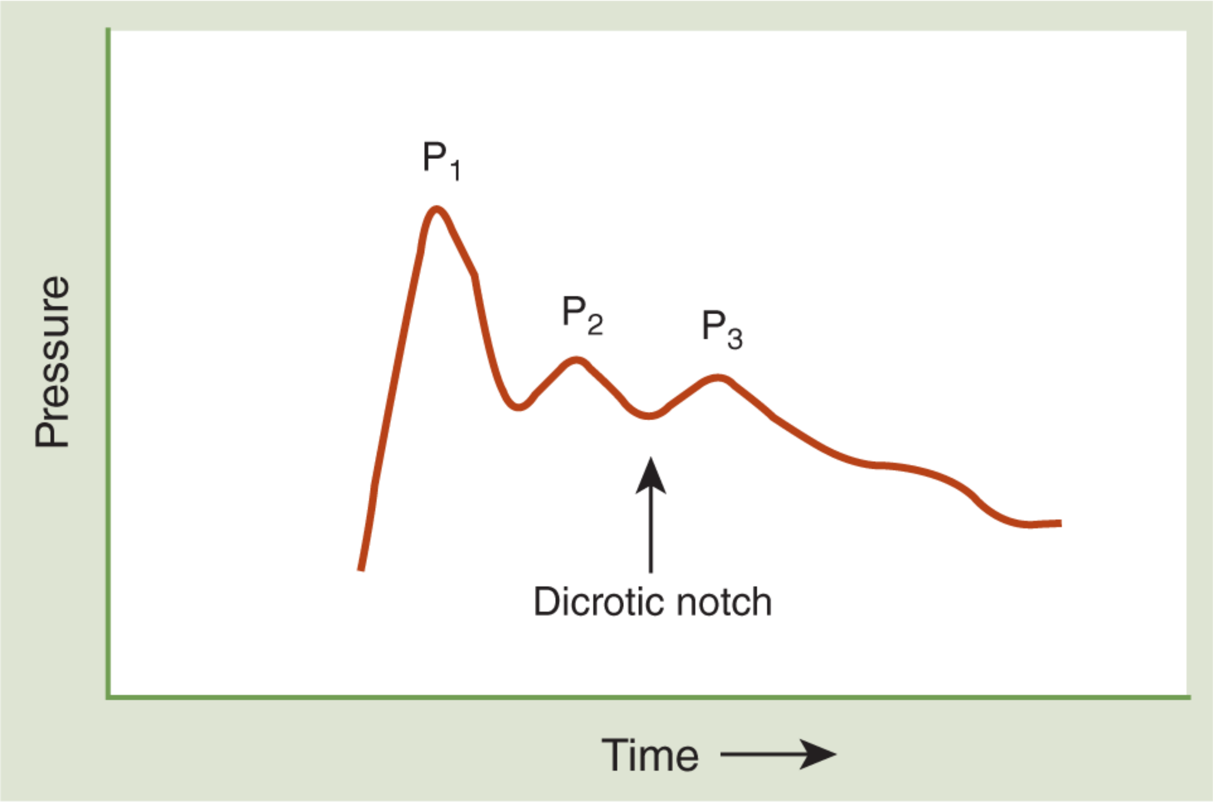

FIGURE 12-47 An intracranial pressure pulse waveform: P1, percussive wave; P2, tidal wave; and P3, dicrotic wave.

© Jones & Bartlett Learning.

Respirations cause an expected small change in the baseline reading, which may be thought of as an additional larger waveform. Normal ICP baseline variations range from 2 to 10 mm Hg and are caused by changes in venous pressure associated with respiratory-induced intrathoracic pressure changes. Increased ICP causes decreased respiratory variations and thus decreases the amplitude of this waveform.

The CCTP should be familiar with the classic pathologic ICP waveform changes. As ICP increases, the respiratory variation decreases and, conversely, the ICP waveform increases in amplitude. As ICP increases further, P2 amplitude increases more than P1 and P3 and eventually becomes the predominant wave in the waveform **FIGURE 12-48A**. There may also be a “rounding off” effect of the waveform, with loss of distinct peaks.

© Jones & Bartlett Learning.

Lundberg A waves are sharp increases in ICP of 50 to 100 mm Hg that last 5 to 10 minutes before decreasing again. These waves are associated with cerebral ischemia and impending herniation **FIGURE 12-48B**. Lundberg B waves are rhythmic, short-duration (lasting 1 to 2 minutes) ICP elevations of up to 30 to 50 mm Hg that represent ongoing cerebral injury and a gradual increase in baseline ICP **FIGURE 12-48C**.

Some of these pathologic changes may occur before the average ICP becomes significantly elevated. Thus, paying close attention to the ICP waveform may facilitate more proactive management of the underlying pathology.

Performing ICP Monitoring

Before performing any procedure, including ICP monitoring, the appropriate equipment should be available and the patient should be prepared for the procedure. It is necessary to ensure the procedure is done in a controlled environment with adequate support staff. Every effort must be made to anticipate difficulties, and providers must have a thorough understanding of troubleshooting techniques.

Equipment

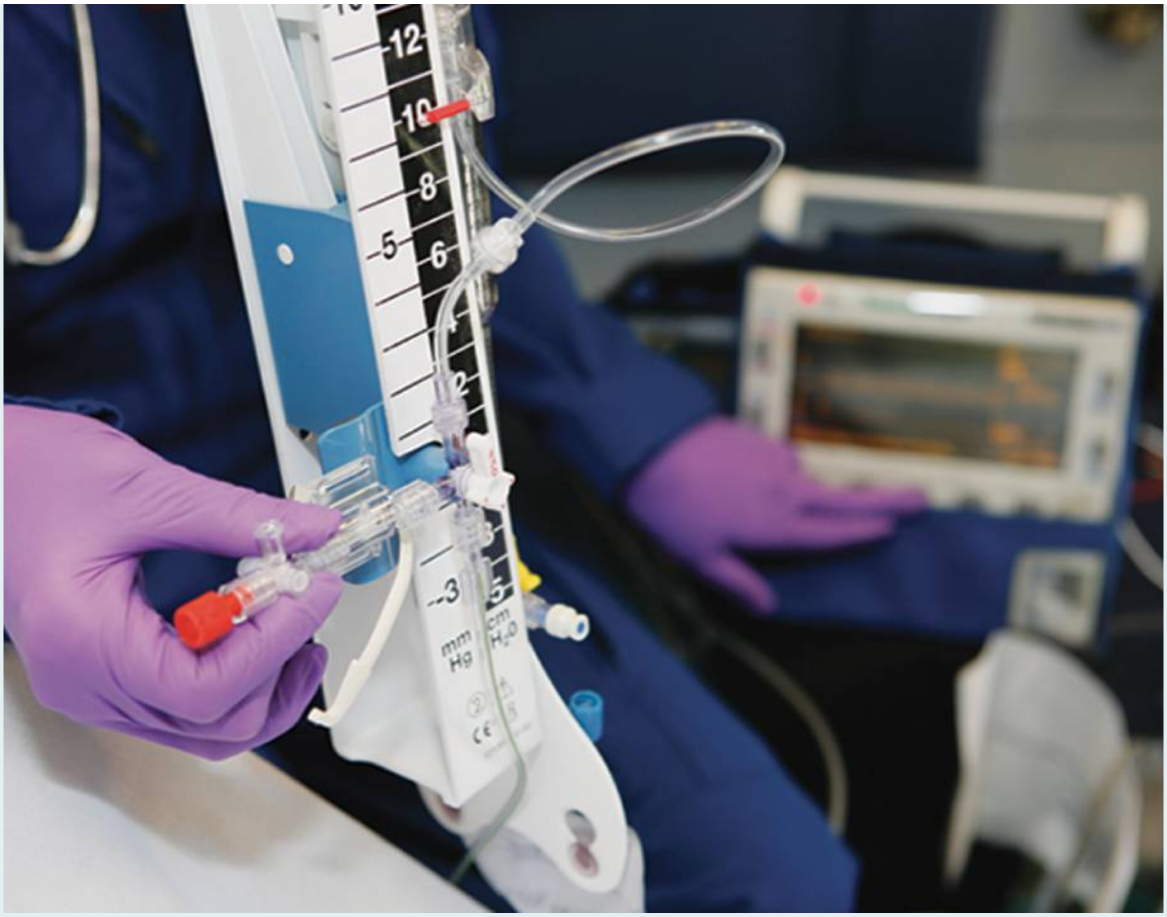
The equipment necessary for ICP monitoring includes the following items:

- External drainage system with a mounting card
- Pressure transducer with 48-inch (122-cm) pressure tubing
- Sterile 0.9% sodium chloride (NaCl) with a sterile 20-mL syringe
- Pressure monitoring cable
- IV tubing
- Manual resuscitator, mask, and 100% oxygen source
- Cardiopulmonary monitor
- Body substance isolation–compliant attire

Procedure

Skill Drill 12-1 shows the procedure for monitoring ICP with the Cordis EDS device **FIGURE 12-49**, one of the devices most commonly used for this purpose. The procedure is also described here:

SKILL DRILL 12-1 Performing ICP Monitoring



Step 1
Assemble the device as instructed per the package insert and per the mounting card, using 0.9% NaCl to flush the system. Place the 48-inch (122-cm) tubing, with connected pressure transducer, on the plastic mounting card. Avoid tension or kinking of the cable.

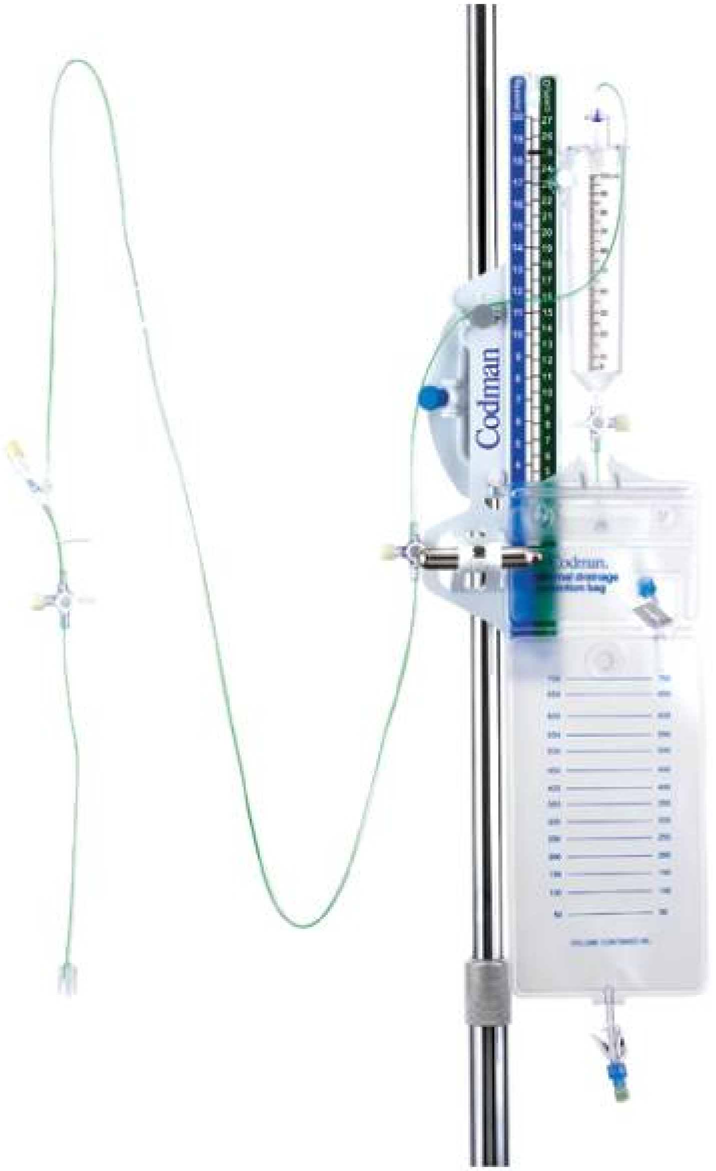

FIGURE 12-49 The Cordis EDS.

Used with permission of Codman, A Johnson & Johnson Company.

1. Assemble the Cordis EDS as instructed per the package insert and per the mounting card diagrammatic instructions, using 0.9% NaCl to flush the system. Place the 48-inch (122-cm) tubing, with connected pressure transducer, on the plastic mounting card **STEP 1**.

2. Avoid tension or kinking of the pressure monitoring cable.
3. Place the patient in semi-Fowler position and position the zero reference point at the outer canthus of the eye **STEP 2**.
4. Obtain the ICP waveform on the cardiopulmonary monitor. Turn the stopcock nearest the patient so that the ICP waveform is visualized **STEP 3**.
5. Zero the transducer at the distal stopcock **STEP 4**.
6. Record the ICP on the printer, and mark and post the strip. Calculate and record the CPP on the strip **STEP 5**.
7. For continuous drainage, turn the stopcock nearest the patient so that drainage resumes and pressure monitoring is discontinued. *Note:* It is recommended that pressure monitoring and CSF drainage not be done simultaneously **STEP 6**.
8. Maintain a clean and intact dressing. If the dressing is soiled or contaminated, change it using a sterile technique.

Precautions

To minimize the risk of an infectious agent entering the CNS during ICP monitoring, an aseptic technique must be used at all times when assembling, manipulating, or accessing the fluid-filled monitoring system. Tight connections must be maintained, and the system must remain free of air to ensure maximal accuracy. Never use a flush device for ICP monitoring. Use only sterile 0.9% NaCl to fill the pressure tubing; do not use a heparinized solution.

To ensure optimal accuracy of the ICP readings, proper leveling and zeroing of the system must be maintained. The proper level for the transducer is at the foramen of Monro, measured at the level of the outer canthus of the eye or, alternatively, at the spine for lumbar drainage. ICP transducers should be capable of measuring a pressure range of 0 to 100 mm Hg, with an accuracy of 2 mm Hg in the range of 0 to 20 mm Hg and at least 10% accuracy for the rest of the measurable range.

Utmost care must be taken when positioning and turning the patient to avoid accidental decannulation or disconnection of the tubing.

Patients are maintained at a 30° to 45° angle, head-up, and neutral position when necessary to minimize the ICP. Use extreme caution when positioning patients and performing therapy to minimize increases in ICP and associated degradations in CPP.

Avoid flexion and hyperextension of the patient's neck and use of the Trendelenburg position, all of which may increase ICP. The system's alarm for high ICP must be maintained in the on position at all times.

Use care when manipulating the drainage system to avoid getting the filter wet. The drainage cylinder should remain in an upright position at all times. If the filter becomes wet and drainage slows or stops, some time may be required for the filter to dry out sufficiently before adequate drainage is reestablished.

Simultaneous drainage and pressure monitoring are not recommended. To ensure precise pressure measurements, perform pressure monitoring only when the stopcock to the drainage system is closed.

Only a small amount of CSF (not to exceed 3 mL) should be drained at one time. Rapid cerebral decompression from CSF over-drainage may result in herniation; such excessive drainage may occur if the system is inadvertently left open or if the patient's ICP is maintained at a higher level than the reference point on the system (as per physician order). The height of the drainage cylinder determines the rapidity with which CSF will drain. The physician's order for drainage must include a pressure reading in either mm Hg or cm H_2O and the height (as marked on the mounting card) at which the drainage cylinder must be maintained. The zero reference point for ICP monitoring always remains the outer canthus of the eye (or for lumbar drainage, the spine).

Adverse Reactions and Interventions

Some patients may experience adverse reactions to ICP monitoring. These reactions and the appropriate interventions to mitigate them are discussed here.

First, if blood is visualized in the pressure tubing (from intracranial hemorrhage), notify the physician.

If a good waveform or accurate ICP cannot be obtained (ie, a dampened waveform appears), flushing the fluid-filled monitoring system (with sterile 0.9% NaCl) may be attempted. First check all connections for tightness. Never flush the system while it is open to the patient. Close the stopcock to the patient, and then attempt to flush the monitoring system. Resume pressure monitoring by reopening the system to the patient. If a poor waveform persists, troubleshoot the system as you would any other device, including debubbling, releveling and zeroing, and changing the electrical cable. If all of these maneuvers fail to correct the poor waveform, notify the physician. The catheter may be occluded with blood or tissue, requiring physician intervention.

An acutely low ICP may indicate acute decompression due to leakage or over-drainage of CSF. Never attempt to tamponade or block leakage from the site around an ICP monitoring device. In this situation, notify the physician immediately.

In the event of acute decompensation (ie, sustained ICP ≥15 mm Hg), hyperventilation may be beneficial. Notify the physician.

Notify the physician immediately if the patient shows signs of decompensation, including altered level of consciousness, restlessness, agitation, lethargy, confusion, motor weakness, seizures, alteration in breathing pattern, increases in BP, bradycardia, vomiting, decortication/decerebration, or coma.

Post-Procedure Care and Documentation

Once ICP monitoring is established, do the following:

1. Ensure that all connections are tight and that the drainage system is positioned at the precise height for drainage according to the physician’s order before leaving the bedside.
2. Relevel and zero the system every 4 hours and as needed.
3. Change the transducer pressure tubing according to local policy (usually every 72 to 96 hours).

4. Post a strip of the ICP in the patient's chart at least once per shift, although ICP will most likely be measured much more frequently. Each posted strip should also have documentation of the corresponding CPP.

Multimodality Monitoring

Although maintaining CPP is important, CPP is only one parameter affecting the delivery of oxygen to the neurons. Ultimately, the CBF and oxygen content of the blood are the prime parameters of concern. Although CPP provides a pressure gradient governing CBF, flow is subsequently affected by the resistance of the cerebral vessels. Neuronal demand for oxygen is governed by the metabolic rate of the neurons; that is, neurons with high activity levels require greater amounts of oxygen than do quiescent neurons. Globally, this principle is described as the **cerebral metabolic rate for oxygen ($CMRo_2$)**:

$$CMRo_2 = CBF \times OEF \times Spo_2$$

The **oxygen extraction fraction (OEF)** indicates how much oxygen is extracted as it passes by and is, therefore, available to support brain functions. It can be measured by the **Fick principle** based on measurements of the arterial and venous oxygen content. The Fick principle is used to determine cardiac output; it states that the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood.

In essence, monitoring only the ICP and CPP provides little information about the overall state of the injured brain and no information about oxygen delivery and usage. Multimodality monitoring involves using a combination of jugular venous bulb oximetry, brain tissue oxygen tension, and transcranial Doppler ultrasonography, thereby providing for a greater understanding of cerebral circulation and oxygen consumption.

In **jugular venous bulb oximetry**, a sampling catheter is placed in the internal jugular vein, directed upward, so that its tip rests in the jugular venous bulb at the base of the brain. Blood samples drawn from this location measure the **mixed venous oxygen saturation (Svo_2)** of blood leaving the brain, which is normally in the range of 50% to 75%. The Svo_2 may fall when there is an imbalance between oxygen consumption and delivery, when CBF decreases, when oxygen use increases, or when cerebrovascular resistance (CVR) increases. Vascular spasm and elevation of CVR are very common after brain injury and are significantly worsened by hyperventilation. Use jugular venous bulb oximetry whenever the patient has experienced prolonged hyperventilation.

Brain tissue oxygen tension ($P_{br}O_2$) monitoring is accomplished by inserting a commercial probe (capable of measuring temperature and oxygenation) into the brain tissue through a bolt. The placement technique is similar to that for ICP monitoring devices and can be done simultaneously with ICP monitoring placement. Brain tissue oxygenation monitoring is more sensitive to focal disruptions of blood flow to particular areas of the brain (depending on catheter placement). Compared to jugular venous bulb oximetry, which detects only global ischemic insults, brain tissue oxygen tension appears to be more accurate and may be more practical for continuous monitoring.

Transcranial Doppler ultrasonography is a noninvasive method of assessing the state of the intracranial circulation. The velocity of flow can be measured in the middle, anterior, and posterior cerebral arteries; the ophthalmic artery; or the internal carotid artery. Doppler ultrasonographic waveform analysis can give further information about the state of blood flow, such as flow acceleration and pulsatility index:

$$(\text{Systolic velocity} - \text{Diastolic velocity}) / \text{Mean velocity}$$

Vasospasm is common after head injury and can be an important cause of neurologic deterioration. This condition usually occurs in the presence of traumatic subarachnoid hemorrhage. Because it leads to an increase in flow velocity, TCD can be useful for monitoring at-risk patients for signs of vasospasm. TCD is indicated for patients whose intracranial hypertension and CPP cannot be maintained by standard therapy.

All of these monitoring technologies assess oxygen delivery to and extraction by the brain; none measures cerebral activity directly. A full EEG is too complex for continuous use in the ICU, but the **cerebral function monitor (CFM)** and the **cerebral function analysis monitor (CFAM)** can both provide summed, averaged, and (in CFAM's case) analyzed outputs of the general state of brain activity. A CFM records a single-channel EEG from two electrodes placed on either side of the head; a third electrode acts as a ground. The CFM is used to assess brain wave activity, indicate the effects of medication administration, and identify seizure activity. It is particularly useful in evaluating the effects of sedation and paralytics.

Patients with severe TBI are intubated to protect their airway and facilitate maximal oxygenation. Standard monitoring for these patients is required, including Spo_2, ECG, MAP, and urine output. When $ETCO_2$ cannot be continuously monitored, these patients also require frequent determination of arterial blood gases, which can be achieved by placement of an intra-arterial catheter. Patients are maintained euvolemic (normal fluid volume status), and central venous pressure measurements are used to guide their therapy. Central venous pressure measurement is covered in Chapter 15, *Hemodynamic Monitoring*.

Normocapnia (normal carbon dioxide tension) is vital for maintenance of ICP, and patients' $ETCO_2$ levels should be continuously measured using waveform capnography. These measurements represent the baseline monitoring requirements for patients with TBI. Patients receiving pressors to maintain MAP and/or CPP would also benefit from an arterial line for continuous monitoring of drug effects.

The role of multimodal monitoring devices remains under investigation but addresses a long-standing need in neurocritical care to obtain information about cerebral blood flow and metabolism in the brain. Treatment thresholds have been published for Sjo_2 (less than 50%) and for $P_{br}O_2$ (less than 15 mm Hg), which are currently the only monitoring systems that have yielded sufficient outcome data in patients with TBI.

Treatment Options for Increased ICP

The best treatment for increased ICP is obviously the removal of the causative lesion, such as a tumor, hydrocephalus, or hematoma. Postoperative increased ICP has become less common with more widespread use of the microscope and special techniques to avoid brain retraction. A patient whose basal meningioma (a tumor near the base of the meninges) has been completely removed usually has a smooth postoperative period. By contrast, a convexity or even falx meningioma (a tumor near the falx cerebri of the meninges) may be easily removed, but the postoperative period may prove difficult. In such a case, problems may arise because of impairment of venous drainage, from either intraoperative injury to veins or postoperative diuretic therapy (a practice in some centers).

Debate persists about whether increased ICP is the cause or the result of brain damage. Not all midline shifts seen in CT scans indicate increased ICP; they may simply mean that ICP was high during the shift. A midline shift takes longer to reverse even after ICP returns to normal. In any event, increased ICP tends to be a temporary phenomenon that lasts for a short time unless the patient experiences a fresh secondary injury due to a clot, hypoxia, or an electrolyte disturbance.

First-Line Versus Second-Line Management

Treatment of increased ICP aims at preventing the secondary events. Clinical and ICP monitoring definitely help in this regard. First-line management consists of general measures geared toward making the patient comfortable, along with effective handling of the ABCs of trauma management. Careful attention to nutrition and electrolytes, bladder and bowel functions, and appropriate treatment of infections should be instituted promptly. Adequate analgesia is often forgotten, but is a must even in unconscious patients.

Second-line management of increased ICP focuses on inducing cerebral vasoconstriction. Osmotherapy consisting of mannitol, hypertonic saline, glycerol, urea, or furosemide may be implemented. Anesthetic agents, including barbiturates, gamma-hydroxybutyrate, and etomidate, and paralytic agents, may also be administered. During transport, preventing hypoxia and hypercarbia, ensuring adequate analgesia, and preventing increased anxiety with reassurance and anxiolytics can all help to avert additional increases in ICP.

Surgical decompression remains controversial. This procedure is performed to counteract increased ICP, which is assumed to be present when neurologic deterioration occurs or when monitoring reveals that ICP is higher than 25 cm H_2O.

CONTROVERSIES

A small group of surgeons initiate second-line management measures in patients in whom ICP is expected to rise without waiting for that increase to actually occur. Many other physicians believe that institution of measures to reduce ICP invariably compromises CBF; they prefer to wait for the rise in ICP before initiating second-line measures.

There is also debate about the appropriate second-line management of increased ICP. Some prefer hyperosmolar therapy; others prefer measures to induce cerebral vasoconstriction, thereby reducing both CBF and ICP. Finally, some providers believe it prudent to initiate both treatments.

Specific Therapeutic Options

Transport treatment is aimed at reducing ICP and providing rapid transport of the patient to a neurologic facility for definitive treatment. Ways to manage increased ICP during transport include the following measures:

1. Maintain elevation of the head of the stretcher at a 30° to 45° angle and maintain alignment of the patient’s head and neck in a neutral position.
2. Consider intubation and mechanical ventilation. For patients with intracranial hemorrhage, increase the minute volume to maintain a

carbon dioxide level of 30 to 35 mm Hg.

3. Consider administering an osmotic diuretic. Osmotic diuretics are low-molecular-weight substances that produce a rapid loss of sodium and water by inhibiting their reabsorption in the kidney tubules and the loop of Henle. They also increase the osmolality of plasma, increasing the diffusion of CSF. Osmotic diuretics are used to reduce intracerebral pressure created by excess CSF. Mannitol is the most commonly used osmotic diuretic, but glycerol is also used for this purpose.
4. Consider administering dexamethasone or methylprednisolone sodium succinate, both of which are corticosteroids, to control inflammation and swelling of brain tissue.
5. Maintain SBP at less than 150 mm Hg. Avoid hypotension, which can be equally deleterious.
6. If a surgical drain (bolt) has been installed, drain the CSF if ICP is greater than 20 cm H_2O.
7. Patients with an intracranial hemorrhage and those who have been taking warfarin (Coumadin), such as patients with atrial fibrillation, should have either plasma or platelets administered en route.

Hyperventilation

As a temporizing measure, hyperventilation is recommended to control elevations in ICP. Hyperventilation aims at keeping the P_{CO_2} between 30 and 35 mm Hg, so that CBF falls and capillary blood volume is reduced, thereby reducing the ICP. Although this intervention is widely used, the reduction of CBF carries a significant risk of inducing cerebral ischemia, especially during the first day following injury, when CBF has been demonstrated to approach one-half the normal value. Prophylactic hyperventilation is not recommended. Hyperventilation should also be avoided in the first 24 hours following injury when CBF is often critically reduced.

Some experts have claimed that a P_{CO_2} of less than 20 mm Hg results in ischemia, although no experimental proof has definitively shown such a relationship. The present trend is to maintain ventilation with P_{CO_2} in the range of 30 to 35 mm Hg and with P_{O_2} in the range of 120 to 140 mm Hg to prevent hypoxia; this is the standard of care for head injuries. When clinical deterioration such as pupillary dilation or widened pulse pressure is observed, hyperventilation may be instituted (preferably by increasing the minute volume) until the ICP decreases. Whenever hyperventilation is implemented, cerebral oxygen delivery should be continuously assessed using jugular venous oxygen saturation or brain tissue oxygen tension measurement.

While the current standard of care recommends maintaining P_{CO_2} in the range of 30 to 35 mm Hg for prophylactic hyperventilation, some experts continue to recommend a range of 25 to 35 mm Hg in the setting of documented or suspected herniation. There is no evidence suggesting this lower limit offers greater benefit or causes harm.

Hyperosmolar Therapy

Hyperosmolar therapy using mannitol also carries the risk of further reducing perfusion to the brain. Mannitol is effective at reducing ICP, but only if it is used properly. Note that this agent is *not* inert and harmless.

Several theories have been advanced concerning the mechanism by which mannitol reduces ICP:

- Mannitol increases cardiac output, which leads to better CPP and cerebral oxygenation.
- Mannitol decreases CSF production.
- Mannitol's diuretic effect may occur mainly around the lesion, where the blood–brain barrier integrity is impaired, so that the drug has no significant effect on the normal brain. For this reason, intra-axial lesions respond better to mannitol than do extra-axial lesions.
- Mannitol may withdraw water across the ependyma of the ventricles in a manner analogous to that associated with ventricular drainage.
- Mannitol may cause cerebral vasoconstriction, with the resultant changes in CBV being responsible for reduction in ICP.

Mannitol is usually given as a 20% solution in bolus doses, as opposed to a continuous infusion. Boluses of 0.25 to 0.5 g/kg given over 10 to 20 minutes may be used and repeated depending on the patient's response.

Mannitol's effect on ICP reaches its maximum 30 minutes after infusion and lasts for a variable period, ranging from 90 minutes to 6 hours or more. The correct dose is the smallest one that will have sufficient effect on ICP. When repeated doses are required, the baseline serum osmolality gradually increases. If this level exceeds 330 mOsm/L, mannitol therapy should cease; there is no role for dehydration in such a case. Further infusions of mannitol will be ineffective in this scenario and are likely to induce renal failure.

Hypertonic saline has been shown to be equal, if not superior, to mannitol in reducing ICP. Although protocols vary, 5% sodium chloride (NaCl) is the concentration most commonly used. Hypertonic saline can be administered in boluses of 100 mL for acute situations, but is more commonly administered as a continuous infusion at rates of 30 to 150 mL/h, adjusted to maintain serum sodium at less than 160 mEq/L.

Diuretics such as furosemide, given either alone or in conjunction with mannitol, can accelerate mannitol's excretion and reduce the baseline serum osmolality prior to the next dose. It is speculated that furosemide complements mannitol and also increases the output. Furosemide may be given before mannitol, so that it reduces circulatory overload.

Special Populations

Children are much more sensitive to fluid shifts than adults. Be very careful when administering fluids to children.

Barbiturates

Barbiturates can lower ICP when other measures fail, but they have no prophylactic value. Barbiturates and hypnotic drugs such as propofol and etomidate act by reducing the CMRO_2 and, concomitantly, reducing CBF. (They also decrease brain metabolism and energy demand, which facilitates healing.) The consequent reduction in CBV leads to a parallel fall in ICP.

Among the barbiturates, phenobarbital is most widely used for this purpose. A loading dose of 10 mg/kg over 30 minutes and a subsequent infusion at 1 to 3 mg/kg/h is a widely used regimen. Close monitoring of ICP and hemodynamic instability should accompany any barbiturate therapy.

Corticosteroids

High-dose corticosteroid therapy (eg, methylprednisone, dexamethasone) is used to lower ICP. Corticosteroids restore cell-wall integrity and help in recovery by reducing edema.

Surgery

Decompressive craniotomies, such as subtemporal decompression, are not recommended to relieve increased ICP. Herniation of the brain through a defect may cause further injury, further edema, and further increased ICP in some patients who undergo this procedure. In occasional cases, when every other measure has failed, a decompression craniotomy may be justified. This action would need to be substantiated by clear evidence of neurologic deterioration and a CT scan that shows an intracranial lesion.

Hyperbaric Oxygen and Hypothermia

Hyperbaric oxygen and hypothermia are experimental techniques (used especially frequently in Japan) to induce cerebral vasoconstriction and reduce CBV and ICP. Considerable evidence supports the use of mild to moderate hypothermia (89.6°F to 93.2°F [32°C to 34°C]) as a treatment for increased ICP, especially when target temperatures are maintained for longer than 48 hours. Cooling reduces the cerebral metabolic rate, leading to a reduction in CBF, ICP, and glutamate release. Fever increases the cerebral metabolic rate and CMRO_2 and occurs commonly in brain-injured patients, especially after intracranial hemorrhage. Therefore, temperature monitoring and control are vital to patient outcomes.

Hyperbaric oxygen therapy (HBOT) has been shown to be neuroprotective in multiple neurologic disorders, but its efficacy in the management of TBI remains controversial. The complementary, synergistic actions of HBOT include improved tissue oxygenation and cellular metabolism as well as anti-apoptotic and anti-inflammatory mechanisms.

Signs and Symptoms

Increased Intracranial Pressure

- Cushing triad: widening pulse pressure, bradycardia, and abnormal respiratory patterns
- Hypertension (increased BP)
- Increased respiratory rate
- Pulmonary edema

Transport Management

Increased Intracranial Pressure

- Intubate and mechanically ventilate the patient. Do not hyperventilate the patient unless acute deterioration occurs.
- Consider administering an osmotic diuretic (mannitol).
- Consider administering dexamethasone or methylprednisolone sodium succinate to control inflammation and swelling.
- Control BP to maintain systolic pressures at less than 150 mm Hg.
- If a surgical drain (bolt) has been installed, drain the CSF if the ICP is greater than 20 cm H_2O.
- For patients who have sustained a hemorrhage and who have been taking anticoagulants, administer reversal agents in an attempt to limit the size and extent of the bleed.

Brain Herniation

Brain herniation is a condition in which a portion of the brain is displaced because of increased ICP, resulting in progressive damage to brain tissue that may include life-threatening damage to the brainstem. This condition is commonly the result of brain swelling (cerebral edema) from a head injury, but it may also result from hemorrhagic stroke or space-occupying lesions, such as primary brain tumor, metastatic brain tumor, or other lesions within the brain. Brain herniation may also occur with bacterial meningitis.

The most common type of brain herniation occurs when a portion of the temporal lobe is displaced through the tentorium (**uncal herniation**), resulting in compression of cranial nerve III, the midbrain, and the posterior cerebral artery. Uncal herniation typically leads to coma and respiratory arrest.

Another critical type of brain herniation occurs when part of the cerebellum is displaced through the foramen magnum (tonsillar herniation). This compresses the brainstem, resulting in destruction of the respiratory center, apnea, decreased perfusion to the rest of the brain, and death. Because this herniation involves the brainstem and spinal cord, the patient will likely be in a coma, present with decerebrate or decorticate posturing, have ipsilateral pupil dilation, and have difficulty maintaining respirations, heart rate and rhythm, and BP. These patients need immediate surgery to install a drain to remove blood and fluids to alleviate the excess pressure. From a transport point of view, management includes the following measures:

1. Intubate the patient and place them on a mechanical ventilator. Hyperventilate the patient to maintain carbon dioxide levels of 25 to 35 mm Hg.
2. Administer mannitol or an equivalent osmotic diuretic.
3. Consider administering corticosteroids such as dexamethasone, especially in the case of a brain tumor.

4. Provide rapid transport to a neurosurgical facility.

Other areas of the brain may sustain herniation, although such injuries occur with less frequency than either uncal herniation or foramen magnum herniation.

Signs and Symptoms

Brain Herniation

- Tachycardia (inability to control heart rate and rhythm)
- Decreased BP (inability to control BP)
- Decreased respiratory rate (inability to control respirations—irregular breathing)
- Abnormal posturing (decorticate/decerebrate)
- A worsening (progressive) LOC (GCS score of 5 or less)
- Pupil changes (dilation of one or both pupils or failure of pupils to constrict with light)

Transport Management

Brain Herniation

- Intubate the patient and place them on a mechanical ventilator, hyperventilating to maintain carbon dioxide levels of 25 to 35 mm Hg.
- Administer mannitol or an equivalent osmotic diuretic.
- Consider administering corticosteroids such as dexamethasone, especially in the case of a brain tumor.
- Provide rapid transport to a neurosurgical facility.

Spinal Cord Injuries

CCTPs may be called on to provide appropriate transportation of patients with SCIs. Suspicion for these injuries may be high as a result of the mechanism of injury, or SCIs may be identified at the transferring facility through imaging studies. These injuries may be either isolated or associated with other injuries, and their presence can complicate management priorities. Rapid and safe transportation of the patient with an SCI to a facility that can provide definitive care is the optimal outcome.

Mechanism of Injury

Acute injuries of the spine are classified according to the mechanism, location, and stability of the injury. Vertebral fractures often occur with or without associated SCI. Simply put, the spine is composed of three anatomic columns. As first described by Francis Denis, MD, the spine is divided longitudinally into the anterior, middle, and posterior columns. The anterior column includes the anterior longitudinal ligament, the anterior half of the vertebral body, and the anterior half of the intravertebral disk. The middle column is composed of the posterior half of the vertebral body, the posterior half of the intravertebral disk, and the posterior longitudinal ligament. Finally, the posterior column consists of all other structures posterior to the posterior longitudinal ligament, including the pedicles, lamina, spinous process, interspinous ligaments, and ligamentum flavum. Disruption of two of three of these columns is, by definition, an unstable injury.

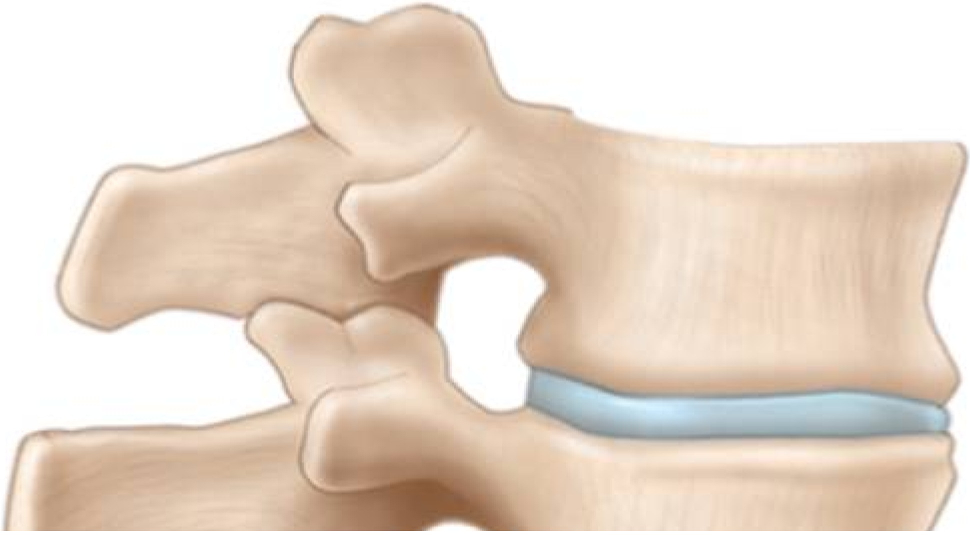
Generally, the types of forces or mechanisms that affect the vertebral column include flexion/extension, vertical compression/longitudinal distraction, rotational, and combined mechanisms.

Flexion-Extension Injuries

Flexion-extension injuries are typically the result of rapid deceleration or a direct blow to the occiput. They most often involve the cervical region; the spinal cord may be injured as a result by compression in the canal. Hyperextension of the head and neck can result in fractures, ligamentous injury, and SCIs of variable stability. The C5-C6 level is most susceptible to this injury from a mechanical standpoint.

Vertical Compression

Vertical compression forces are transmitted through vertebral bodies and directed either inferiorly through the skull or superiorly through the pelvis or feet. They typically result from a direct blow to the crown (parietal region) of the skull or rapid deceleration from a fall through the feet, legs, and pelvis. Compression forces can cause herniation of disks, subsequent compression of the spinal cord and nerve roots, and fragmentation of vertebral bodies into the canal. Forces transmitted through the vertebral body may cause fractures, ultimately shattering the vertebral body and producing a “burst” or compression fracture, either with or without associated SCI. In falls, most injuries involve the thoracolumbar junction; the lower cervical spine is often involved, with axial loads being placed on the vertebral column **FIGURE 12-50**.



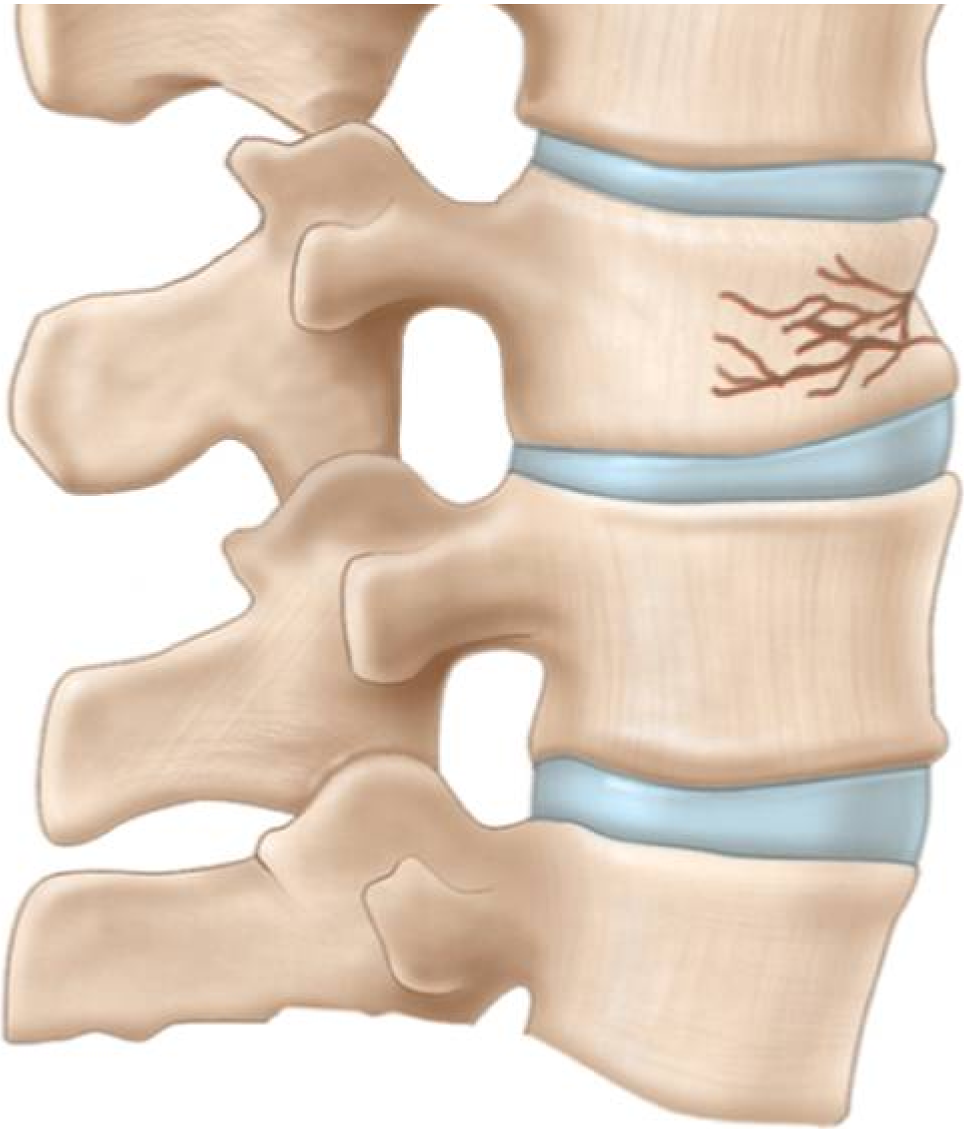


FIGURE 12-50 A compression fracture of the vertebra.

© Jones & Bartlett Learning.

Rotation With Flexion

A **rotation-flexion injury** often occurs in the thoracolumbar interface. These injury patterns can involve stable or unstable fractures and dislocations.

Primary Versus Secondary Spinal Cord Injury

Primary SCI

Primary spinal cord injury is a result of the initial trauma. Penetrating trauma may either lead to transection of neural elements or cause concussive injury to the spinal cord (as in gunshot wounds); the outcomes may be either complete or incomplete injuries. Blunt trauma may displace ligaments and bone fragments, resulting in compression of points of the spinal cord or an incomplete dislocation of the vertebral body. Hypoperfusion and ischemia may also result from this type of injury to the spinal vasculature. Necrosis from prolonged ischemia leads to permanent loss of function.

Spinal cord contusions may be caused by fracture, dislocation, or direct trauma. These injuries are associated with edema, tissue damage, and vascular leakage. Hemorrhagic disruption may cause temporary or permanent loss of function despite normal radiographs.

Cord laceration usually occurs when a projectile or bone enters the spinal canal. Such an injury is likely to result in hemorrhage into the cord tissue, swelling, and disruption of some portion of the cord and its associated communication pathways.

Special Populations

Osteoporosis in older adult patients contributes to a high rate of spinal injury, which may occur even with minimal trauma (eg, ground level falls or falls from a seated position). The CCTP should maintain a high index of suspicion for spinal injury in this population, paying special attention to possible C1-C2 injuries that include dens fractures and transverse ligament disruption.

Special Populations

Patients with a history of ankylosing spondylitis or diffuse idiopathic skeletal hyperostosis warrant extra care and attention. These conditions put patients at increased risk of spinal fractures. Even nondisplaced fractures in this population can be unstable and lead to potential SCI.

Secondary SCI

Secondary spinal cord injury occurs due to progression of the primary SCI. The initial injury can trigger a cascade of inflammatory responses that may result in further deterioration. These effects can be exacerbated by exposing neural elements to further hypoperfusion, hypoxemia, hypoglycemia, and hypothermia. Although some SCIs may be unavoidable, the prehospital provider should minimize the risk of further (secondary) injury by providing stabilization —that is, through spinal motion restriction and neutral alignment. In addition, minimizing heat loss and maintaining oxygenation and perfusion are key elements in the care of a patient with a possible SCI.

Complete Versus Incomplete SCI

As noted earlier, SCIs may be classified as complete or incomplete. The degree of SCI is best determined 24 hours after the initial injury; the initial dysfunction may be temporary, and there may be some potential for recovery.

Complete SCI

Complete spinal cord injury involves complete disruption of all tracts of the spinal cord, with no sensory and motor function more than three segments below the level of injury. When the injury affects the patient’s cervical spine, quadriplegia can result. Injury to the thoracic spine can result in paraplegia.

Incomplete SCI

In an **incomplete spinal cord injury**, the patient retains some degree of cord-mediated function more than three segments below the level of injury. Several types of incomplete SCI syndromes have been identified.

Anterior cord syndrome results from the displacement of bony fragments into the anterior portion of the spinal cord, often as the result of flexion injuries or fractures. The anterior spinal artery provides blood to the anterior two-thirds of the spinal cord; disruption of this flow presents as an anterior cord syndrome. Typical physical findings include motor paralysis below the level of the insult, with loss of pain and temperature sensation, but preservation of proprioception.

In **central cord syndrome**, hyperextension injuries to the cervical area present with hemorrhage or edema to the central cervical segments. This type of damage is rarely associated with fractures or bone disruption; more often, it occurs in conjunction with tears to the anterior longitudinal ligament. Central cord syndrome is frequently seen in older patients, who may already have a significant degree of cervical spondylosis and stenosis as the result of arthritic changes. A brief episode of hyperextension can exert pressure on the spinal cord within the relatively diminished spinal canal. Within the central cord, motor (efferent) fibers are distributed in a unique fashion, with more cervical and thoracic motor and sensory tracts being found there than in the periphery of the cord. The patient with central cord syndrome will present with greater loss of function in the upper extremities than in the lower extremities, with variable loss of sensation to pain and temperature (sacral sparing). The patient may also have some bowel and bladder dysfunction. The prognosis for central cord syndrome is typically good; many patients regain all motor function or have only some residual weakness in the hands.

Brown-Séquard syndrome occurs when penetrating trauma is accompanied by hemisection of the cord and complete damage to all spinal tracts on the involved side. Injury to the corticospinal motor tracts causes motor loss on the same side as the injury, but below the lesion. Damage to the dorsal column causes loss of sensation to light touch, proprioception, and vibration on the same side as the injury (below it). Disruption of the spinothalamic tracts causes loss of sensation to pain and temperature on the opposite side of the injury, below the lesion.

Posterior cord syndrome is associated with extension injuries. This relatively rare syndrome produces dysfunction of the dorsal columns, presenting as decreased sensation to light touch, proprioception, and vibration, while most other motor and sensory functions remain intact. Recovery of function is less likely than with central cord syndrome, but the overall prognosis remains good with therapy and rehabilitation.

Spinal and Neurogenic Shock

Spinal shock is a temporary local neurologic condition that occurs immediately after spinal trauma and involves impaired function of reflex arcs at and below the level of the injury. Patients may present with variable degrees of acute spinal injury, potentially with flaccid paralysis, flaccid sphincters, and absent reflexes. Sensory function below the level of injury will be impaired. Spinal shock usually subsides within 24 to 72 hours, when the spinal cord–mediated reflex arc below the level of injury resumes function. Patients who regain functionality of this arc, yet still have absence of distal motor or sensory function below the level of injury, have a complete cord injury and are unlikely to regain neurologic function. Those with some motor and sensory function below the level of injury are considered to have incomplete injury.

Neurogenic shock results from the temporary loss of sympathetic tone at and below the level of injury; the resultant unchecked parasympathetic stimulation then leads to cardiovascular consequences. The marked hemodynamic and systemic effects typically manifest as the triad of hypotension, bradycardia, and warm, flushed skin. Hypotension occurs as the result of absent or impaired peripheral vascular tone with the loss of alpha receptor stimulation; blood pools in the enlarged vascular space, causing relative hypovolemia and making the patient extremely sensitive to sudden position changes; and cardiac preload decreases, resulting in decreased stroke volume and cardiac output. Bradycardia is the product of the unopposed vagal response: The adrenal gland loses its sympathetic stimulation and does not produce epinephrine or norepinephrine to compensate for the loss of vascular tone. Warm, flushed skin is a result of peripheral vasodilation. Central hypothermia and absence of sweating are also seen because of the loss of sympathetic stimulation and thermoregulation. The classic presentation of neurogenic shock is a hypotensive, bradycardic patient whose skin is warm, flushed, and dry below the level of the spinal lesion.

Transport Management

Evaluate patients for decubitus ulcers, and document any findings in the medical chart. Consideration during packaging should include appropriate positioning to avoid putting pressure on areas at risk for tissue breakdown. Pay particular attention to the coccyx, occiput, and heels.

Assessment of SCI

A patient with an SCI should have a thorough assessment by the CCTP before transport. During this initial assessment, the CCTP should perform a comprehensive neurologic exam. This assessment will provide a baseline with which to compare future assessments when looking for acute changes. SCIs may be severe enough to threaten patients’ lives and often leave patients with significant disability.

As part of the initial assessment prior to transport, the CCTP should take the time to perform a physical examination of the patient before packaging. For patients with SCI, it may be particularly important to focus on the following aspects of patient assessment.

When appropriate, visually inspect the neck. Look for obvious deformities and assess crepitus or the presence of pain while maintaining appropriate spinal motion restriction.

Evaluate the patient’s airway before transportation. If the patient is not already intubated, perform a thorough and complete assessment of the airway. Consider the likelihood of respiratory failure and the need for definitive airway management during transportation. Patients with high SCI (above C3 through C5) may have an altered ability to breathe and ventilate during transport. They may also tire from the work of breathing as the result of muscular weakness from the SCI or owing to an inability to clear secretions. Managing the airway in a patient with cervical fracture or SCI can be difficult in the best of circumstances. If judged to be appropriate, intubate the patient at the referral facility under controlled circumstances and with appropriate support, if available, depending on that facility's resources (eg, anesthesia, surgeon, emergency medicine).

If appropriate and not previously done, assess the patient's back for tenderness and deformity. Palpate the spine for tenderness and deformity (such as step-offs). Assess for strength in the upper and lower extremities and the presence of sensation, including comparison of both sides.

Ongoing patient assessment, particularly of the patient's pulse, motor, and sensory function, is extremely important, because increased swelling can contribute to progressive deterioration of the patient's neurologic status. On arrival at the receiving facility, it will be important to provide an accurate and up-to-date patient report to the accepting medical staff.

CONTROVERSIES

When spine clearance cannot be done clinically, CT scans of the cervical spine should be performed. Plain radiographs of the cervical spine can be used with pediatric patients but have poor sensitivity in adults. Sometimes, however, a transferring hospital cannot perform a rapid CT scan while awaiting arrival of the CCTP team, such as when a CT scan would delay the transport. It is also prudent to limit CT exposure when possible to decrease a younger person's risk of cancer later in life; with younger patients, radiographs are still frequently used to minimize this risk. It is also prudent to avoid exposing women of childbearing age to excess radiation when possible.

The CCTP should always confirm whether spine clearance has been done, and obtain specific details from the transferring personnel. Appropriate documentation of this clearance should be evident in the medical record before transport begins.

In general, patients with identified or highly suspected cervical or thoracolumbar injury should not be cleared and should be transported with appropriate spinal motion restriction (ie, supine on the stretcher, with a properly fitted cervical collar and sufficiently secured shoulder and torso straps to limit gross motion). In most cases, patients with neurologic deficits despite the absence of identified radiologic abnormalities should be assumed to have injury and should be transported with appropriate spinal motion restriction in place. An isolated cervical spine injury may be initially managed with an appropriately fitted collar in place. Thoracolumbar fractures should be managed with lower spinal motion restriction during transport. If in doubt, implement full spinal motion restriction precautions.

Unless contraindicated based on their specific injury, patients should be transported with the head of the stretcher elevated at least to a 30° angle to minimize the risk of aspiration.

Special Populations

Children younger than 10 years have heads that are proportionally larger than their bodies—an anatomic factor that frequently leads to spinal injuries from the occiput to C3. In contrast, children older than 10 years have injury patterns similar to those of adults. Because the head is proportionally larger in younger children, it is important to appropriately immobilize these pediatric patients in a neutral position. This may require padding under the shoulders and back to maintain a neutral alignment in relation to the head.

Signs and Symptoms

Spinal Cord Injury

- May have flaccid paralysis below the level of injury
- May have loss of sensation to pain, temperature, and proprioception below the level of injury; loss may be unilateral
- May have disproportionate upper extremity motor impairment compared with lower extremities
- Bradycardia
- Hypotension
- Hypothermia
- Priapism in males

Transport Management

Spinal Cord Injury

- Identify and correct life-threatening problems (ABCs).
- Maintain spinal stabilization and neutral alignment of the vertebral column.
- In patients with multiple injuries, provide appropriate volume resuscitation with IV fluids and blood component therapy as appropriate.
- Rapidly identify and treat hypotension and hypoxia.
- Maintain normothermia.
- In patients with an isolated SCI, support BP after adequate resuscitation with vasoactive medications such as phenylephrine, norepinephrine, or dopamine.
- Patients may require atropine, transcutaneous pacing, or transvenous pacing for bradycardia.
- Provide rapid, safe transportation to a definitive care facility.

Management of SCI

A patient with an SCI should be treated as having a true neurologic emergency, and the CCTP should make every effort to rapidly assess, treat, and transport the patient to the closest appropriate facility while maintaining appropriate spinal motion restriction. These patients should be transported in a way that minimizes jostling and movement to prevent further SCI. Immediate identification and aggressive management of hypotension and hypoxia will also help to prevent anoxic injury to the spinal cord.

Management Priorities

Priorities of management include rapid identification and correction of life-threatening problems. Appropriately secure and manage the airway, especially in patients with higher-level cervical fractures. Use mechanical ventilation or bag-mask ventilation to support breathing in patients who are intubated or have tracheotomies. End-tidal capnography and pulse oximetry are mandatory for assessing and monitoring respiratory status. Careful assessment, including pulse oximetry, of breathing in nonintubated patients is important when monitoring for progressive respiratory failure.

Frequent monitoring of BP by noninvasive means or by an arterial line during transport will alert providers to hypotension. Appropriate large-bore IV access (minimum of two IV sites) or appropriate central venous access should be in place prior to transport, as should bladder catheterization.

Adequate volume resuscitation with appropriate IV fluids and blood component therapy is necessary for patients with multiple injuries. These patients should be suspected to be experiencing hemorrhage and hemorrhagic shock unless these conditions were ruled out at the transferring facility. Patients with identified isolated neurogenic shock should be treated with volume resuscitation and vasoactive medications.

Patients with SCI may have a loss of thermoregulation from vasodilation and require monitoring of temperature and treatment to maintain normothermia, including warm IV fluids, blankets, and increased temperature in the transporting vehicle. Because bradycardia sometimes results from SCI, the use of atropine, transcutaneous pacers, and transvenous pacemakers may be warranted in patients with high-level cervical lesions (C1 through C5).

Pharmacotherapy

Patients with SCI may require various pharmacologic interventions during transport. Pain associated with fractures or other injuries will require judicious use of opioids. IV opiates can be useful in the management of pain associated with transportation, movement, and the injury itself. Fentanyl, a short-acting synthetic opiate, has less of an effect on BP and may be used as first-line therapy for these patients to control pain and to reduce the risk of hypotension. Midazolam (Versed) or lorazepam (Ativan) may be used for sedation after appropriate pain control has been established and other correctable causes of agitation such as hypoxia have been excluded. The risk of secondary injury as the result of movements from acute agitation must be balanced with potential airway and ventilatory compromise as well as the value of conducting a reliable neurologic exam.

The use of corticosteroids in the acute phase of SCI is no longer recommended.

As noted earlier, patients with SCI may also have neurogenic shock. This condition requires vasoactive medications to support BP (eg, phenylephrine) once adequate resuscitation has occurred. Patients in neurogenic shock may also have bradycardia; in such a case, atropine is required on an urgent basis to support the heart rate and BP.

CONTROVERSIES

Recent outcomes data on use of corticosteroids immediately following initial SCI and during interfacility transfer have failed to show significant improvements and, in fact, have suggested rates of important complications are increased with this therapy. As a consequence, most spine surgeons have abandoned the practice of administering corticosteroids to patients with SCI.

Complications of SCI

The complications of SCI are consistently implicated in the high morbidity and mortality and the high financial cost associated with this type of injury. Acute-phase complications of SCI include the potential for aspiration or respiratory arrest, especially with high cervical injuries. Lower cervical lesions may preserve the diaphragm, but the loss of intercostal muscles will ultimately impair coughing and deep breathing, predisposing the patient to atelectasis and pneumonia. To prevent these complications, transport patients with the head of the stretcher elevated at least to a 30° angle as appropriate based on any underlying vertebral column instability.

Deep vein thrombosis and pulmonary embolism are late complications that may result from immobility and can become potentially life threatening. Consider applying sequential compression devices to the lower legs for prolonged transports to reduce the risk of deep vein thrombosis subsequent to pulmonary embolism.

Pressure ulcers from immobility are also problematic in conjunction with SCI. Proper padding and positioning are important during the transfer phase.

To reduce the occurrence of urinary tract infections in patients with SCI, avoid the use of Foley catheters. When these catheters are necessary, use appropriate sterile technique during their placement, securing the device to the patient’s leg and keeping the Foley bag in a dependent location to prevent backflow of urine into the bladder.

Autonomic dysreflexia is typically a late complication of SCI but may occur acutely. It commonly occurs with injuries above T6 and results from the loss of coordinated autonomic responses. In this condition, an irritation, pain, or stimulus affects the nervous system below the SCI. The affected area sends signals to the brain, but they are unable to reach the brain. The body responds with a reflex action that constricts the blood vessels and increases BP. If left uncontrolled, this cascade can cause a stroke, seizure, and even death. Patients present clinically with evidence of a massive, uninhibited, uncompensated cardiovascular response as the result of noxious stimulation of the sympathetic nervous system below the level of injury. Unabated sympathetic nervous system stimulation results in vasoconstriction and hypertension (SBP sometimes exceeds 200 mm Hg). This leads to compensatory parasympathetic stimulation and causes bradycardia and vasodilation above the level of the lesion, whereas vessels below the SCI remain constricted. The selective vasodilation results in flushed, diaphoretic skin and nasopharyngeal vessel congestion. Other symptoms include headache, nausea, and anxiety.

Common precipitators of autonomic dysreflexia include bladder distention, bowel impaction, bladder infection, pressure ulceration, fractures, and constrictive clothing. Indwelling catheters should be evaluated for obstruction or kinking and flushed to ensure their patency. In patients without an indwelling catheter, draining the bladder acutely with a temporary catheter should be considered to rule out distention as a cause. Identify irritating foci and treat them appropriately, such as removing light clothing, resolving bowel/bladder problems, or treating a decubitus ulcer.

If the source of autonomic dysreflexia cannot be found or minimized to an effective extent, it may be necessary to reduce the patient’s BP with vasodilators. Agents to consider are ones with a rapid action and a short duration (eg, nitrates, nitropaste, hydralizine, labetolol). A trial of beta blockers may also help to reduce cardiovascular response. If autonomic dysreflexia is left untreated, the patient may experience seizures, intracranial hemorrhage, and even death.

Signs and Symptoms

Autonomic Dysreflexia

- Hypertension

- Headache
- Nasal congestion
- Anxiety
- Nausea
- Blurred vision
- Bradycardia common, but tachycardia may also occur
- Diaphoresis and flushing above SCI
- Piloerection above SCI

Transport Management

Autonomic Dysreflexia

- Monitor BP frequently.
- Search for, identify, and correct inciting stimuli (ie, reposition the patient and check the bladder and bowels for irritation or obstruction).
- If the source cannot be found or minimized, reduce the BP with a beta blocker or vasodilators.

Stroke

Mechanism of Injury

Stroke, also referred to as cerebrovascular accident, occurs when a disruption of blood flow to the brain results in a neurologic deficit persisting for more than 24 hours. When deficits completely resolve within 24 hours, the event is referred to as a **transient ischemic attack (TIA)**. Perfusion to oxygen-sensitive brain tissue may be interrupted when a blood vessel is occluded or when the structural integrity of a blood vessel is compromised, allowing blood to escape into the brain tissue or into the subarachnoid space. Care must be initiated quickly to restore proper blood flow and reduce loss of normal neurologic function.

Types of Stroke

A **hemorrhagic stroke** occurs when there is bleeding in the intraparenchymal space (intracerebral hemorrhage) or subarachnoid space (subarachnoid hemorrhage), causing direct or secondary damage to cerebral tissue. This type of stroke is less common and produces worse outcomes as compared to ischemic strokes.

An **ischemic stroke** occurs when cerebral blood flow is decreased, usually because of an occlusion of a blood vessel. The occlusion can be due to either a thrombus or an embolus. Hypoperfusion secondary to hypotension can also cause an ischemic stroke. An estimated 87% of all strokes are ischemic strokes.

A **thrombotic stroke** is largely the result of an accumulation of atherosclerotic plaques inside cerebral blood vessels, especially at bifurcations, which narrow the lumen of the vessel and hinder blood flow. Rupture of a local plaque can lead to localized clotting, which then significantly diminishes or completely stops blood flow distal to the occlusion.

In an **embolic stroke**, an embolus from the heart or lower circulation travels and lodges in a smaller cerebral vessel, resulting in loss of blood supply. Only 30% of ischemic strokes are thought to be caused by an embolus. Myocardial complications, such as atrial fibrillation, valvular heart disease, myocardial infarction, ventricular aneurysm, and cardiomyopathy, are known risk factors for embolus formation.

A **focal ischemic stroke** occurs when an area of marginally perfused tissue, the ischemic penumbra, surrounds a core of ischemic cells. As blood flow continues to dwindle, the ischemic cells become injured and finally die. The result is infarction and irreversible loss of brain tissue, which eventually softens and becomes necrotic. The size of the stroke depends on the size and location of the occluded vessel and the availability of collateral blood flow.

In a **global ischemic stroke**, severe hypotension or cardiac arrest produces a transient drop in blood flow to all areas of the brain. The areas of the brain affected first, known as the watershed areas, consist of the cortical territories between the anterior cerebral artery, the middle cerebral artery, and the posterior cerebral artery.

Assessment of Stroke

The hallmark of stroke is the sudden onset of focal neurologic signs that often occur in combination, corresponding to the anatomic area of ischemia or infarction. The CCTP can use abbreviated prehospital stroke assessment tools to identify patients suffering from stroke. Examples include the Cincinnati Prehospital Stroke Scale **TABLE 12-24** and the Los Angeles Prehospital Stroke Screen **TABLE 12-25**. There are multiple acceptable prehospital stroke assessment tools and little evidence to show strong superiority of one over the others. Choice of a prehospital stroke assessment tool varies by region and system. Although useful in the hospital setting, the National Institutes of Health's stroke scale is not practical for evaluating patients during transport because it is very involved; nonetheless, the CCTP should become familiar with this scale's values because they indicate the severity of illness.

TABLE 12-24 Cincinnati Prehospital Stroke Scale[a]

Assessment	Normal	Abnormal
Facial Droop. Ask the patient to smile and show the teeth.	Both sides of the face move equally well.	One side of the face does not move as well as the other.
Arm Drift. Ask the patient to close the eyes and hold the arms out with palms up for 10 seconds.	Both arms move the same, or both arms do not move.	One arm does not move, or one arm drifts down compared with the other.
Abnormal Speech. Ask the patient to say, "The sky is blue in Cincinnati" or "You can't teach an old dog new tricks."	The patient uses the correct words with no slurring.	The patient slurs words, uses inappropriate words, or is unable to speak.

[a] Interpretation: If any assessment criterion is abnormal, the probability of a stroke is 72%.

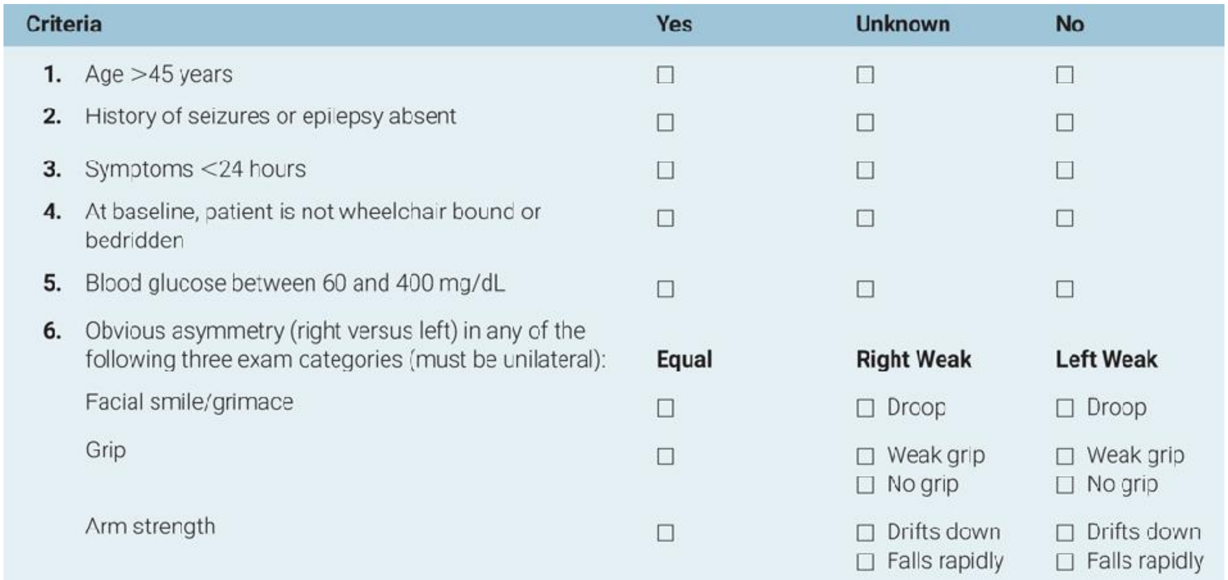
TABLE 12-25 Los Angeles Prehospital Stroke Screen[a]



Criteria	Yes	Unknown	No
1. Age >45 years	☐	☐	☐
2. History of seizures or epilepsy absent	☐	☐	☐
3. Symptoms <24 hours	☐	☐	☐
4. At baseline, patient is not wheelchair bound or bedridden	☐	☐	☐
5. Blood glucose between 60 and 400 mg/dL	☐	☐	☐
6. Obvious asymmetry (right versus left) in any of the following three exam categories (must be unilateral):	**Equal**	**Right Weak**	**Left Weak**
Facial smile/grimace	☐	☐ Droop	☐ Droop
Grip	☐	☐ Weak grip ☐ No grip	☐ Weak grip ☐ No grip
Arm strength	☐	☐ Drifts down ☐ Falls rapidly	☐ Drifts down ☐ Falls rapidly

[a] Interpretation: If criteria 1 through 6 are marked yes, the probability of a stroke is 97%.

Description

In addition to focal neurologic signs and stroke tools, noncontrast CT scanning is important to help determine whether the patient’s symptoms are being caused by an occlusion or bleeding or whether any **hemorrhagic conversion** (a secondary hemorrhage at the site of an ischemic stroke lesion) is present. These findings have significant implications for decision making about treatment.

Early in the evaluation, the CCTP should consider possible “stroke mimics.” These conditions can cause symptoms clinically similar to stroke, but actually involve a different pathologic process that may benefit from other interventions. A stroke mimic of particular importance to the CCTP is hypoglycemia. All patients with suspected stroke should be assessed for hypoglycemia early in their assessment and treated as indicated. Other possible stroke mimics include seizure, migraine, hyponatremia, and other metabolic derangements, all of which may be considered in the hospital setting.

Complications of Stroke

In addition to neurologic deficits corresponding to the anatomic areas of infarction, other complications from strokes are possible. Cerebral edema sufficient to produce clinical deterioration occurs in 10% to 20% of patients with ischemic stroke and can result in intracranial hypertension. In this case, the edema results from a loss of normal metabolic function of cells and peaks at 3 to 5 days. Intracranial hypertension may, in turn, cause significant complications, as discussed earlier in this chapter. Hemorrhagic conversion can also occur. In addition, patients who have had a stroke may exhibit seizure activity due to damaged neurons.

Management of Stroke

Once stroke is suspected, the CCTP should determine the time of symptom onset or “last known well” time, as this information is key to hospital care providers’ determination of the most appropriate therapy. The “last known well time” is either the time of symptom onset, if known, or the last time the patient was known to be at their baseline.

In general, during evaluation and transport, the CCTP should support the patient’s cardiopulmonary function, provide continuous monitoring of neurologic function, and maintain normal blood glucose levels. Patients with stroke are at increased risk for respiratory compromise from aspiration, upper airway obstruction, and hypoventilation. Frequent reassessment of airway and respiratory function is necessary because hypoxemia will worsen ischemic brain injury, contributing to a worse outcome. Patients with suspected stroke should not routinely be given supplemental oxygen unless they are hypoxic.

Hemodynamic status is also vital information in stroke patients. BP targets vary depending on the clinical situation. In patients with known ischemic stroke, simple measures may be taken to improve CPP, such as positioning the patient supine and allowing permissive hypertension. Many systems’ parameters allow BPs up to 220/120 mm Hg in patients not being treated with fibrinolytic therapy in an effort to maintain adequate CPP. Local protocols may vary regarding the exact vital sign parameters.

After evaluation in the hospital setting, clinicians will determine whether the patient would benefit from a reperfusion therapy such as fibrinolytic therapy or mechanical thrombectomy. This decision depends on the patient’s last known well time, type of symptoms, and comorbidities.

Fibrinolytic Therapy

In some cases, the CCTP may provide transport for patients who have experienced a stroke and have received or are actively receiving fibrinolytic therapy. If a stroke patient’s symptoms are disabling, a CT scan shows no hemorrhage, the symptom onset is within 4.5 hours, and the patient does not have any contraindications, fibrinolytic therapy may be administered to restore circulation to ischemic brain tissue. Studies have shown that in appropriate patient populations, earlier fibrinolytic therapy produces better neurologic outcomes, underscoring the importance of timely evaluation and treatment of these patients. Fibrinolytic therapy may also be available in certain circumstances when the time of symptom onset is unknown, such as in cases of "wake-up" stroke after a cerebral perfusion scan has been completed in the hospital setting and shows the patient would benefit from the therapy.

The only fibrinolytic agent currently used for the treatment of ischemic stroke is tPA, also referred to as alteplase. A thrombolytic agent, tPA binds to fibrin on a clot surface and converts plasminogen to plasmin, which degrades the clot. It is typically given as an initial bolus, followed by an infusion over an hour. Therefore, the CCTP may provide transport to a patient actively receiving tPA and should be aware of possible complications of this treatment.

Before therapy is initiated, inclusion and exclusion criteria for IV fibrinolytic therapy should be reviewed to decrease the risk of complications. Refer to the American Heart Association's website for the most up-to-date list of inclusion and exclusion criteria. Exclusion criteria generally include the following concerns:

- History of intracranial neoplasm, AVM, or aneurysm
- Bleeding concerns, in the form of either current bleeding or a bleeding disorder
- History of recent stroke
- Recent noncompressible vascular puncture
- Major surgery or trauma in the past 3 months
- SBP of greater than 180 mm Hg
- Pregnancy and up to 1 month postpartum

Possible complications of tPA therapy include intracranial hemorrhage, orolingual angioedema, acute hypotension, and systemic bleeding. When transporting a patient who has received or is receiving tPA, the patient's hemodynamic status should be closely managed, with a BP goal of less than 180/105 mm Hg; risk of hemorrhage increases with higher BP levels. The patient should be continuously monitored for any neurologic deterioration, which would be concerning for possible intracranial hemorrhage. Sudden mental status change, neurologic deterioration, sudden vital sign changes, or severe headache may be signs of intracranial hemorrhage in this setting.

If intracranial hemorrhage is suspected, the tPA infusion should be stopped immediately and the base hospital should be contacted for further orders. The BP goal may be lowered. The patient should be closely monitored for mental status deterioration and need for airway interventions. In the hospital setting, a patient would be taken for an immediate repeat CT scan to evaluate for hemorrhage. If such a bleed is found, reversal of thrombolytic and anticoagulation therapy would be initiated with cryoprecipitate, tranexamic acid, and possibly other medications or blood products, depending on the clinical situation. Reversal of anticoagulation therapy is discussed further in Chapter 10, *Resuscitation, Shock, and Blood Products*.

Endovascular Interventions

Rapid technological advances in recent years have made endovascular interventions for reperfusion therapy increasingly valuable. IV tPA is less effective for strokes caused by proximal or large-vessel occlusions, and the subset of patients with these kinds of strokes can benefit significantly from endovascular interventions. As technology rapidly evolves in this field, the window of time for these patients to receive endovascular interventions will continue to expand.

Intra-arterial thrombolysis uses an endovascular approach to administer local tPA at the site of the occlusion. It may be combined with a mechanical intervention. One study found improved clinical outcomes with this intervention at 90 days post treatment, but more recent studies have not shown any significant clinical benefit compared to standard treatment. The current American Heart Association/American Stroke Association guidelines state that intra-arterial thrombolysis may be considered in a subset of patients who have contraindications to IV fibrinolysis.

CONTROVERSIES

The standard of care for LVO strokes has been to administer IV tPA to these patients prior to transfer to the neurointerventional radiology suite. However, since the promising results of several landmark studies from 2014 to 2015 (MR. CLEAN, ESCAPE, EXTEND IA, SWIFT-PRIME, and REVASCAT) were published, hospitals have begun using acute endovascular therapy for these patients. More recently, studies have brought the role of tPA into question, demonstrating a reperfusion rate of only 7% to 15% when this medication is used to treat LVO strokes. Further, a 2020 study published in the *New England Journal of Medicine* found that endovascular therapy alone was noninferior to tPA plus endovascular therapy.

Additional studies are ongoing at large comprehensive stroke centers, but early data support a shift in the treatment of LVO stroke, with patients receiving rapid transfer for endovascular interventions without IV tPA.

Mechanical thrombectomy is an endovascular surgical intervention that has been shown to have a significantly positive effect on neurologic outcomes compared to fibrinolytic therapy alone in stroke patients with an LVO. In this procedure, arterial catheterization is performed and a device is used to retrieve the clot, with the aim of restoring circulation to the affected area of cerebral tissue. In general, patients with an LVO stroke who are within 24 hours of symptom onset may be considered for mechanical thrombectomy. As with fibrinolytic therapy, the benefit of mechanical thrombectomy depends heavily on time from symptom onset: It should be done as expeditiously as possible for maximum benefit. Factors such as the exact vessel affected, time since symptom onset, and severity of symptoms may affect the level of benefit. These procedures are typically performed at endovascular-capable comprehensive stroke centers.

Signs and Symptoms

Left Hemisphere Ischemic Stroke

- Right hemiparesis
- Right-side sensory loss
- Right visual field deficit
- Poor right conjugate gaze
- Dysarthria

- Aphasia
- Difficulty in reading, writing, or calculating

Right Hemisphere Ischemic Stroke

- Left hemiparesis
- Left-side sensory loss
- Left visual field deficit
- Poor left conjugate gaze
- Dysarthria
- **Extinction** of left-side stimuli
- Neglect of the left visual space
- Spatial disorientation

Brainstem/Cerebellum/Posterior Hemisphere Ischemic Stroke

- Motor or sensory loss in all four limbs
- Crossed signs
- Limb or gait ataxia
- Dysarthria
- Dysconjugate gaze
- Nystagmus
- Amnesia
- Bilateral visual field deficits

Small Subcortical Hemisphere or Brainstem (Pure Motor) Ischemic Stroke

- Weakness of the face and limbs on one side of the body without abnormalities of higher brain function, sensation, or vision

Small Subcortical Hemisphere or Brainstem (Pure Sensory) Ischemic Stroke

- Decreased sensation of the face and limbs on one side of the body without abnormalities of higher brain function, motor function, or vision

Adapted from Adams HP, Brott TA, Crowell RM, et al. Guidelines for the management of patients with acute ischemic stroke: a statement for healthcare professionals from a special writing group of the Stroke Council, American Heart Association. *Circulation*. 1994;90(3):1588.

Transport Management

Stroke

- Determine the time of symptom onset.
- Support the patient's cardiopulmonary function.
- Provide continuous monitoring of neurologic function.
- Maintain normal blood glucose levels.
- Reassess airway and respiratory function frequently.
- Maintain oxygen saturation greater than 94%.

Stroke Systems of Care

Given the prevalence of stroke and the time-sensitive nature of effective interventions, organized and coordinated stroke systems of care are extremely important. Regions should have a plan in place that addresses the following needs:

- Strategy for minimizing stroke morbidity and mortality using public education
- Dispatch instructions and triage strategies
- EMS protocols and training
- Coordination between primary stroke centers, comprehensive stroke centers, and rehabilitation centers
- Continuous quality improvement

Further, the regional plan should define criteria for activating the stroke system and for selecting the appropriate transport destination.

The rapid advancements in endovascular interventions have prompted stroke systems to continually evolve. As mentioned, criteria for stroke system activation change frequently due to the ever-expanding time window during which patients may benefit from time-sensitive interventions. It is vital that prehospital and CCT agencies stay current with these changes.

CONTROVERSIES

Given the significant benefit of endovascular interventions for patients with LVO strokes, the medical community continues to debate how transport destinations should be determined for stroke patients from the field. Historically, given the time-dependent nature of tPA, nearly all stroke patients have been brought to the nearest tPA-capable facility, which is usually not a comprehensive stroke center. At that facility, if imaging reveals the presence of an LVO, the patient may be transported to an endovascular center if indicated. Clearly, this system delays time to mechanical thrombectomy for some patients. Systems must improve early access to mechanical thrombectomy while avoiding delay of tPA therapy for patients who need it or overtriaging patients to comprehensive stroke centers. Many systems are piloting programs to address this problem, such as implementation of mobile stroke units or field triage directly to comprehensive stroke centers for certain patients. This is an emerging area of research in the EMS community and a consensus on best practice does not yet exist.

Intracerebral Hemorrhage

Intracerebral hemorrhage is bleeding directly into the cerebral tissue that causes cerebral tissue destruction, cerebral edema, and increased ICP. The most common cause of spontaneous intracerebral hemorrhage is hypertension-induced vessel rupture. Other causes include anticoagulation or fibrinolytic therapy, coagulation disorders, drug abuse, and hemorrhage into cerebral infarcts or brain tumors.

Symptoms of intracerebral hemorrhage may begin as local neurologic dysfunction related to the area of the brain in which a vessel has ruptured. The patient may also report the presence of a severe headache, nausea, and vomiting. As ICP continues to rise, however, the patient will oftentimes become unconscious (a key finding that helps differentiate this condition from ischemic stroke) and may require ventilatory support. The time it takes for deterioration to progress is related to the amount and speed of bleeding.

The CCTP should provide adequate attention to the management of cardiopulmonary function. If intubation is necessary, the CCTP should perform it as soon as the patient's level of consciousness becomes inadequate for airway control or vomiting begins to endanger airway patency. If intracerebral hemorrhage has been confirmed before transport, orders may be given to reduce BP to decrease ongoing bleeding. An overly aggressive reduction in BP, however, may compromise cerebral perfusion pressure, especially in the patient with an elevated ICP.

Patients on anticoagulation therapy, such as those taking warfarin, will likely need to be given reversal agents. Reversal agents may be in progress during transport. Reversal of anticoagulation is discussed further in Chapter 10, *Resuscitation, Shock, and Blood Products*.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage is bleeding into the subarachnoid space; this bleeding is usually arterial in nature. Most subarachnoid hemorrhages are caused by rupture of a cerebral aneurysm or AVM. Other causes include hypertensive intracerebral hemorrhages that progress to subarachnoid hemorrhage and bleeding from a cerebral tumor. This chapter focuses on the two most frequent causes of subarachnoid hemorrhage.

An **aneurysm** is an outpouching of the wall of a blood vessel that results from weakening of the vessel’s wall. Although most aneurysms are congenital, others can be attributed to trauma or infection, or are idiopathic in nature. As an individual with a congenital cerebral aneurysm matures, BP rises and places stress on the wall of the weakened vessel. Eventually, the vessel balloons, which may lead to compression of adjacent brain tissue and focal neurologic dysfunction. If the aneurysm ruptures, arterial blood is sent into the subarachnoid space at high pressure. As blood fills the space, ICP rises and cerebral perfusion pressure falls.

An **arteriovenous malformation (AVM)** is a tangled mass of arterial and venous blood vessels that shunt blood directly from thickly walled arteries to thinly walled veins without the benefit of pressure being reduced by an intervening capillary bed. One or more cerebral arteries, known as feeders, provide blood to an AVM. These feeders enlarge over time, increase the volume of blood shunted through the malformation, and increase the overall mass effect on adjacent brain tissue. Eventually, veins may no longer be able to accommodate the high mean pressure; they may then rupture, causing blood to fill the subarachnoid space. As this happens, ICP rises and cerebral perfusion pressure falls.

Like patients with intracerebral hemorrhage, patients on anticoagulation therapy for subarachnoid hemorrhage will likely need to be given reversal agents, which may be in progress during transport. Reversal of anticoagulation is discussed further in Chapter 10, *Resuscitation, Shock, and Blood Products*.

Assessment of Subarachnoid Hemorrhage

The patient with a subarachnoid hemorrhage characteristically has an abrupt onset of pain, oftentimes described as “the worst headache I have ever had.” A loss of consciousness, nausea, vomiting, focal neurologic deficits, photophobia, and nuchal rigidity may accompany the headache. As ICP increases, the patient may become comatose or die.

Management of Subarachnoid Hemorrhage

When caring for a patient with a subarachnoid hemorrhage, the CCTP must focus on maintaining cardiopulmonary function. This frequently involves airway management and ventilatory support as the patient’s level of consciousness and vomiting endanger the airway. The CCTP may also take steps to prevent an unnecessary rise in ICP, such as limiting head movement and elevating the head during transport. Common complications of subarachnoid hemorrhage include rebleeding (ie, a second subarachnoid hemorrhage in an unsecured aneurysm), cerebral vasospasm, hyponatremia, and hydrocephalus.

Signs and Symptoms

Subarachnoid Hemorrhage

- Onset of pain
- Worst headache of the patient’s life
- Loss of consciousness
- Nausea
- Vomiting
- Focal neurologic deficits
- Photophobia
- Nuchal rigidity

Transport Management

Subarachnoid Hemorrhage

- Take measures to maintain the patient’s cardiopulmonary function.
- Manage the patient’s airway.
- Provide ventilatory support if necessary.
- Limit movement of the patient’s head; elevate the head during transport.

Acute Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) comprises a group of immune-mediated polyneuropathies, all of which share a common constellation of features often provoked by an infection. The overall worldwide incidence of GBS is 1 to 2 per 100,000 people, with the incidence increasing by 20% for every 10 years of life. This syndrome is more common in males.

The primary clinical presentation of GBS is a progressive, usually symmetric muscle weakness that varies from mild to complete paralysis. Patients often present for medical care several days to a week after the onset of symptoms. Typically, the weakness begins in the legs, but in 10% of patients it may begin in the upper extremities or face.

Patients with known or suspected acute GBS may be transported to referral centers and may exhibit significant or complete paralysis of all four extremities, respiratory, and facial muscles. Ventilator support is required in as many as 30% of all patients with GBS and is highly likely to be required in patients with acute GBS. Autonomic nervous system dysfunction is also common in patients with acute GBS, who may demonstrate wide swings in BP, significant tachycardia, and hemodynamic changes requiring ICU-level monitoring and treatment. Pain, primarily in the back and extremities, is present in 66% of patients with this condition.

Initial diagnosis of GBS is based on clinical presentation, including progressive, mostly bilateral (symmetric) muscle weakness with depressed or absent deep tendon reflexes. Confirmatory diagnosis of GBS can be made if CSF and neurophysiology studies show a typical pattern of abnormalities.

Treatment, especially during transport, is largely supportive. Close observation of respiratory effort in nonintubated patients with GBS is imperative, as deterioration can occur rapidly. Tachycardias rarely require treatment. Pressors may be needed for hypotension once any fluid volume deficits are corrected. Beta blockers or other antihypertensives may be needed for significant hypertension (sustained MAP >125 mm Hg), although careful consideration should be given to identifying potential causes of autonomic dysreflexia such as pain, acute urinary retention, or hypoxemia. These patients may also have significant pain, requiring narcotic analgesia.

Seizures and Epilepsy

When a nerve cell is stimulated, its action is transmitted to other cells by excitatory neurotransmitters and balanced by inhibitory neurotransmitters that slow communications. Overactivity by excitatory transmitters or underactivity by inhibitory transmitters can result in a seizure.

Seizure activity can be caused by many different factors, such as fever, glucose imbalance, electrolyte imbalances, head injuries and hemorrhagic strokes, and toxins. Epilepsy, for example, is a disorder featuring recurrent seizures caused by abnormal discharges in the brain cells; it is often idiopathic. Although monitoring of nonmotor seizures may be the only care needed, tonic-clonic and focal seizures that may compromise the airway require immediate action.

Care for patients with seizure should initially center on maintaining the airway, protecting the patient, and providing oxygen. Do not attempt to restrain a patient who is actively seizing. Instead, establish an IV line and monitor the patient’s cardiac status. Also, check the patient’s blood glucose level, and administer glucose if indicated. Check the patient’s temperature to ensure that fever is not an issue. Body temperature can be lowered by administering normal saline, giving acetaminophen, and cooling down the patient without causing shivering.

If the patient is actively seizing, administer an anticonvulsant. The drugs most commonly given during transport for this purpose are lorazepam, diazepam, midazolam, and levetiracetam. Patients with a history of epilepsy are often taking phenytoin or levetiracetam, both of which can be given intravenously. In the prehospital arena, and for initial management of seizures in an emergency or critical care setting, midazolam has shown superiority to other agents and is considered the first-line drug of choice. Midazolam can be administered intranasally, intravenously, intramuscularly, or through an oral or rectal tube.

Transport Management

Seizures

- Manage the patient's airway.
- Maintain oxygen saturation greater than 92%.
- Do not attempt to restrain the patient if the patient is actively seizing.
- Establish an IV line.
- Monitor the patient's cardiac status.
- Check the patient's blood glucose level and administer glucose if indicated.
- Check the patient's temperature.
- To lower the patient's body temperature, administer normal saline, give acetaminophen, and cool the patient without causing shivering.
- If the patient is actively seizing, administer an anticonvulsant (eg, lorazepam, diazepam, midazolam, levetiracetam).
- If the patient has epilepsy, give levetiracetam, phenytoin, fosphenytoin sodium, carbamazine, or phenobarbital.

Transport Considerations

Prior to Transport

Before considering transport of a patient with a neurologic emergency, it is imperative to consider potential complications that the patient may experience. To this end, it is advisable to ensure that all diagnostic tests and surgical procedures have been completed when at all possible before transport.

Although patient-related risk factors are difficult to identify, equipment-related complications (which occur in as many as one-third of transports) may be controlled more easily. During critical care transport, the following types of equipment may be present and may require troubleshooting:

- Cardiac monitor, to monitor cardiac status: Check for sufficient batteries, charging, a general check, and waveform capnography.
- Ventilator with waveform capnography, to monitor and control ventilation: Check for sufficient oxygen and gas supply, ventilator tubing, oxygen and circuit connections, and capnography hookup.
- Infusion pumps, to administer medications: See the manufacturer’s troubleshooting chart.
- ICP monitoring, to measure and control ICP: Check for sterility, keep the fluid level, and refer to the manufacturer’s troubleshooting manual.
- Cerebral function monitor, to assess sedation, monitor brain wave activity, predict and monitor seizure activity, and monitor the onset and effectiveness of paralytics: See the manufacturer’s troubleshooting chart.

Most interfacility transports do not involve ICP monitoring or CFM monitoring. When such monitoring is used, patients are usually placed on a ventilator, cardiac monitor, and medications administered by IV pump.

Scene and Interhospital Transport Considerations

Apart from intracranial hemorrhage, the major early risks to the patient with head injury are hypoxia and hypertension. The ABCs are always the first priority. Urgent attention to the ABCs will help reduce cerebral hypoxia and hypoperfusion. Normoxia and normocarbia should be achieved as soon as practically possible.

The patient with a severe closed head injury should be presumed to have an elevated ICP, and factors that may further increase ICP should be avoided. Some critical care transport systems advocate the use of ear and eye protection for such patients to prevent spikes in ICP caused by outside stimuli from aircraft or sirens (mostly applicable in patients with seizure). Overperfusion, hypertension, inadequate sedation, hyperpyrexia, and inappropriate anesthetic agents can increase ICP as well. Likewise, intubation and endotracheal suction cause sharp, albeit transitory, spikes in ICP. In patients with a reduced volume reserve (hypovolemic), however, these stimuli may initiate a prolonged increase in ICP. Pressure waves may be avoided by providing fluid resuscitation adequate to maintain CPP. Any sedation should be administered at a level that is sufficient to prevent coughing or gagging during transport.

Minimum requirements for monitoring patients during transport are continuous ECG, pulse oximetry, and intermittent measurements of BP, respiratory rate, and pulse rate. In specific patients, capnometry, continuous BP reading, and further monitoring (eg, monitoring of ICP and cardiac output and filling pressures) may be beneficial. Unfortunately, many of the complications reported during transport are caused by equipment malfunction. Given this reality, the CCTP must be familiar with all equipment and monitoring devices in use to ensure optimal patient outcomes and avoid complications from equipment misuse or malfunction.

Of particular importance is the possibility of measuring the major ventilation parameters, such as tidal volume or minute ventilation.

Although many transport ventilators do not display the actual tidal volumes delivered, judicious use of $ETCO_2$ monitoring will allow the CCTP to observe the effects of mechanical ventilation on the patient during transport and to make appropriate adjustments. One way to reduce inadvertent ventilation problems is to use the best possible monitoring equipment, particularly equipment that focuses on tidal or minute ventilation. Bearing in mind the limitations of many portable ventilators, consider the use of sophisticated transport carts equipped with a standard ICU ventilator and the necessary gas supply. Such carts can be hooked to the patient's bed and moved fairly easily. Monitoring devices and infusion pumps can be integrated into the cart and powered with its battery. Such equipment is being increasingly used during interhospital transports.

Flight Considerations

Most fixed-wing aircraft used for medical transport have the ability to pressurize the cabin as the altitude increases and to depressurize the cabin as the altitude decreases. These aircraft have a chart indicating cabin pressure as a function of altitude. Ideally, the cabin pressure should closely match the original ground pressure. Thus, when feasible, the pilot should fly at altitudes where cabin pressure can be maintained as near to the original departure pressure as possible.

If this synchronization of pressures cannot be achieved in flight, adjustments must be made. If the patient is intubated, the endotracheal cuff pressure should be decreased with altitude to prevent damage to the trachea, and then reinflated during descent to prevent leakage. While recent research suggests that altitude-induced changes in cuff pressures may be clinically inconsequential, the CCTP should be equipped to monitor cuff pressures during transport and adjust them as needed. Adjust the pressure inside indwelling catheters and colostomy bags to prevent breakage. If the patient has a drain and the ICP is monitored, maintain the ICP at less than 20 cm H_2O by draining off excess fluids. If the patient does not have a drain, monitor for any changes in status. If the patient shows changes in the respiratory rate or pattern, or develops any changes in cardiac function (ie, arrhythmias or significant changes in heart rate), these signs may indicate herniation. In such a case, the aircraft must immediately descend to an altitude at which the condition can be managed.

When targeting ventilation to specific $ETCO_2$ parameters, remember that high altitudes require lower $ETCO_2$ values to achieve the same results seen at sea level.

Summary

Management of neurologic emergencies requires an in-depth understanding of brain, spinal, and cranial nerve anatomy and physiology. In addition, the CCTP must be familiar with the complexity of severe TBI, recognize the early signs and symptoms of TBI, and understand how early intervention can influence these patients' outcomes.

The CCTP should make every effort to preserve cerebral perfusion and oxygenation as the primary goal in the initial care for patients with neurologic emergencies. Current guidelines call for careful monitoring of oxygenation and preventing hypoxia by keeping Pao_2 (partial pressure of arterial oxygen) above 60 mm Hg and/or oxygen saturation greater than 90% at all times. In patients who exhibit signs and symptoms of cerebral herniation during field management or transport, initial management consists of hyperventilation. Mannitol may be helpful in treating increased ICP and cerebral herniation, but should be used judiciously given its other physiologic effects. The use of analgesia, sedation, and neuromuscular blockade is critical during transport to minimize the risks associated with increased ICP and to maximize safety in the transport setting. The CCTP should also be mindful of the potential for hypoglycemia in patients with neurologic emergencies, because this condition may mimic TBI or stroke; thus, hypoglycemia should be considered in all patients with an altered LOC until ruled out by applicable diagnostic and laboratory confirmations.

To a large extent, the treatment of neurologic emergencies depends on the ability to distinguish between primary and secondary injuries. A key aspect of managing secondary injuries is managing the effects of the injury—namely, CPP and ICP.

A CCTP who is involved in the transport of patients with neurologic emergencies should be mindful of the complexities associated with these conditions. If possible, most diagnostic tests and treatments should be performed prior to transport. Although a number of patient-related risk factors can be identified in any neurologic transport, the rate of equipment-related adverse events in transport is substantially higher with these types of injuries. This requires careful attention to the personnel, equipment, and monitoring in use at any given time.

CASE STUDY

You and your critical care transport team are requested at the three-bed emergency department (ED) of a small community hospital to transfer a 60-year-old woman who was brought in moments ago by local EMS complaining of a severe headache.

As part of your history taking, you interview the patient's husband, who is present at her bedside. He reports that his wife just buried her mother yesterday and has been under a lot of stress dealing with her mother's affairs. He states that she has been complaining of a headache for the past few days, but it has become worse, increasing in severity.

When the patient's husband arrived home after work, he found his wife lying on the couch. He dimmed the lights, put a cool washcloth on her forehead, and gave her two aspirins. He went into the kitchen to start preparing dinner when he heard her vomiting. Upon entering the room, he saw that his wife was projectile vomiting and called 9-1-1.

During your interview with the patient, she confirms what her husband reported and adds that she has been having blurred vision today as well. She attributed the headache and nausea to stress over her mother's death. While you are obtaining information on her past medical conditions, the patient reports that she has a history of high BP and has not been taking her medication for the past week, trying to save money to pay for her mother's funeral. She denies having any other medical problems or taking any other medications.

Your initial physical exam of the patient reveals a normal GCS score of 15. She is able to follow complex commands and move all extremities. She has no decreased level of consciousness and has equal strength bilaterally in all extremities, and all of her cranial nerves are intact. Her BP is 192/110 mm Hg, consistent with the ED staff's measurements. The patient is on a cardiac monitor, which reveals a heart rate of 95 beats/min, with normal sinus rhythm. Her respiratory rate is 18 breaths/min, and her lungs are clear to auscultation in all lung fields. Oral temperature is 99.6°F (37.6°C). The patient rates her headache as a 10 on a scale of 0 to 10, with 10 being the worst pain in her life.

The patient is prepared for transport. The ED staff has placed an IV line in the patient's right antecubital vein, infusing normal saline at a keep-the-vein-open rate. The patient is placed on the stretcher with the head of the bed elevated at 45° angle. You and your team load the patient into your critical care ambulance and initiate seizure precautions during the transport.

During transport to the referral center, the patient has a tonic-clonic seizure. You administer 2 mg of lorazepam IV and no further seizures occur.

1. What is going on with this patient?
2. Why is the head of the bed elevated at a 45° angle?

3. Why are seizure precautions initiated, and what does the seizure precaution entail for the ambulance crew?
4. What are some possible complications that could occur during the transport of this patient and how would the critical care transport team handle them?

At the referral center, an emergency CT scan of the patient's head is ordered. It reveals a small, right subarachnoid hemorrhage with bleeding into the suprasellar cistern, indicating a grade 2 subarachnoid hemorrhage. (In 1968, Drs. Hunt and Hess developed a grading scale for the classification of cerebral aneurysm. The grading scale ranges from grade 1, an asymptomatic or minor headache, to grade 5, a deep coma.) Neurosurgery is consulted and a cerebral angiogram is ordered. The cerebral angiogram reveals a 4-mm, berry-shaped, right middle cerebral aneurysm located at a bifurcation.

The patient is admitted to the neurosurgery ICU and scheduled for surgery the next morning. A clipping of the right middle cerebral artery is performed without complication. An IVC is placed to monitor the patient's ICP. The surgeon's postoperative order states to maintain a SBP of 140 mm Hg or lower, to perform hourly neurologic exams, and to maintain an ICP of less than 15 mm Hg and a CPP of greater than 80 mm Hg. The patient remains on the ventilator until the following morning, when a postoperative CT scan is performed. The scan reveals no complications and no recurrence of bleeding. She is extubated that day and discharged home 6 days later without further complications.

5. What are some of the common reasons why an individual might have a cerebral aneurysm?
6. List the three major postoperative complications that may occur following a cerebral aneurysm.

Analysis

This patient has a cerebral aneurysm. Elevating the head of the bed will help reduce her increased ICP.

Seizure precautions include the following measures: avoiding the use of lights and siren; keeping lights dimmed in the ambulance compartment; padding the side rails of the patient's stretcher; verifying that airway equipment is readily available, such as oxygen delivery systems, nasal and oral airways, bag-mask device, suction, catheters, and suction equipment; and being prepared to administer diazepam or lorazepam.

Possible complications in this patient include increased ICP, hypertension, respiratory depression and failure, and brain herniation. The CCTP should not treat her hypertension during the transfer unless directed to do so by the receiving facility or neurosurgeon. The hypertension state is intended to provide increased cerebral perfusion to any potentially vasospastic areas. In general, patients should be maintained in a normotensive state with a SBP of 110 to 160 mm Hg. Keeping the head of the bed elevated and avoiding overstimulation of the patient will help reduce her ICP.

Patients with respiratory depression and failure may require rapid sequence intubation. Patients with potential increased ICP should be premedicated with a short-acting opioid such as fentanyl, usually 3 mcg/kg IV. A sedative should always be used unless the patient is deeply comatose.

Nondepolarizing neuromuscular blockers such as rocuronium or vecuronium, unlike succinylcholine, do not cause fasciculations. Etomidate may be used as an alternative induction agent. This hypnotic agent will not increase ICP, but it is contraindicated in patients younger than 10 years. If etomidate is used, lidocaine is theoretically unnecessary.

The patient's $PaCO_2$ level should be maintained between 36 and 42 mm Hg. Hyperventilation should be avoided unless the patient shows signs of herniation.

Causes of cerebral aneurysms include neoplastic disease, atherosclerosis, brain trauma, infection, and congenital defects. Clip ligation—a surgical procedure that blocks the aneurysm from the circulation by placement of a clip—is usually performed to repair cerebral aneurysms.

Potential postoperative complications of clip ligation of a cerebral aneurysm include recurrence of bleeding (especially in the first 24 hours), cerebral vasospasm, and electrolyte disturbances, such as hypernatremia. Vasospasm will decrease blood flow to the brain and cause the death of nerve cells, so medication may be administered to prevent it. The patient may also be given medications to address other potential complications.

PREP KIT

Ready for Review

- A majority of patients with neurologic emergencies who require transport will have traumatic brain injury (TBI).
- The nervous system can be divided into the CNS, which consists of the brain and spinal cord, and the PNS, which consists of the spinal and cranial nerves.
- Afferent pathways (ascending pathways) carry sensory impulses toward the CNS; efferent pathways (descending pathways) carry motor impulses away from the CNS to effector organs, such as muscles (smooth and skeletal) or glands.
- The voluntary (somatic) nervous system is composed of nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument; the involuntary (autonomic) nervous system is divided into the sympathetic and parasympathetic branches.
- The brain is a very delicate organ that requires the protection afforded by the skull. Although the skull is primarily a protective structure, excessive forces can cause a fracture to the adult skull and force bone fragments into the vulnerable brain tissue.
- Openings at the base of the skull (foramina) allow cranial nerves and blood vessels to enter and exit the cranial cavity. These openings also weaken the area, leaving it susceptible to fracture.
- The cranial meninges consist of three layers: the dura mater (a two-layer structure adherent to the internal surface of the cranium), the arachnoid mater (a thin layer loosely enclosing the brain), and the pia mater (a vascular membrane that adheres to the surface of the brain and follows its contours).
- The lateral ventricles extend from the frontal lobe to the occipital lobe of the brain. These structures are important when ICP

monitoring, cerebrospinal fluid (CSF) drainage, or placement of a CSF shunt is undertaken.

- Cerebrospinal fluid fills the ventricular system and surrounds the brain and spinal cord in the subarachnoid space. It protects the CNS by acting as a shock absorber in case of minor acceleration and deceleration and by helping to remove waste products from cerebral tissue.
- Any obstruction to the normal flow of CSF may produce high CSF pressure and lead to brain damage.
- The cerebrum consists of two cerebral hemispheres, which are divided into four paired lobes: the frontal, parietal, temporal, and occipital lobes.
- The brainstem acts as a bridge between the cerebral hemispheres and the spinal cord; all motor and sensory fibers travel through this structure. The brainstem consists of three parts: the midbrain, the pons, and the medulla oblongata.
- The cerebellum, which coordinates voluntary movement, consists of three major parts: the cortex, the white matter, and four pairs of deep cerebellar nuclei.
- The reticular formation, which is composed of both motor and sensory tracts, includes centers for BP, respiration, and heart rate function.
- The overall goal of cerebral circulation is to provide enough blood to supply oxygen, glucose, and nutrients so that oxidation of glucose can take place.
- The blood–brain barrier regulates the transport of nutrients, ions, water, drugs, and waste products to and from the brain through the process of selective permeability.
- The spine usually consists of 33 irregular bones (vertebrae) that articulate to form the vertebral column; ligaments and muscles stabilize these skeletal components.
- Flexion of the vertebral column beyond the range of 60% to 70% may damage structural ligaments and allow excess vertebral

movement that could expose the spinal cord to injury.

- The spinal cord transmits nerve impulses between the brain and the rest of the body. The 31 pairs of spinal nerves emerge from each side of the spinal cord and are named for the vertebral region and level from which they arise.
- The sympathetic nervous system is controlled by the brain’s hypothalamus. A SCI at or above the level of T6 may disrupt the flow of sympathetic communication.
- When the sympathetic nerves are stimulated and produce autonomic dysreflexia, the parasympathetic nerves attempt to control the rapidly increasing BP by slowing the heart rate.
- The intracellular transport of protein and organelle materials is essential for all mammalian cells, especially neurons; when it becomes disrupted, disease can result.
- The foundation of neurologic care is a thorough serial assessment, which not only allows the CCTP to track patient trends but also may allow the CCTP to identify which parts of the system are damaged.
- In some cases, the CCTP may assess cranial nerves, motor function, and sensory function; perform reflex testing; and evaluate meningeal irritation if the initial assessment was done quickly or if there is time for these assessments during transport.
- The mental and emotional component of the neurologic examination assesses the patient’s ability to understand and interact with the environment by addressing the level of consciousness; general behavior; and thought processes, including memory, attention and concentration, abstract thought, and judgment.
- Awareness and arousal are the fundamental constituents of consciousness and should be evaluated and documented repeatedly.
- Arousal is assessed initially by the AVPU scale. The Glasgow Coma Scale is then commonly used to document and trend the patient’s level of arousal over time.

- When evaluating the patient’s awareness, the CCTP should assess the patient’s orientation to time, place, and person.
- A variety of neurologic pathologies—including pain, hypoxia, anxiety, and expanding intracranial lesions—may initially manifest themselves through changes in general behavior.
- The Mini-Mental State Examination is a simple, easily applied test of higher cognitive functions that consists of a series of questions testing orientation, registration, attention and calculation, recall, and language.
- Abnormalities of speech can reflect dysfunction in any component or process of communication. For example, aphasia encompasses any loss or impairment of language function as a result of brain damage.
- Certain nerves are more commonly tested in patients who are critically ill or injured: optic (CN II), oculomotor (CN III), trochlear (CN IV), trigeminal (CN V), abducens (CN VI), facial (CN VII), acoustic (CN VIII), glossopharyngeal (CN IX), vagus (CN X), and hypoglossal (CN XII).
- Cranial nerve I, which is responsible for olfaction, should be assessed in patients with head trauma, when pathology at the base of the skull is suspected, and in patients who exhibit an altered mental status.
- Each eye should be evaluated individually to assess the optic nerve. These tests should include evaluation of visual acuity, visual fields, pupillary response, and the fundi.
- The CCTP should closely observe two parameters to assess the oculomotor, trochlear, and abducens nerves: the position of the eyeball and the position of the upper eyelid.
- To test the motor portion of the facial nerve, the CCTP should instruct the patient to wrinkle the forehead, close the eyelids tightly, smile or grimace to show the teeth, and whistle.
- Rotational and caloric stimuli are used to assess the vestibular division of the acoustic nerve. The CCTP performs this evaluation to determine the brainstem function of unconscious patients.

- To test the glossopharyngeal and vagus nerves, the CCTP should direct the patient to open their mouth and say, “Ah,” then should stimulate the gag reflex with the tongue blade.
- To assess the hypoglossal nerve, the CCTP observes the tongue for fasciculations and atrophy, tests for muscle strength by having the patient push the tongue against the inside wall of the cheek, and checks for deviation with tongue protrusion.
- The motor examination focuses on muscle tone and strength, as the CCTP puts the muscles through the normal range of motion.
- As part of the assessment of sensory function, the CCTP should examine and document pain, temperature, and touch.
- The most common pathologic reflexes, all of which indicate pyramidal tract disease, include the plantar response, Babinski sign (the most important), Oppenheim sign, Gordon sign, and Hoffmann sign.
- Signs of meningeal irritation include generalized throbbing headache progressing in severity, progressive photophobia, and nuchal rigidity.
- The presence of the Lhermitte phenomenon, in which forward flexion of the neck produces an electric shock feeling, indicates cervical pathology.
- The centers for control of vital functions are found within the brainstem, so changes in vital signs can signal changes in the patient’s overall neurologic status.
- The CCTP should repeatedly check the following physiologic variables: BP, heart rate and rhythm, respiratory rate, pulse oximetry, end-tidal carbon dioxide, central venous pressure, temperature, and ICP.
- Hypertension is the effect on BP most often seen as a result of neurologic injury, especially in case of increased ICP.
- Alterations in body temperature—hypothermia or hyperthermia—are possible in the presence of neurologic injury, especially if the hypothalamus is damaged.

- Neurologic diagnostics with which the CCTP should be familiar include computed tomography, computed tomography angiography, magnetic resonance imaging, cerebral angiography, transcranial Doppler ultrasonography, electroencephalography, and lumbar puncture.
- Laboratory studies, other than routine blood studies, biopsy, and CSF analysis, are not routinely used in the diagnosis and management of neurologic emergencies.
- Two types of TBI are distinguished: primary (direct) injury, in which traumatic forces cause physical or functional disruption of brain tissue; and secondary (indirect) processes, which occur after the initial injury and lead to brain dysfunction or cellular damage (eg, hypoxia and ischemia).
- Primary brain injury can occur as a result of two mechanisms: contact phenomena injuries (direct trauma to the head) and acceleration-deceleration injuries (sudden changes in velocity).
- Secondary injury involves more delayed mechanisms of brain damage; if left uncorrected, it will adversely affect brain function integrity.
- Cerebral perfusion pressure (CPP) is the primary determinant of blood flow to injured brain tissue when an injury has impaired the ability of the cerebral circulation to autoregulate in response to fluctuations in systemic BP.
- Common injuries to the scalp include abrasions, contusions, lacerations, and avulsions. Treatment usually focuses on controlling bleeding, cleaning and dressing the area, and, in case of avulsions, evaluating for fractures.
- Skull fractures result from a direct, and often high-force, blow to the cranium; they are present in more than 50% of patients with a severe TBI.
- To perform the halo test for leaking CSF, collect escaping fluid from the nose, mouth, or ears onto a gauze pad. The appearance of a target or halo symbol, consisting of a dark red circle surrounded by a lighter yellow one, is considered a positive halo

sign. This sign should be interpreted with caution, as it has poor sensitivity and specificity.

- Raccoon eyes (periorbital ecchymosis) and Battle sign (retroauricular ecchymosis) may not appear until several hours after a head injury.
- Fractures of the bones of the face may indicate possible underlying brain injury.
- Many facial injuries have very grotesque presentations accompanied by copious bleeding and may potentially distract the CCTP from other, more serious injuries.
- Mandible fractures can cause life-threatening airway compromise if the patient is in the supine position.
- Airway control is the first assessment priority for patients with facial injuries. After securing the airway, the CCTP can assess for the presence of facial fractures by grasping the hard palate and rocking it back and forth. The CCTP should also check for malocclusion and dental trauma, test extraocular muscles to rule out orbital fractures, and look for facial elongation and periorbital ecchymosis.
- Injuries to the brain can be either focal (lesions large enough to be observed directly) or diffuse (eg, concussions and diffuse axonal injuries).
- Treatment for patients with cerebral contusions and lacerations is largely supportive. It includes monitoring for—and aggressively treating—evidence of rising ICP resulting from hematoma formation.
- An epidural hematoma is an accumulation of blood between the inner periosteum and the dura mater as the result of an injury. The patient with an EDH may present with a history of a brief period of unconsciousness, followed by a lucid period lasting for minutes to several hours, which ends with a rapid deterioration of consciousness from drowsiness, to lethargy, and to coma as a mass effect and herniation develop.

- Mannitol is an osmotic diuretic that can reduce both the increased ICP resulting from an increase in CSF volume and intraocular pressure. It does not reduce the volume of blood that accumulates in the case of an EDH.
- High-energy impacts may result in a subdural hematoma—bleeding that accumulates between the dura mater and arachnoid mater. These injuries are six times more common than EDHs and have a higher mortality rate.
- Intracerebral hemorrhages often occur in the same areas as cerebral contusions. They produce headaches, deteriorating levels of consciousness, hemiplegia on the contralateral side, and dilated ipsilateral pupils.
- Signs and symptoms of mild TBI include loss of consciousness, loss of memory for events immediately before or after the event that precipitated the injury, altered mental status, and focal neurologic deficits.
- The clinical presentation of diffuse axonal injury includes a sequence of events beginning with immediate unconsciousness, leading to a longer period of confusion and associated posttraumatic amnesia, and followed by a protracted recovery time. Treatment for this condition is supportive.
- In adults, the normal ICP is 5 to 15 mm Hg. Increased ICP may be precipitated by intracranial bleeding, cerebral edema, mass formation, or inability to regulate the production and removal of CSF.
- Many physiologic factors may alter cerebral blood flow (CBF). Increases in CBF resulting from hypoxia or hypercapnia (increased levels of carbon dioxide in blood), for example, will cause an increase in ICP once the normal compensating mechanisms have been exhausted.
- Poor airway and ventilatory control contribute to hypoxia, hypercapnia, and hypotension, and will further damage the already critically ill brain.

- CPP is responsible for the movement of blood through the brain. The homeostatic mechanisms that manage CPP are often lost after head trauma, such that the patient with TBI may have increased cerebral vascular resistance; this phenomenon renders the brain more susceptible to changes in BP.
- CPP should be maintained between 70 and 90 mm Hg—by using fluids and pressors if necessary—to reduce the risk of poor outcomes for patients with increased ICP.
- Increased ICP is a sustained elevation in pressure above 20 mm Hg. The most common causes of increased ICP are cerebral bleeding, tumors, hydrocephalus, and trauma.
- Cushing triad is the combination of progressively increasing SBP (widening pulse pressure), abnormal respirations, and bradycardia.
- Respiratory changes noted with increased ICP include Cheyne-Stokes respirations (with midbrain involvement), sustained hyperventilation (with midbrain and pons involvement), and rapid and shallow respirations followed by ataxic breathing (with upper medulla involvement).
- Increased ICP produces pulmonary edema owing to the increased sympathetic activity resulting from the effects of this increased pressure on the hypothalamus, medulla, or cervical spinal cord.
- The primary goals of ICP monitoring are identification of ICP trends and evaluation of therapeutic interventions to minimize ischemia in the brain-injured patient.
- Contraindications to ICP monitoring include CNS infection, coagulation defects, anticoagulant therapy, scalp infection, severe midline shift resulting in ventricular displacement, and cerebral edema resulting in ventricular collapse.
- Potential complications of ICP monitoring include intracranial infection, intracerebral hemorrhage, air leakage into the ventricle or subarachnoid space, CSF leakage, over-drainage of CSF (leading to ventricular collapse and herniation), occlusion of the

catheter with brain tissue or blood, and inappropriate therapy because of erroneous ICP readings.

- Noninvasive ICP monitoring involves assessment for clinical deterioration in neurologic status, evidenced by signs such as bradycardia, increased BP, and pupillary dilation.
- Intraventricular monitoring is one of the most popular techniques for invasive ICP monitoring. It is also therapeutic, as it provides the ability to drain CSF; the CCTP must monitor any fluid drained for amount, color, and clarity at hourly intervals.
- A subarachnoid screw (bolt) may be used to monitor ICP, although its accuracy is less than that of the more direct ventriculostomy drain.
- Interpretation of the ICP waveform provides the CCTP with real-time information that may provide clues about the patient's impending deterioration and allows for earlier targeted interventions.
- To minimize the risk that an infectious agent will enter the CNS during ICP monitoring, aseptic technique must be used at all times when assembling, manipulating, or accessing the fluid-filled monitoring system.
- To ensure optimal accuracy of ICP readings, proper leveling and zeroing of the ICP monitoring system must be maintained.
- Avoid flexion and hyperextension of the neck and positioning the patient in a Trendelenburg position when conducting ICP monitoring. Simultaneous drainage and pressure monitoring are not recommended.
- Notify the physician immediately if a patient with increased ICP shows signs of decompensation—altered LOC, restlessness, agitation, lethargy, confusion, motor weakness, seizures, alteration in breathing pattern, increases in BP, bradycardia, vomiting, decortication/decerebration, or coma.
- Patients with TBI should be intubated to protect the airway and allow maximal oxygenation. Standard monitoring for all such

patients is required, including oxygen saturation, ECG, mean arterial pressure, and urine output.

- Normocapnia (normal carbon dioxide tension) is vital for maintaining ICP, and neurologic patients' $ETCO_2$ levels should be continuously measured using a capnometer.
- To perform brain tissue oxygen tension monitoring, a commercial probe (capable of measuring temperature and oxygenation) is placed into the brain tissue through a bolt. This type of monitoring is relatively sensitive for monitoring focal disruption of blood flow to particular areas of the brain.
- The best treatment for increased ICP is the removal of the causative lesion (eg, tumor, hydrocephalus, or hematoma). In the field, treatment aims at preventing the secondary events associated with increased ICP, by reducing ICP and providing rapid transport of the patient to a neurologic facility for definitive treatment.
- First-line management of increased ICP consists of general measures aimed at making the patient comfortable (including adequate analgesia), along with effective handling of the ABCs of trauma management.
- Second-line management of increased ICP involves induced cerebral vasoconstriction, which may take the form of hyperventilation, hyperbaric oxygen, or hypothermia. Osmotherapy consisting of mannitol, glycerol, urea, or furosemide may also be implemented.
- Anesthetic agents, including barbiturates, gamma-hydroxybutyrate, and etomidate, and paralytic agents may also be used in patients with increased ICP.
- Hyperventilation aims at keeping the PCO_2 between 30 and 35 mm Hg, so that CBF falls and CBV is reduced, thereby reducing ICP. Prophylactic hyperventilation is not recommended.
- Hyperbaric oxygen and hypothermia are experimental techniques to induce cerebral vasoconstriction and reduce CBV and ICP.

- Brain herniation is a condition in which a portion of the brain is displaced because of increased ICP, resulting in progressive harm to brain tissue that may include life-threatening damage to the brainstem. Transport management includes intubation, mechanical ventilation, administration of an osmotic diuretic (eg, mannitol) and possibly corticosteroids, and rapid transport.
- Acute injuries of the spine are classified according to the associated mechanism, location, and stability of the injury.
- Stable vertebral fractures do not involve the posterior column; therefore, they pose less risk to the spinal cord. Unstable injuries involve the posterior column of the spinal cord and carry a higher risk of complicating SCI and progression of injury without appropriate treatment.
- Flexion injuries result from forward movement of the head, typically as the result of rapid deceleration (eg, in a car crash), or from a direct blow to the occiput. Rotation-flexion injuries, which often result from high acceleration forces, can produce a stable dislocation in the cervical spine. Hyperextension of the head and neck can result in fractures and ligamentous injuries of variable stability.
- Vertical compression injuries typically result from a direct blow to the crown (parietal region) of the skull or rapid deceleration from a fall through the feet, legs, and pelvis. In these injuries, forces transmitted through the vertebral body ultimately shatter the vertebral body and produce a “burst” or compression fracture with or without associated SCI; patients may also develop herniation of disks, subsequent compression of the spinal cord and nerve roots, and fragmentation into the canal.
- Primary SCI—injury that occurs at the moment of impact—can involve either penetrating or blunt trauma. Penetrating trauma typically results in transection of nonregenerative neural elements and complete injuries; blunt trauma may displace ligaments and bone fragments, resulting in compression of points of the spinal cord or an incomplete dislocation of the vertebral body. Spinal

cord concussion, spinal cord contusion, and cord laceration are all types of primary SCI.

- Secondary SCI occurs when multiple factors permit a progression of the primary SCI and result in further deterioration. Exposing neural elements to further hypoxemia, hypoglycemia, and hypothermia can exacerbate these effects.
- The CCTP should minimize the chance of secondary SCI through stabilization (ie, spinal motion restriction and neutral alignment). Minimizing heat loss and maintaining oxygenation and perfusion are other key elements in the care of a patient with a possible SCI.
- The degree of SCI—that is, complete versus incomplete—is best determined 24 hours after the initial injury; the initial dysfunction may be temporary, and there may be some potential for recovery.
- Spinal shock is a temporary local neurologic condition that occurs immediately after spinal trauma and involves reflex arc dysfunction; neurogenic shock results from the temporary loss of autonomic function, which controls cardiovascular function, at the level of injury.
- A patient with SCI should be treated as having a true neurologic emergency, and the CCTP should make every effort to rapidly assess, treat, and transport the patient to the closest appropriate facility while maintaining in-line stabilization of the vertebral column.
- Short-acting, reversible sedatives are recommended for the acute, agitated patient after a correctible cause of the agitation (eg, hypoxia) has been excluded.
- Acute-phase complications of SCI include the potential for aspiration or respiratory arrest, especially in patients with high cervical injuries.
- Autonomic dysreflexia is evidenced by hypertension, headache, blurred vision, anxiety, cool clammy skin, and sweating above the injured site. Treatment consists of identifying and treating the cause (ie, repositioning the patient and checking the bladder and

bowels for irritation or obstructions) and reducing the BP with a beta blocker.

- Stroke occurs when blood flow to the brain is disrupted, resulting in a neurologic deficit persisting for more than 24 hours. When deficits completely resolve within 24 hours, the event is referred to as a transient ischemic attack.
- Types of stroke include ischemic (caused by occlusion of a blood vessel by a thrombus or embolus), thrombotic (caused by accumulation of atherosclerotic plaques inside cerebral blood vessels that block blood flow), embolic (occurring when an embolus lodges in a smaller cerebral vessel), focal ischemic (caused by ongoing reduction of blood flow to already ischemic cells), and global ischemic (caused by severe hypotension or cardiac arrest that produces a transient drop in blood flow to all areas of the brain).
- The hallmark of stroke is the sudden onset of focal neurologic signs that oftentimes occur in combination.
- The CCTP can use abbreviated prehospital tools to identify patients suffering from stroke, such as the Cincinnati Prehospital Stroke Scale and the Los Angeles Prehospital Stroke Screen.
- Once stroke is suspected, the CCTP should determine the time of symptom onset or the last known well time.
- The CCTP should support the stroke patient’s cardiopulmonary function, provide continuous monitoring of neurologic function, and maintain normal blood glucose levels.
- Frequent reassessment of airway and respiratory function is needed to avoid hypoxemia in patients with stroke; supplemental oxygen may be given to hypoxemic patients.
- If a stroke patient’s symptoms do not resolve, a CT scan shows no hemorrhage, and the symptom onset occurred within the last 4.5 hours, fibrinolytic therapy may be used to restore circulation to ischemic brain tissue. Providers must understand the role of tissue plasminogen activator, a thrombolytic agent, for patients who have experienced a stroke.

- Endovascular interventions are now the gold-standard reperfusion therapy for strokes caused by large-vessel occlusion.
- Given the prevalence of stroke and the time-sensitive nature of the most effective interventions, organized and coordinated stroke systems of care can improve patient outcomes.
- Intracerebral hemorrhage is bleeding directly into the cerebral tissue. The most common cause of spontaneous intracerebral hemorrhage is hypertension-induced vessel rupture. Symptoms include local neurologic dysfunction, severe headache, nausea, and vomiting. As the ICP continues to rise, the patient may lose consciousness and require ventilatory support. Intubation may be necessary, and orders may be given to reduce BP to decrease ongoing bleeding.
- The patient with a subarachnoid hemorrhage (typically caused by either an aneurysm or an arteriovenous malformation) characteristically has an abrupt onset of pain, sometimes accompanied by loss of consciousness, nausea, vomiting, focal neurologic deficits, photophobia, and nuchal rigidity. As the ICP increases, the patient may become comatose or die.
- Care for the patient with a subarachnoid hemorrhage includes measures to maintain cardiopulmonary function, manage the airway, provide ventilatory support (if necessary), and limit movement of the patient’s head.
- Guillain-Barré syndrome (GBS) comprises a group of immune-mediated polyneuropathies, all of which share a common constellation of features often provoked by an infection.
- Fever, glucose imbalance, electrolyte imbalances, head injuries, hemorrhagic strokes, and toxins can cause seizure activity.
- Epilepsy is a disorder characterized by recurrent seizures caused by abnormal discharges in the brain cells.
- Care for patients with seizure focuses on the ABCs and administration of an anticonvulsant, if the patient is actively seizing.

- Minimum requirements for monitoring patients with neurologic emergencies during transport are continuous ECG, pulse oximetry, and the intermittent measurement of BP, respiratory rate, and pulse rate.
- Other pieces of equipment that should be available—and working properly—to monitor the patient with neurologic emergency during transport include a cardiac monitor, a ventilator with waveform capnography, infusion pumps, an ICP monitor, and a cerebral function monitor.
- Apart from intracranial hemorrhage, the major early risks to the patient with head injury are hypoxia and hypotension. For this reason, management of the ABCs is always the first priority.
- The biggest challenge when transporting patients by aircraft is dealing with pressure variations and oxygen availability at increasing altitudes. Oxygen content in pressurized cabin air is less than that at normal ground level, so the CCTP must be prepared to administer supplemental oxygen to nonintubated patients.

Vital Vocabulary

afferent pathways Ascending pathways that carry sensory impulses toward the central nervous system.

aneurysm A weakened portion of the wall of an artery where the blood creates a localized dilation or bulge; it can involve the intact wall or be classified as dissecting, in which case the artery wall ruptures and blood pools between the inner and outer artery wall.

anterior cord syndrome Displacement of bony fragments into the anterior portion of the spinal cord, often as the result of flexion injuries or fractures, that disrupts blood flow in the anterior spinal artery.

aphasia Any loss or impairment of language function as a result of brain damage.

arachnoid mater The middle layer of the meninges, which contains blood vessels that give it the appearance of a spider web.

arteriovenous malformation (AVM) A cluster of abnormally formed blood vessels that have a higher rate of bleeding than average vessels.

autonomic dysreflexia A potentially life-threatening complication of spinal cord injury that results from the loss of parasympathetic stimulation. It is characterized by a massive, uninhibited, uncompensated cardiovascular response as the result of some stimulation of the sympathetic nervous system below the level of injury. Also called autonomic hyperreflexia.

axonal transport The movement of organelles and proteins along a nerve cell axon into and out of the cell body.

basal ganglia Masses of nuclei located deep in the cerebral hemispheres that play a major role in fine motor function.

basilar skull fracture A fracture along the base of the skull.

Battle sign Migration of blood to the mastoid region, posterior and slightly inferior to the ear, resulting in discoloration; also called retroauricular ecchymosis.

blood–brain barrier A network of endothelial cells and astrocytes (neuroglia) in the brain that regulates the transport of nutrients, ions, water, drugs, and waste products to and from the brain through the process of selective permeability.

brain herniation Displacement of a portion of the brain from its correct location within the cranial cavity to a different location.

brain tissue compliance The change in brain volume resulting from a change in pressure.

brain tissue oxygen tension ($P_{br}O_2$) A method of monitoring temperature and oxygenation via placement of a commercial probe into the brain tissue through a bolt; it can be done simultaneously with ICP monitoring placement.

Broca area Part of the frontal lobe that is located at the inferior frontal gyrus and that participates in the formulation of words.

Brown-Séquard syndrome Loss of function as a result of penetrating trauma accompanied by hemisection of the spinal cord and complete damage to all spinal tracts on the involved side; it is characterized by loss of motor function and sensation of light touch, proprioception, and vibration on the ipsilateral side and loss of temperature and pain sense on the contralateral side.

caloric test A method for assessing vestibular function that involves the raising and lowering of the temperature in the external auditory canal; also called Bárány test.

cauda equina The collection of individual nerve roots into which the spinal cord separates at the L2 vertebra.

central cord syndrome A syndrome in which cavities form in the central portions of the spinal cord, usually in the cervical area; it may be due to a tumor, a genetic mutation, or trauma. The syndrome presents along with hemorrhage or edema to the central cervical segments.

cerebral angiography A procedure that uses imaging and a contrast material or dye to view and find abnormalities in the blood vessels in the brain.

cerebral aqueduct The narrowest portion of the brain's ventricular system; it provides communication with the fourth ventricle, which lies between the brainstem and the cerebellum.

cerebral blood flow (CBF) The amount of blood flow the brain requires to maintain homeostasis. In a 24-hour period, the brain requires 1,000 L of blood to obtain 71 L of oxygen and 100 g of glucose.

cerebral cortex The outermost layer of the cerebrum.

cerebral function analysis monitor (CFAM) A device that can provide summed, averaged, and analyzed outputs of the general state of brain activity.

cerebral function monitor (CFM) A device that can provide summed and averaged outputs, but not analysis, of the general state of brain activity.

cerebral hemispheres The name for each half of the brain (right or left); each of these areas contains one of the paired lobes (occipital, parietal, temporal, and frontal).

cerebral metabolic rate for oxygen ($CMRO_2$) A measurement used to determine neuronal demand for oxygen. Neurons with high activity rates require greater amounts of oxygen.

cerebral perfusion pressure (CPP) The pressure gradient across the brain; it provides an estimate of perfusion adequacy: CPP = MAP – ICP.

choroid plexus A cluster of nerve roots at the lateral and the third and fourth ventricles of the brain that produce cerebrospinal fluid.

circle of Willis A system of arteries located at the base of the skull that (in most people) is able to compensate for reduced blood flow from any one of the major contributors to cerebral circulation.

comminuted fracture A type of skull fracture in which the skull is splintered or shattered into many pieces.

complete spinal cord injury A complete disruption of all tracts of the spinal cord, with permanent loss of all cord-mediated functions below the level of transaction.

computed tomography (CT) A type of scan that provides a mathematically reconstructed view of multiple cross-sections of the body, including the brain; it should be performed on almost every patient with abnormal neurologic findings.

computed tomography angiography (CTA) A form of imaging that includes the injection of an IV contrast agent into the patient moments before CT scanning and results in improved imaging of arterial structures.

conjugate movement Movement of both eyes together in the same direction.

contact phenomena injuries Injuries that occur as the direct result of trauma to the head, including local effects such as scalp laceration, skull fracture, hematoma, and intracerebral hemorrhage.

contrecoup injury A situation in which an impact occurs on one side of the head, causing the brain to move within the cranial vault and forcibly contact the opposite side of the skull, resulting in damage on that side of the brain; also called transitional injury.

corpus callosum A large tract of transverse fibers that provides a communication link between the two cerebral hemispheres.

cranial nerves (CN) The 12 nerves arising directly from the brain that govern many of the senses and the functions of muscles in the eyes, face, and pharynx.

Cushing triad A cascade of events provoked when intracranial pressure rises to the level of the arterial pressure, vasoconstriction occurs in an effort to shift fluid volumes in the cranium, and the ensuing brain displacement puts pressure on the medulla oblongata by pushing it into the foramen magnum, resulting in disturbances in breathing, heart rate, and blood pressure.

delayed traumatic intracranial hemorrhage (DTICH) Hemorrhage that occurs within the first 3 to 10 days following an injury to the occipital-parietal region via a coup-contrecoup mechanism.

depressed skull fracture A type of skull fracture in which a portion of the skull is depressed; the scalp and dura may or may not be torn.

diaphragma sellae An extension of the dura mater that forms a roof over the sella turcica, which contains the pituitary gland.

diastatic stellate fracture A fracture involving injury to a bone with separation of an epiphysis; it is prevalent in abused children.

diencephalon Portion of the cerebrum consisting of the thalamus, the hypothalamus, the subthalamus, and the epithalamus.

diffuse axonal injury (DAI) A deep-brain injury in which shearing forces damage the integrity of the axon at the node of Ranvier, which consequently alters the axoplasmic flow.

diplopia Double vision.

doll's eye test An oculocephalic reflex test that is performed on the unconscious patient by rapidly rotating the head from side to side and observing the eye movement.

dorsal Toward the back surface of an object; posterior.

dura mater The outer membrane of the meninges.

dural venous sinuses Endothelial-lined spaces between the periosteal and meningeal layers of the dura mater.

dysarthria Difficulty articulating words caused by neurologic impairment affecting the vocal apparatus.

dysconjugate movement Lack of symmetric movement between the two visual axes.

dysphonia Difficulty producing intelligible speech caused by physical impairment at the level of the larynx.

Edinger-Westphal nucleus Part of the midbrain that is responsible for mediating the autonomic reflex centers for pupillary accommodation to light.

efferent pathways Descending pathways that carry motor impulses away from the central nervous system.

electroencephalography (EEG) A procedure that records the electrical activity of the brain by measuring brain waves.

embolic stroke A condition in which a blood clot, known as an embolus, forms in one part of the body and travels through the bloodstream to the brain or neck.

epidural hematoma (EDH) An accumulation of blood between the inner periosteum and the dura mater; also called extradural hematoma.

epithalamus An area of the cerebrum that is located in the dorsal portion of the diencephalon and contains the pineal gland.

extinction A test of sensation discrimination in which the CCTP simultaneously touches opposite, corresponding areas of the patient's body and asks the patient where the touch is felt; it is intended to identify sensory inattention.

extradural space A potential space between the cranial bones and the periosteal layer of the dura that becomes a real space only when blood from torn vessels pushes the periosteum from the cranium and accumulates; also called epidural space.

falx cerebelli A fold of dura mater that forms the division between the two lateral lobes of the cerebellum.

falx cerebri A double fold of dura mater that divides the cerebrum into right and left hemispheres by descending vertically into the longitudinal fissure that extends from the frontal lobe to the occipital lobe.

Fick principle A method of indirectly determining cardiac output, in which the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood.

fissures Deep grooves between adjacent gyri of the brain.

flat fracture The least common type of depressed skull fracture, in which the depressed segment does not have any connection with the cranial vault.

flexion-extension injury A spinal cord injury that results from forward movement of the head, typically as the result of rapid deceleration, or from a direct blow to the occiput.

focal ischemic stroke A condition in which an area of marginally perfused tissue, the ischemic penumbra, surrounds a core of ischemic cells; the cells will eventually die without medical intervention.

foramen magnum The opening at the base of the skull through which the bundle of nerve fibers constituting the spinal cord exits.

foramen of Luschka An opening at the lateral portion of the base of the fourth ventricle that leads to the subarachnoid space and is essential for the normal flow of cerebrospinal fluid; part of the brain’s ventricular system.

foramen of Magendie An opening at the medial portion of the base of the fourth ventricle that leads to the subarachnoid space and is essential for the normal flow of cerebrospinal fluid; part of the brain’s ventricular system.

foramen of Monro An opening in the skull that connects the two lateral ventricles with the third ventricle, a central cavity; part of the brain’s ventricular system.

Foster Kennedy syndrome A tumor or abscess at the base of the frontal lobe that affects the olfactory nerve.

frontal lobe The largest of the four lobes of the brain; it lies underneath the frontal bone of the skull and is separated posteriorly from the parietal lobe by the central fissure and inferiorly from the temporal lobe by the lateral fissure. The frontal lobe is responsible for a variety of cognitive and motor functions.

fundus The optic disk, macula, and blood vessels on the back wall of the internal eyeball.

global ischemic stroke A condition in which severe hypotension or cardiac arrest produces a transient drop in blood flow to all areas of the brain.

gyri Convolutions on the surface of the cerebrum that functionally increase the cortical surface area.

halo test A test for leaking CSF that is accomplished by collecting and assessing fluid that drains from the nose, mouth, or ears; a dark red circle of fluid surrounded by a lighter yellow one is a positive halo sign.

hemorrhagic conversion The condition in which, after the brain tissue surrounding the stroke has died, renewed blood flow to the region (eg, triggered by medication) is no longer held in place by the tissue, resulting in hemorrhage.

hemorrhagic stroke A condition in which bleeding in the intraparenchymal space or subarachnoid space causes direct or secondary damage to cerebral tissue.

hypothalamus An area of the cerebrum located below the thalamus that forms the floor and the anterior walls of the third ventricle. It is responsible for the maintenance of homeostasis and the implementation of behavioral patterns.

incomplete spinal cord injury A disruption of the tracts of the spinal cord in which the patient retains some degree of cord-mediated function.

internal capsule A massive bundle of efferent and afferent fibers connecting the various subdivisions of the brain and spinal cord.

intervertebral foramen A space in the middle of the vertebra that allows the exit of a peripheral nerve root and spinal vein as well as the entrance of a spinal artery on both sides at each vertebral junction.

intracerebral hemorrhage Direct bleeding into the brain parenchyma.

intracranial pressure (ICP) The pressure exerted by brain tissue, intracranial vascular contents, and cerebrospinal fluid in the closed, nondistensible cranial cavity.

intracranial temperature (ICT) Core brain temperature or homeostatic mean gradient temperature of 101.1°F (38.4°C).

involuntary (autonomic) nervous system The sympathetic and parasympathetic branches of the nervous system, whose fibers connect the structures of the CNS with smooth muscle, cardiac muscle, and glands.

ischemic stroke A condition in which an artery to the brain becomes blocked by a thrombus, embolus, trauma, or vasospasm (often due to drugs).

jugular venous bulb oximetry A technique in which a sampling catheter is placed in the internal jugular vein and directed upward so that its tip rests in the jugular venous bulb at the base of the brain; samples of blood can then be drawn to measure mixed venous oxygen saturation (SvO_2).

Le Fort criteria A categorization of facial fractures involving the maxilla in which the fractures are differentiated based on the location of fracture lines and the extent of mobility of facial structures on physical examination.

Lhermitte phenomenon A condition in which forward flexion of the neck produces an electric shock feeling, usually running down the back.

limbic lobe Part of the temporal lobe that is the seat of emotions and instincts; also called the rhinencephalon.

linear skull fracture A type of skull fracture characterized by a single fracture line.

linear stellate fracture A fracture with multiple linear fractures radiating from the site of impact.

lumbar puncture A procedure in which a needle is inserted first into the lumbar portion of the back and then into the subarachnoid space to obtain spinal fluid for testing or to administer drugs.

magnetic resonance imaging (MRI) A noninvasive procedure that obtains computer images of internal organs and the body through the use of radiofrequency pulses and a magnetic field.

mean arterial pressure (MAP) The mean between the systolic and diastolic blood pressures (SBP and DBP): $MAP = DBP + (SBP – DBP)$.

medulla oblongata The lowermost portion of the brainstem.

midbrain A small area of the brainstem extending between the diencephalon, the pons, and the third ventricle.

mild TBI Concussion; a traumatically induced physiologic disruption of brain function that occurs without structural damage.

Mini-Mental State Examination A simple, easily applied test of higher cognitive functions.

mixed venous oxygen saturation (SvO_2) A measurement of the oxygenation of blood leaving the brain, which is normally in the range of 50% to 75%.

Monro-Kellie doctrine A theory developed by two Scottish anatomists, who stated that the central nervous system is enclosed in a rigid compartment along with cerebrospinal fluid, whose total volume tends to remain constant; an increase in any component—whether brain, blood, or CSF—will cause an increase in pressure and decrease the volume of one of the other elements.

motor area Part of the frontal lobe containing pyramidal cells that control voluntary motor function on the opposite side of the body.

neurocranium The part of the skull that encloses and protects the brain.

neurogenic shock A temporary loss of autonomic function, which controls cardiovascular function, at the level of a spinal cord injury; it is characterized by marked hemodynamic and systemic effects.

normal-pressure hydrocephalus (NPH) An accumulation of CSF that causes the ventricles of the brain to enlarge. The enlarged ventricles of a patient with this condition may not cause increased intracranial pressure.

nuchal rigidity Marked resistance to head movement in any direction that is suggestive of meningeal irritation.

occipital lobe The lobe of the brain that occupies the most posterior portion of the cerebrum; it is the primary receptive area for vision, specifically the interpretation of visual stimuli.

optic disk The most prominent structure visible in the eye; it represents the termination of the optic nerve.

oxygen extraction fraction (OEF) The fraction of oxygen extracted from the blood as it passes by to maintain normal oxygen delivery and, consequently, normal brain functions.

parietal lobe The lobe of the brain situated directly posterior to the frontal lobe on the other side of the central fissure; it is largely responsible for sensory functions.

pia mater The innermost layer of the meninges, which rests directly on the brain or spinal cord.

ping-pong ball fracture A pediatric greenstick fracture of the skull.

plexus A cluster of nerve roots that permits peripheral nerve roots to function as a group.

pons Part of the brainstem located between the midbrain and the medulla oblongata; it relays information to and from the brain and spinal cord along fiber tracts.

posterior cord syndrome Extension injury that produces dysfunction of the dorsal columns, presenting as decreased sensation to light touch, proprioception, and vibration.

prefrontal area Part of the frontal lobe that provides control of thought, concentration, depth and ability to think abstractly, memory, and autonomic nervous system response, concomitant to emotional change.

premotor area Part of the frontal lobe that is adjacent to the motor area and helps coordinate certain movements.

primary spinal cord injury Spinal cord injury that occurs at the moment of impact.

proprioception The ability to perceive the position and movement of one’s own body or limbs.

ptosis Drooping of an eyelid.

raccoon eyes Orbital fractures and hemorrhage into the surrounding tissue; also called periorbital ecchymosis.

reticular activating system (RAS) A diffuse system that extends from the lower brainstem to the cerebral cortex; it controls the sleep-wakefulness cycle, consciousness, the ability to direct attention to a specific task, and the perception of sensory input that might alter behavior.

reticular formation (RF) A set of neurons that extends from the upper level of the spinal cord; through the medulla, pons, and midbrain; and into the thalamus and cerebral cortex. It has both excitatory and some inhibitory capabilities, and can enhance, suppress, or modify impulse transmission.

rotation-flexion injury A spinal cord injury to C1-C2, the only area of the spine that allows for significant rotation, in which rotation with abrupt flexion produces a stable dislocation in the cervical spine. In the thoracolumbar spine, rotation-flexion forces typically cause fracture rather than dislocation.

rotational force An injury-producing force in which the head moves around its center of gravity.

rubrospinal tract Part of the midbrain that controls the tone of flexor muscles.

secondary spinal cord injury Spinal cord injury in which multiple factors permit a progression of the primary spinal cord injury; the ensuing cascade of inflammatory responses may result in further deterioration.

spinal shock The temporary local neurologic condition that occurs immediately after spinal trauma; it is characterized by swelling and edema of the spinal cord and can lead to a physiologic transection, mechanically disrupting all nerve conduction distal to the injury.

stereognosis The ability to sense an object’s form through touch.

stroke A disruption of blood flow to the brain that results in a neurologic deficit persisting for more than 24 hours.

subarachnoid hemorrhage (SAH) Bleeding between the arachnoid mater and the dura mater.

subdural hematoma (SDH) Bleeding that accumulates between the dura mater and the arachnoid mater.

subdural space The dura-arachnoid junction; this potential space may develop into a real one if a blow to the head causes a loss of blood into the cranial meninges.

subthalamus An area of the cerebrum that is located below the thalamus and is closely related to the basal ganglia in function.

sulci Grooves between adjacent gyri.

tectospinal tract Part of the midbrain that controls reflex motor movements in response to visual and auditory stimuli.

temporal lobe The lobe of the brain that is located beneath the temporal bone of the cranium; its primary functions relate to hearing, speech, behavior, and memory.

tentorium cerebelli A fold of the dura mater that separates the occipital lobes of the cerebrum from the cerebellum and brainstem, thereby dividing the brain into upper and lower compartments.

thalamus The largest portion of the diencephalons. It acts as a relay station for motor and sensory activity; basic neuronal activity; and memory, thought, emotion, and complex behavior.

thrombotic stroke A condition that occurs when the blood supply to part of the brain is disrupted by a thrombus, or blood clot.

transcranial Doppler (TCD) ultrasonography A noninvasive method of assessing the state of intracranial perfusion and monitoring of cerebral blood flow velocity through thinner areas of the skull. It is used in patients following rupture of an intracranial aneurysm to assess for vasospasm, to identify intracranial lesions following a stroke, and to detect cerebral blood flow changes associated with increased ICP.

transient ischemic attack (TIA) A temporary disruption in the blood flow to the brain that lasts less than 24 hours and has temporary side effects.

translational force An injury-producing force in which the head's center of gravity moves along a linear path.

true fracture The most common type of closed skull fracture, in which the depressed segment has contact with the cranial vault.

two-point discrimination A test of sensation discrimination that measures the shortest distance at which the sides of two separate points of a compass or calipers can be distinguished from each other.

uncal herniation The most common type of brain herniation, in which a portion of the temporal lobe is displaced, resulting in compression of cranial nerve III, the midbrain, and the posterior cerebral artery.

uncus The medially curved anterior part of the hippocampal gyrus.

ventral Toward the abdomen; anterior.

vertebral body The anterior weight-bearing structure within the spine.

vertical compression Forces transmitted through vertebral bodies and directed either inferiorly through the skull or superiorly through the pelvis or feet (eg, from a direct blow to the parietal region of the skull or rapid deceleration from a fall through the feet, legs, and pelvis).

viscerocranium The bones making up the facial skeleton.

voluntary (somatic) nervous system The nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument.

Wernicke area Part of the temporal lobe that is responsible for comprehension of both written and spoken words.

CHAPTER 13

Burns

Jeremy Lacocque, DO

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the layers and functions of the skin (pp 642–643).
2. List the major causes of burn injury (p 644).
3. Describe the anatomy of a burn (pp 644–645).
4. Explain the process of the body's systemic inflammatory response to a burn (p 645).
5. Explain the factors that determine the classification of burn injury, including body surface area and burn depth (p 646).
6. Describe the classifications of burn injuries, including superficial burns, partial-thickness burns, deep partial-thickness burns, full-thickness burns, subdermal burns, as well as major burns, moderate burns, and minor burns (p 645).
7. Identify the methods for calculating the total body surface area burned, including the rule of nines and the Lund-Browder chart (p 648).
8. Describe criteria for referral of patients to a burn center (pp 648–649).
9. Discuss assessment considerations for a burn patient's airway, breathing, and circulation (pp 649–652).
10. List situations in which the critical care transport professional (CCTP) should suspect an inhalation injury (pp 652–654).
11. Discuss the roles of edema and compartment syndrome in relation to a burn injury (pp 659–660).
12. Describe the process of stopping a burn, including irrigation, cooling, decontamination, and special considerations (p 652).
13. Discuss management of a burn patient's airway, breathing, and circulation (pp 652–655).
14. Explain various fluid resuscitation formulas, including the American Burn Association's *Advanced Life Support Course* 2018 guidelines and the Parkland formula (pp 654–655).
15. Describe the parameters for adjusting the fluid infusion rate (pp 654–655).
16. Describe how to manage and dress burn wounds (pp 655–656).
17. Discuss pain management of burn patients (p 657).

18. Discuss special situations relating to burn injuries, such as hypothermia, the need for gastric decompression, renal failure, and rhabdomyolysis (pp 657–658).
19. Discuss management of specific burns, including ocular burns, facial burns, ear burns, circumferential burns, hand and foot burns, genitalia burns, pediatric burns, electrical burns, and chemical burns (pp 658–665).
20. List the types of burns that may suggest potential child maltreatment (p 662).
21. Discuss toxic epidermal necrolysis and Stevens-Johnson syndrome, including the similarity between their management and the management of patients with severe burns (pp 665–666).

Introduction

According to the American Burn Association (ABA), approximately 1 million burn injuries occur each year in the United States, resulting in approximately 486,000 emergency department (ED) visits, 40,000 hospitalizations, and 3,275 fire- and burn-related deaths. The highest incidence of burns occurs (1) in the first few years of life and (2) between 20 and 29 years of age. Serious burns occur most often in males (71%), with the majority of these burns resulting from flame. Of patients who seek medical attention for burns, 85% utilize emergency medical services (EMS), suggesting that while burns account for a very small percentage of EMS responses, the majority of critically burned patients will be seen by field EMS providers.

Approximately 30,000 patients are admitted to specialized burn centers or burn units each year, with the majority of these patients requiring transfer to receive this specialized care. Burn centers are large facilities that admit more than 100 patients per year, whereas burn units are specialized facilities that have fewer than 100 admissions per year. In 2020, there were 132 burn centers in the United States, with an average of 200 admissions per facility per year. The average size of a burn injury that requires admission is 14% of total body surface area (TBSA). Approximately 4% of patients admitted to burn centers do not survive.

The principles of acute burn management taught in paramedic and nursing courses are the foundation for caring for these patients. However, the first 24 hours of care after a burn are crucial. Factors such as unrecognized injuries from associated trauma, complications of treatment such as fluid overload, and comorbidities such as diabetes or chronic obstructive pulmonary disease (COPD) may complicate care, and the condition of a patient who initially appears to be stable may worsen acutely. Given that complications of burns may develop during the transport of the patient to a burn facility, the critical care transport professional (CCTP) must ensure that adequate resuscitation and stabilization continue during transport. Knowledge of common complications and the timing of treatments are important for safe and effective transport to specialty care centers.

Anatomy and Function of the Skin

The skin is the largest organ of the body, and its function is as vital to survival as that of any other organ. A basic understanding of skin anatomy and function will help the CCTP understand burn treatment and potential complications. The skin is a multilayered structure, in which the epidermis and the dermis represent the principal components **FIGURE 13-1**. The epidermis and dermis are divided into additional levels that have specific functions.

Description

The Epidermis

The epidermis generally consists of four layers (thin skin), except on the palms, fingertips, and soles of the feet, where it has five layers (thick skin). Each layer has a different composition. The layers of the epidermis, in order from deep to superficial, are the stratum basale, which is attached to the underlying dermis; the stratum spinosum (prickly layer); the stratum granulosum; the stratum lucidum (thick skin only); and most superficially, the stratum corneum.

The epidermis contains pigment cells known as melanocytes, immune cells known as Langerhans cells, and a network of capillaries found in its lower layers. While the epidermis does contain some receptors for touch, the nerve receptors that transmit pain are actually located in the deeper dermis layer. The outer layer of the epidermis, the stratum corneum, provides a barrier to prevent water loss from deeper structures, and is constantly losing cells as a result of sloughing. It takes approximately 2 to 3 weeks for a cell to make its way from the lowest layer of the epidermis to become a keratinocyte and eventually be sloughed off. Because the epidermis serves as the first barrier to injury and infection, it is injured more often than other layers and is constantly repairing itself.

The Dermis

The **dermis** lies beneath the epidermis and is a dynamic layer of thick connective tissue that, like the epidermis, is in a state of constant turnover. The cell types found here are fibroblasts, macrophages, white blood cells, and the occasional mast cell. The dermis is also richly supplied with nerve fibers, blood vessels, and lymphatic vessels. The major portions of the hair follicles and the oil and sweat glands are also found in the dermis.

The dermis is divided into two layers: the papillary and reticular layers. The thin, superficial papillary layer is composed of connective tissue, which forms the anchoring system for the epidermis. It is also heavily invested with blood vessels and has the highest blood flow of all the dermal layers, which is important for temperature regulation. These blood vessels are found in nipple-like projections called dermal papillae that indent the overlying epidermis. The dermal papillae also house free nerve endings (pain receptors) and touch receptors.

The reticular layer accounts for 80% of the dermis. Its dense, irregular connective tissue is responsible for the durability of the skin and anchors skin appendages. Interlocking collagen fibers run through the reticular layer in various planes, usually parallel to the skin.

Regions between these bundles form **lines of cleavage** in the skin **FIGURE 13-2**. These lines run longitudinally in the skin of the head and limbs and in a circular pattern around the neck and trunk. Understanding these anatomic features is important when considering where to make incisions for escharotomies and fasciotomies, because incisions made parallel to these lines cause the skin to gape less and heal more readily than incisions made across cleavage lines.

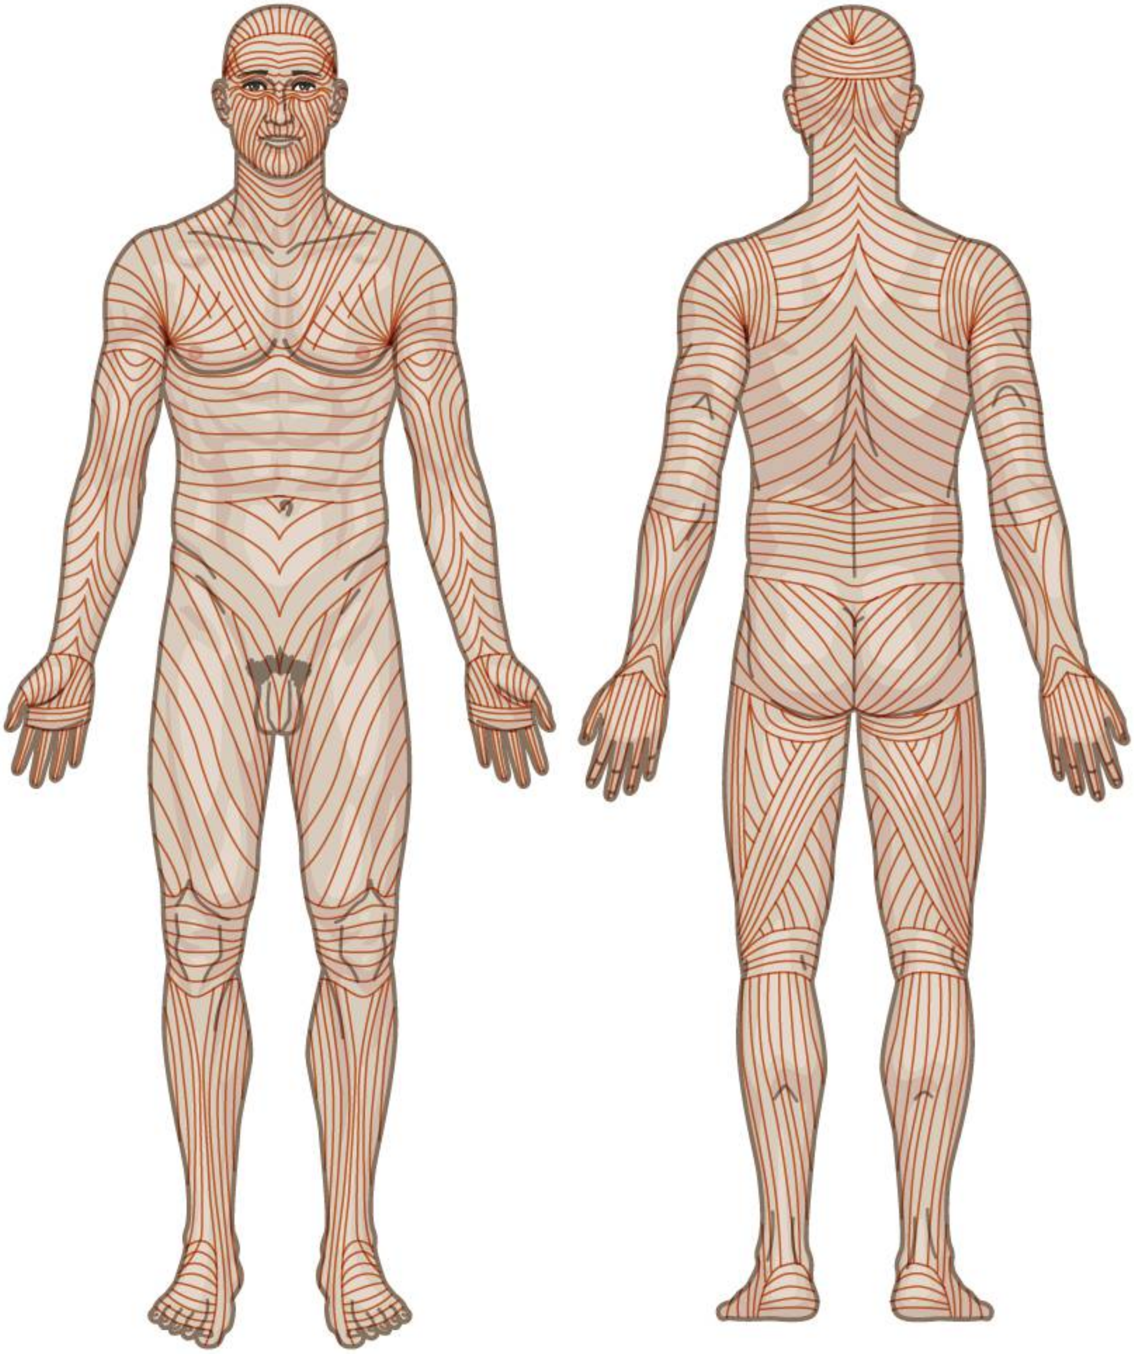

FIGURE 13-2 The skin’s lines of cleavage. Incisions made parallel to these lines heal more easily than incisions made perpendicular to these lines.

© Jones & Bartlett Learning.

Description

Collagen fibers give the skin both strength and resiliency against injury. Collagen also helps maintain hydration of the skin—an important concern after a major burn. Another concern is the adverse effect that burns have on the elastin fibers, which provide the stretch–recoil properties of the skin.

Deep in the dermis lies the hypodermis, which is composed of subcutaneous fat, connective tissue, sweat glands, muscle, and bone.

The Process of Healing

Proteins that are produced in the dermis, such as collagen and fibronectin, support the continuously reproducing epidermis and play a major role in wound healing. Multiple cell types are contained in the dermis when it is undamaged, but many more are attracted to the area when it is wounded.

Fibroblasts produce proteins such as collagen, fibronectin, and other substances responsible for skin repair. Macrophages are normally present in the tissues, but increase in number after an injury. They release chemical messages that help attract other cells to the wound site and orchestrate organized healing. Endothelial cells build capillaries and restore blood flow after an injury. Collectively, the fibroblasts, macrophages, platelets, and endothelial cells play a vital role in the wound healing process of the skin. Unfortunately, the inflammatory response that is responsible for burn healing may also create multiple complications, as discussed later in this chapter.

Functions of the Skin

The skin has multiple functions, including protective, immunologic, thermoregulation, maintenance of fluid and electrolyte balance, metabolic, neurosensory, and social functions. All of these capabilities are essential for the body's normal functioning, and any or all of them can be impaired in a burn injury. The degree of dysfunction is determined by the extent and depth of the burn.

The epidermis serves as a barrier that protects the body from desiccation (drying out) and maintains fluid balance by preventing excess loss of fluid through evaporation. An intact epidermis is also relatively effective at preventing the entry of toxins and bacteria. Burn injuries result in damage to the epidermis, increasing the risk of fluid loss through evaporation from the skin and allowing the direct entry of bacteria through the compromised skin.

The neurosensory function of skin is also important for social and interactive functioning. This ability to sense temperature and touch may be impaired or absent in the burned patient.

The skin maintains a complex mechanism by which wound healing and skin repair occur. In severe burns, this intrinsic healing mechanism may be irreparably damaged, necessitating skin grafting for wound closure.

Because of its elastic properties, the dermis protects the body from minor trauma and assists in the regulation of fluid balance through its influence on blood flow. This regulation of blood flow is also a major mechanism by which the body regulates temperature. Because the skin is responsible for fluid and temperature regulation, large burns (greater than 20% of TBSA in adults and 15% to 18% of TBSA in children) can cause massive fluid loss, shock, and hypothermia, even on a hot day.

Damaged skin is also more susceptible to pressure injuries such as pressure sores. Finally, the skin is a sensory organ, so burns can cause intense pain and jeopardize the patient’s ability to recognize touch.

Physiology of Burns

Causes of Burns

Burns can occur from a variety of mechanisms: flame/flash, scald (eg, water or grease), contact, electrical, chemical inhalation, radiation, or any thermal source. In addition, some medical conditions such as **Stevens-Johnson syndrome** and **toxic epidermal necrolysis (TEN) syndrome** cause burnlike injuries and are treated similarly to thermal burns. Regardless of the mechanism of injury, all burns share common features—the destruction of skin and an impairment of its ability to perform its functions.

The agent, temperature, and duration of exposure determine the size and depth of a burn. A **thermal burn** created by exposure to a heat source having a temperature greater than 113°F (45°C) can cause cell damage and denaturing of cellular proteins; the latter phenomenon eventually causes cell death. At temperatures of 120°F (48.9°C), an exposure for 5 minutes is enough to cause a full-thickness burn, and at temperatures greater than 159°F (70.6°C), it takes only 1 second to create a full-thickness burn in a healthy adult. These temperatures and times may vary when children and older adults are affected.

Anatomy of a Burn

The most heavily damaged area of a burn is referred to as the **zone of coagulation**; it is the area of skin that came into direct contact with the source of heat. In the zone of coagulation, the tissue is destroyed and clotting results in impairment of circulation to the surrounding tissues.

The surrounding areas of injury are referred to as the zone of stasis and the zone of erythema. The **zone of stasis** is characterized by injured tissue and stagnant blood flow resulting in ischemic tissues. It may appear red and **hyperemic** (filled with an increased amount of blood) initially, but within 24 hours after injury, blood flow will cease in the area and ischemia results. By the third day after the injury, the zone of stasis becomes white because of avascular necrosis.

The area surrounding the zone of stasis is the outermost area known as the **zone of erythema** owing to its increased blood flow. This area has sustained minimal damage and will recover from the injury.

Systemic Inflammatory Response of the Burned Patient

Although inflammation is necessary for the normal healing process to occur, excessive inflammation results in undesirable effects on other tissues and organs. Burns of greater than 20% of TBSA trigger a systemic inflammatory response, in which cells in the body migrate to the areas of injury to effect repairs. A blood-rich environment is necessary for these cells to function properly.

In larger areas of injury, the vascular endothelium becomes “leaky,” allowing the “repairing” cells to make their way from the vasculature into the wound. When this process occurs at noninjured sites in the body, undesirable results may occur, including the following:

- Proteins may leak into subcutaneous tissues at uninjured sites, or the pressure at which proteins and fluids are exuded into the lungs may be lowered, making pulmonary edema more likely.
- The mediators can suppress the immune system.
- The leaky endothelial cells of the intestinal vasculature may allow bacteria normally found in the bowel to flow into the bloodstream (a process known as translocation), causing sepsis, even in the absence of a burn wound infection.
- Cardiac output may be impaired. Although the mechanism is unclear, myocardial contractility is suppressed after a significant burn injury.

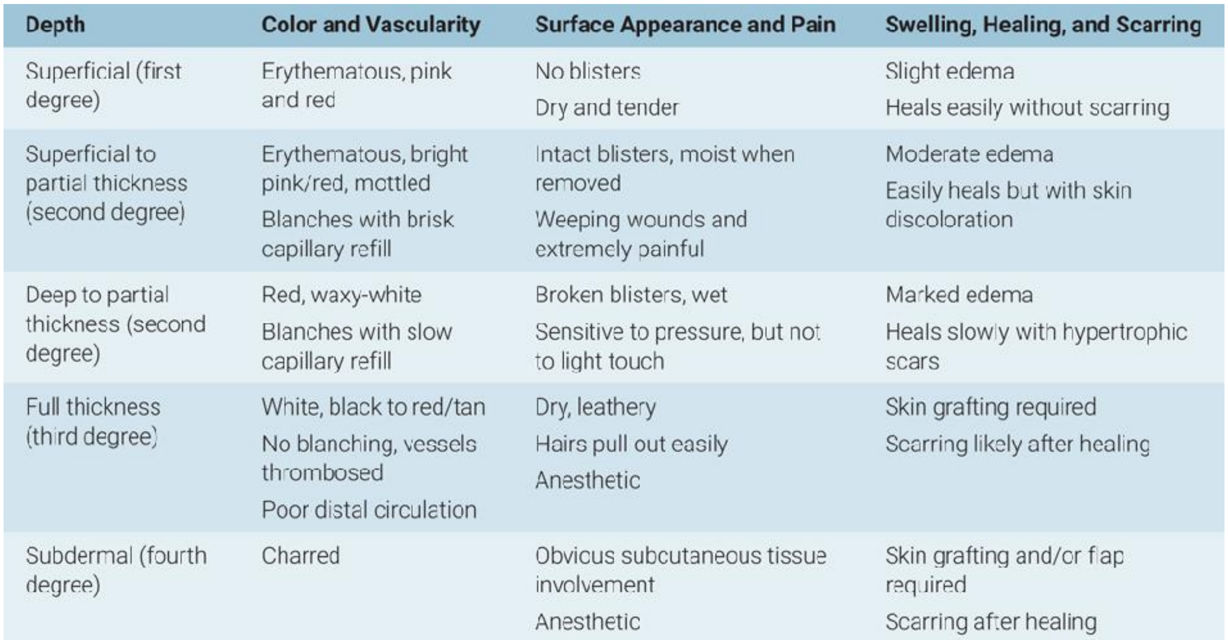
Regardless of the cause, the inflammatory response from a burn injury, although necessary to promote burn healing, may result in untoward effects.

Classification of Burn Injuries

The severity of a burn depends on (1) the extent, depth, and location of the burn injury; (2) the age of the patient; (3) the etiologic agents involved; (4) the presence of inhalation injury; and (5) any coexisting injuries or preexisting illnesses.

Two classification systems for the depth of burns exist. The system describing first- through fourth-degree burns is widely known and used, but is less predictive of the need for surgical intervention than the simple partial- or full-thickness descriptions **TABLE 13-1**. Both systems are discussed here.

TABLE 13-1 Classification of Burns



Depth	Color and Vascularity	Surface Appearance and Pain	Swelling, Healing, and Scarring
Superficial (first degree)	Erythematous, pink and red	No blisters Dry and tender	Slight edema Heals easily without scarring
Superficial to partial thickness (second degree)	Erythematous, bright pink/red, mottled Blanches with brisk capillary refill	Intact blisters, moist when removed Weeping wounds and extremely painful	Moderate edema Easily heals but with skin discoloration
Deep to partial thickness (second degree)	Red, waxy-white Blanches with slow capillary refill	Broken blisters, wet Sensitive to pressure, but not to light touch	Marked edema Heals slowly with hypertrophic scars
Full thickness (third degree)	White, black to red/tan No blanching, vessels thrombosed Poor distal circulation	Dry, leathery Hairs pull out easily Anesthetic	Skin grafting required Scarring likely after healing
Subdermal (fourth degree)	Charred	Obvious subcutaneous tissue involvement Anesthetic	Skin grafting and/or flap required Scarring after healing

Description

Burn Extent and Depth

A **superficial burn**, or first-degree burn, involves only the epidermis and is usually the result of ultraviolet light exposure (sunburn), very minor scald injury, or flash burn. The skin is hyperemic but not blistered with such a burn, and healing occurs without scarring in approximately 7 days.

A **partial-thickness burn**, or second-degree burn, is classified as superficial or deep. In a **superficial partial-thickness burn** (superficial second-degree burn), the epidermis and part of the dermis are involved, but the deeper layers of the dermis are spared, including the sweat glands, sebaceous glands, and hair follicles. These burns are typically caused by hot liquids or minimal contact with flame. Blisters form, and the injured skin is red and painful to touch. These burns do not typically require skin grafting unless they are extensive and occur on areas of the body with thin skin such as the face, hands, genitals, and feet. Superficial partial-thickness burns will heal in 14 to 21 days, and the extent of scarring depends on the extent of the burn. A **deep partial-thickness burn** (deep second-degree burn) is most often the result of steam, oil, or flames, and involves the deeper layers of the dermis. These burns may be difficult to distinguish from full-thickness burns. The skin is blistered but not charred and is painful to touch. Healing takes 21 days or more and may require surgical grafts. Scarring may be moderate and depends on the extent and location of the burn.

A **full-thickness burn**, or third-degree burn, involves the entire thickness of the dermis down to the subcutaneous fat. All epidermal and dermal structures, including nerve endings in the burned area, are destroyed, resulting in a pale, painless, leathery charred area of skin. Full-thickness burns will not heal spontaneously, and surgical skin grafting is necessary. These burns result in significant scarring.

A **subdermal burn**, or fourth-degree burn, involves the deep structures of muscle and bone, larger blood vessels, and nerves. These injuries are severe and life threatening. Like full-thickness burns, they will not heal spontaneously and require surgical intervention.

Superficial, partial-thickness, full-thickness, and subdermal burns are shown in **FIGURE 13-3**.

Description

Burn Size

As stated previously, the depth of the burn is only one factor determining its severity; the size of the burn also informs this determination. Numerous methods are available to estimate the body surface area (BSA) involved in a burn. Regardless of the method used, accuracy improves with experience in applying that method.

The **rule of nines** is the most commonly used formula. It is based on the fact that large regions of the adult body can be divided into areas that represent roughly 9% of the total body surface area (TBSA), or multiples of 9% **FIGURE 13-4**. For infants and children, an amended rule is used that adjusts the rule of nines to account for the relatively large head and small lower extremities.

Description

Special Populations

Fetal mortality is closely linked to maternal mortality when considering burn patients. Generally speaking, a pregnant patient with burns greater than 60% TBSA has a high rate of fetal mortality.

For patients with scattered irregular burns or small burns, the patient’s hand may be used to estimate the burn area. In children and adults, the patient’s hand represents 1% of the patient’s TBSA.

Studies have shown that the **Lund-Browder chart** **FIGURE 13-5** is actually more accurate than the rule of nines for calculating the BSA burned. Consequently, it is the preferred method for estimating burn size in most burn centers. However, this chart is difficult to memorize, so the rule of nines remains the most commonly used method in the prehospital environment.

Description

Burn Severity

The ABA classifies burns into three categories: major, moderate, and minor.

Major Burn Injury

Major burn injuries include the following:

- Burns involving 25% or more of TBSA in adults
- Burns involving 20% or more of TBSA in children younger than 10 years and adults older than 40 years
- Full-thickness burns involving 10% or more of TBSA
- All burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment
- High-voltage electrical burns
- Burns complicated by inhalation injury or major trauma
- Burns sustained by high-risk or debilitated patients

Moderate Burn Injury

Moderate burn injuries include the following (note that this list excludes high-voltage injuries):

- Burns of 15% to 25% of TBSA in adults with less than 10% full-thickness injury
- Burns involving 10% to 20% of TBSA in children younger than 10 years and adults older than 40 years with less than 10% full-thickness injury
- Full-thickness burns involving 10% of TBSA or less in any patient younger than 50 years that do not present a threat to functional or cosmetic impairment of the eyes, ears, face, hands, feet, or perineum

Minor Burn Injury

Minor burn injuries include the following:

- Partial-thickness burns involving less than 15% of TBSA in adults

- Burns involving 10% of TBSA in children younger than 20 years and adults older than 50 years
- Full-thickness burns involving 2% or less of TBSA that do not present a serious threat of functional or cosmetic risk to the eyes, ears, face, hands, feet, or perineum

Criteria for Referral to a Burn Center

According to the ABA, patients may be transferred to a burn center or burn unit when they meet the following criteria:

- Partial-thickness burns greater than 10% of TBSA.
- Burns that involve the face, hands, feet, genitalia, perineum, or major joints.
- Third-degree burns in any age group.
- Electrical burns, including lightning injury.
- Chemical burns.
- Inhalation injury.
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality.
- Any patients with burns and concomitant trauma (eg, fractures) for whom the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be stabilized initially in a trauma center before being transferred to a burn center. Physician judgment will be necessary in such situations, and transfer decisions should be made in concert with the regional medical control plan and triage protocols.
- Burned children in hospitals without qualified personnel or equipment for the care of children.
- Burn injury in patients who will require special social, emotional, or rehabilitative interventions.

Patients who meet these criteria or have a major burn injury should be transferred to a specialized burn center to ensure appropriate acute care, rehabilitation, and long-term care. Patients who meet the criteria for moderate burn injury should be hospitalized and consideration given to transferring care to a specialized burn center. Patients with minor burn injuries can usually be managed as outpatients.

Assessment

The CCTP should assess burn patients much as they would any other patient. Nevertheless, particular complications and findings associated with burns must be detected and the appropriate corrective actions taken to ensure the optimal outcome for the patient **FIGURE 13-6**.

Description

A complete initial assessment and focused history and physical exam should be performed on patients with burns, always using caution whenever a cervical spine injury is suspected. Keep in mind that explosions may produce cervical spine injuries that may not be as obvious as the visible multiple burns. The CCTP should not rely on the history and examinations conducted by others because their level of training may not be equivalent to that of the CCTP. In addition, the patient's condition may have changed since the last physical exam.

As always during interfacility transfers, the CCTP should perform an initial evaluation of the patient for life-threatening conditions and then obtain a history from the patient and/or family members and a report from the nursing staff. To avoid an excessive delay in initiating the transfer, the CCTP should review the chart for the most relevant information. The CCTP can then fill in the remaining details by asking the patient, staff, or family. A focused history and physical exam of the patient should be performed to assess for complications that need corrective action and to document the patient's condition.

Airway

The CCTP should pay special attention to the airway of the burned patient, particularly if the patient was burned as the result of a confined-space fire. Inhaling heated gases from combustion damages the respiratory tract. Inhaled gases, particles, and other debris may damage the respiratory epithelium, resulting in increased mucus production, impairment of mucociliary function, and eventual cell death. Inflammatory changes in the airway occur *within 2 hours of burn injury*. Bacteria colonize the damaged airway and infection is present microscopically within 72 hours. The extent of the inflammatory response is directly proportional to the amount of smoke inhaled and the length of exposure.

The CCTP should inspect the patient's airway and face for any evidence of inhalation injury and, if present, consider performing rapid sequence intubation (RSI) if the transport time will be prolonged or the patient's condition shows any deterioration. Preemptive airway control is necessary because of the worsening edema that occurs after fluid resuscitation, which may potentially cause airway obstruction and necessitate placement of a surgical airway. If the CCTP observes stridor, progressive hoarseness, any change in the patient's voice, wheezing that does not respond to bronchodilators, or significant burns inside the mouth, the patient should be intubated *immediately using RSI*, with instruments for performing a surgical airway also being readily accessible.

Indications for early intubation include the following conditions:

- Extensive facial burns
- Stridor or progressive hoarseness
- Significant changes in voice
- Burns inside the mouth

- Burn extent of more than 40% to 50% of TBSA
- Difficulty swallowing
- Signs of airway obstruction
- Use of accessory muscles
- Respiratory fatigue
- Poor oxygenation or poor ventilation
- Inability to handle secretions (need for frequent nasotracheal suctioning)
- Significant edema or risk for significant edema
- Mental status inadequate for airway protection

Singed nasal hairs alone are *not* an indication for intubation.

The CCTP should reevaluate the patient's airway frequently to assess for potential compromise due to edema. In addition, the airway should be secured in patients with an altered mental status or a Glasgow Coma Scale score of 8 or less after a major burn or any injury. If the patient is to be intubated for an elevated carboxyhemoglobin level, water should be used to fill the endotracheal tube cuff in preparation for hyperbaric therapy. However, it is often difficult for the CCTP to predict which patients will need hyperbaric oxygen, and an air-filled cuff can always be changed to water prior to initiating hyperbaric treatment.

If RSI is not within the scope of practice for CCTPs in your jurisdiction, note that attempted intubation in the setting of an inhalation injury is likely to result in worsened edema and potentially a failed airway. In this situation, the CCTP must perform a risk-benefit assessment of airway management without RSI. Consider delaying the transfer of the patient until someone skilled in airway management and capable of RSI can manage the airway.

Breathing

During the initial assessment, the CCTP should assess the patient's breathing rate and depth along with the breath sounds (also known as lung sounds). Even though noncardiogenic pulmonary edema may develop as a result of inhalation injury or fluid overload from aggressive fluid replacement, needed fluids should never be withheld. Start appropriate oxygen therapy immediately in the patient with major burns. Although COPD often raises concerns regarding oxygen therapy, high-flow oxygen should never be withheld from a hypoxic patient, and the CCTP should be prepared to assist with ventilation if needed.

Examination of the patient’s chest should include a search for full-thickness circumferential burns, which may significantly impair ventilation by limiting expansion of the chest. A field escharotomy, a procedure in which an incision is made through the edematous burned skin to restore mobility to the chest or circulation to an extremity, is rarely, if ever, needed. Although it takes time for tissues to desiccate (dry out) and a constrictive **eschar** (the leathery covering of a burn injury) to develop, the CCTP will encounter burn patients at varying times after injury and an escharotomy may sometimes be necessary. For example, the CCTP may need to perform chest wall escharotomies in extreme cases with extended transport times. Emergent chest wall escharotomy may be performed (if the CCTP’s scope of practice allows) to facilitate adequate movement of the chest wall.

If available, the CCTP should review the arterial blood gas levels as part of breathing assessment, paying particular attention to the oxygenation and carboxyhemoglobin levels. Treat wheezing with bronchodilators, as is standard practice. Another therapy to consider is delivery of humidified oxygen for inhalation injuries (in the absence of wheezing) using a nebulizer with normal saline only and no bronchodilators.

Burn patients may have experienced significant trauma from explosions or motor vehicle crashes (MVCs) resulting in fires. In such situations, it is easy to overlook conditions such as a pneumothorax or hemothorax while treating the obvious burn. Repeated patient examinations should be aimed at identifying these conditions.

Patients with carbon monoxide poisoning may present with symptoms of hypoxia, but without cyanosis. The classical teaching is that patients present with cherry red skin, although this condition may not be identified until postmortem. The CCTP should be aware of the limitations of pulse oximetry in the patient with carbon monoxide poisoning; it may not provide an accurate depiction of the patient's oxygenation status. Carbon monoxide poisoning is covered in Chapter 21, *Toxicologic Emergencies*.

Cyanide poisoning should be considered if the assessment of the burn patient reveals intense air hunger, metabolic acidosis, or sudden cardiovascular collapse and the patient has been the victim of a confined-space fire. Begin appropriate therapy such as hydroxocobalamin.

Circulation

Burn patients may have impaired cardiac output. This decreased cardiac output may stem from a variety of causes, including high levels of circulating inflammatory mediators, carbon monoxide poisoning, or cyanide poisoning. Assessment of the burned patient should include an evaluation of cardiac output, capillary refill, jugular vein distention, breath sounds, pulse rate, and blood pressure. Burn patients who have been victims of other trauma such as MVCs or explosions may have myocardial contusions, cardiac tamponade, or abdominal or solid-organ injuries.

Assessment of the patient's circulation should include evaluation of the extremities and digits for circumferential burns that have impaired circulation. Edema in the arms and legs may also impair circulation. Circumferential deep partial-thickness burns cause impairment of circulation because of their tough, leathery nature. Impaired circulation may result in an absence of pulses, delayed capillary refill, or mottling and discoloration of the extremity. Early identification of circulatory impairment in the extremities is crucial to preventing tissue necrosis and amputation. The CCTP should perform escharotomy on patients with circumferential burns and a lack of distal circulation if the local scope of practice allows.

In the arms and legs, edema may develop deep in compartments created by the tough nonelastic fascia surrounding and separating the muscles. This edema can compress the blood vessels and nerves, which impairs blood flow and sensation and results in **compartment syndrome**. The symptoms of compartment syndrome are collectively known as the five Ps: pain, pallor, paralysis, paresthesias, and pulselessness. The affected extremities may also be cold (poikilothermia, sometimes called the sixth P). Providers should be mindful that many of these signs are late findings in compartment syndrome. Pain, considered the hallmark of this condition, is an early sign. It is typically out of proportion to the injury or physical findings and may occur on passive stretching of the compartment. Nevertheless, compartment syndrome may be difficult to detect on this basis in burn patients, because burns are expected to be painful. To treat compartment syndrome, patients undergo **fasciotomy**, a surgical incision of the tough and fibrous fasciae that separate the compartments to relieve the pressure. Fasciotomies are typically not performed by prehospital providers and should be carried out only by properly trained personnel.

The assessment of a patient’s circulation should also include determining the adequacy of fluid resuscitation. Fluid resuscitation in burn patients should be guided by formulas such as the ABA and Parkland formulas (discussed later in the chapter); however, in patients with significant comorbid conditions such as congestive heart failure or renal failure, the assessment of the patient’s fluid status may play a greater role in guiding fluid replacement. Pulse rate, oxygen saturation, and breath sounds must all be considered in determining the patient’s fluid balance. In patients with adequate renal function, the CCTP should monitor urine output closely to ensure an output of at least 50 mL/h (0.5 to 1.0 per kilogram of body weight per hour) for the adult. Pulse rate is not a good indicator of the adequacy of fluid resuscitation, as it may remain elevated because of pain and the release of catecholamines associated with burns. If **myoglobinuria** (an accumulation of myoglobin in the renal tubules) develops, give additional fluids to reach a urine output of at least 100 mL/h. Myoglobinuria should be suspected if the urine becomes dark, brown, or bloody.

Signs and Symptoms

Compartment Syndrome

- The five Ps: pain, pallor, paralysis, paresthesias, and pulselessness
- Possibly cold-affected extremities (poikilothermia)

Transport Management

Compartment Syndrome

- Keep the involved extremity elevated.
- Monitor pulses, sensation, and motor function.
- Do not place anything on the extremity that is compressive, such as splints or bandages.
- Monitor for increased pain (pain out of proportion is the hallmark of this syndrome).
- Provide supportive care (ie, maintain body temperature, analgesics, IV fluids, and appropriate oxygen).

Signs and Symptoms

Myoglobinuria

- Dark, brown, or bloody urine

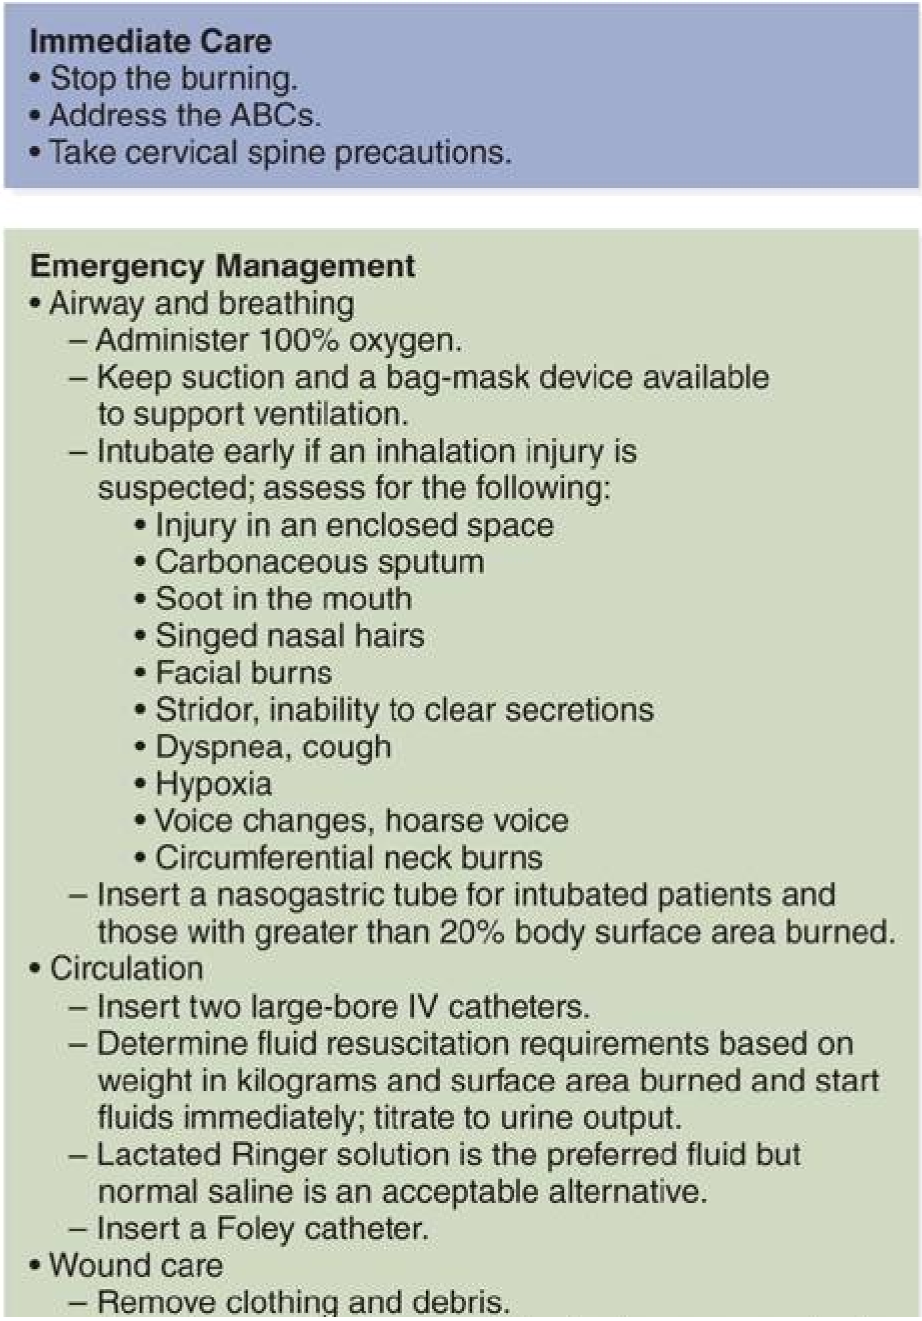
Transport Management

Myoglobinuria

- Administer additional fluids so that urine output is at least 100 mL/h.

Management

The CCTP's management of burns includes many different areas of focus. **FIGURE 13-7** shows an algorithm for the management of a burn patient.

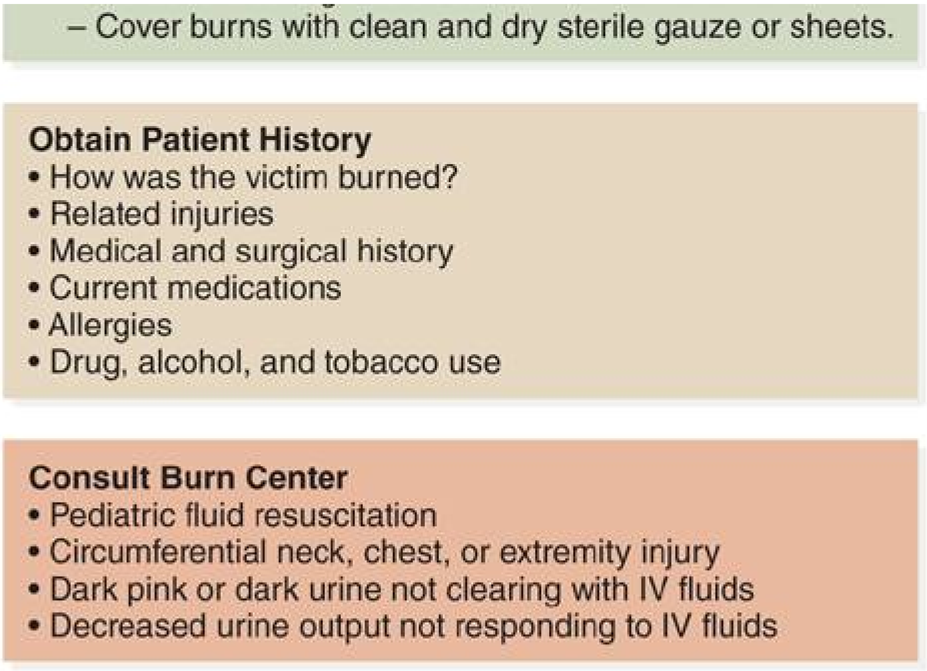


Immediate Care

- Stop the burning.
- Address the ABCs.
- Take cervical spine precautions.

Emergency Management

- Airway and breathing
  - Administer 100% oxygen.
  - Keep suction and a bag-mask device available to support ventilation.
  - Intubate early if an inhalation injury is suspected; assess for the following:
    - Injury in an enclosed space
    - Carbonaceous sputum
    - Soot in the mouth
    - Singed nasal hairs
    - Facial burns
    - Stridor, inability to clear secretions
    - Dyspnea, cough
    - Hypoxia
    - Voice changes, hoarse voice
    - Circumferential neck burns
  - Insert a nasogastric tube for intubated patients and those with greater than 20% body surface area burned.
- Circulation
  - Insert two large-bore IV catheters.
  - Determine fluid resuscitation requirements based on weight in kilograms and surface area burned and start fluids immediately; titrate to urine output.
  - Lactated Ringer solution is the preferred fluid but normal saline is an acceptable alternative.
  - Insert a Foley catheter.
- Wound care
  - Remove clothing and debris.



– Cover burns with clean and dry sterile gauze or sheets.

Obtain Patient History
- How was the victim burned?
- Related injuries
- Medical and surgical history
- Current medications
- Allergies
- Drug, alcohol, and tobacco use

Consult Burn Center
- Pediatric fluid resuscitation
- Circumferential neck, chest, or extremity injury
- Dark pink or dark urine not clearing with IV fluids
- Decreased urine output not responding to IV fluids

FIGURE 13-7 Algorithm for the management of a burn injury.

Abbreviations: ABC, airway, breathing, and circulation; IV, intravenous

Description

Stopping the Burn

Removing the patient from the source of the burn is an obvious first step. Cooling with irrigation to stop the burning process is appropriate but should last for no longer than 3 to 5 minutes. Studies of burn patients treated by EMS show a tendency toward overcooling, such that 42% of patients arrive at the hospital in a hypothermic state. Irrigation of a thermal burn older than 30 minutes provides little to no benefit. Copious irrigation is indicated for chemical burns but may also be beneficial if molten metals, synthetic materials, or tar adhere to the skin. Irrigation dissipates heat, so it should be continued until the burning has stopped and the material is cool **FIGURE 13-8**. In addition, cold inhibits lactate production and acidosis, thereby promoting catecholamine function and cardiovascular homeostasis in the wound.

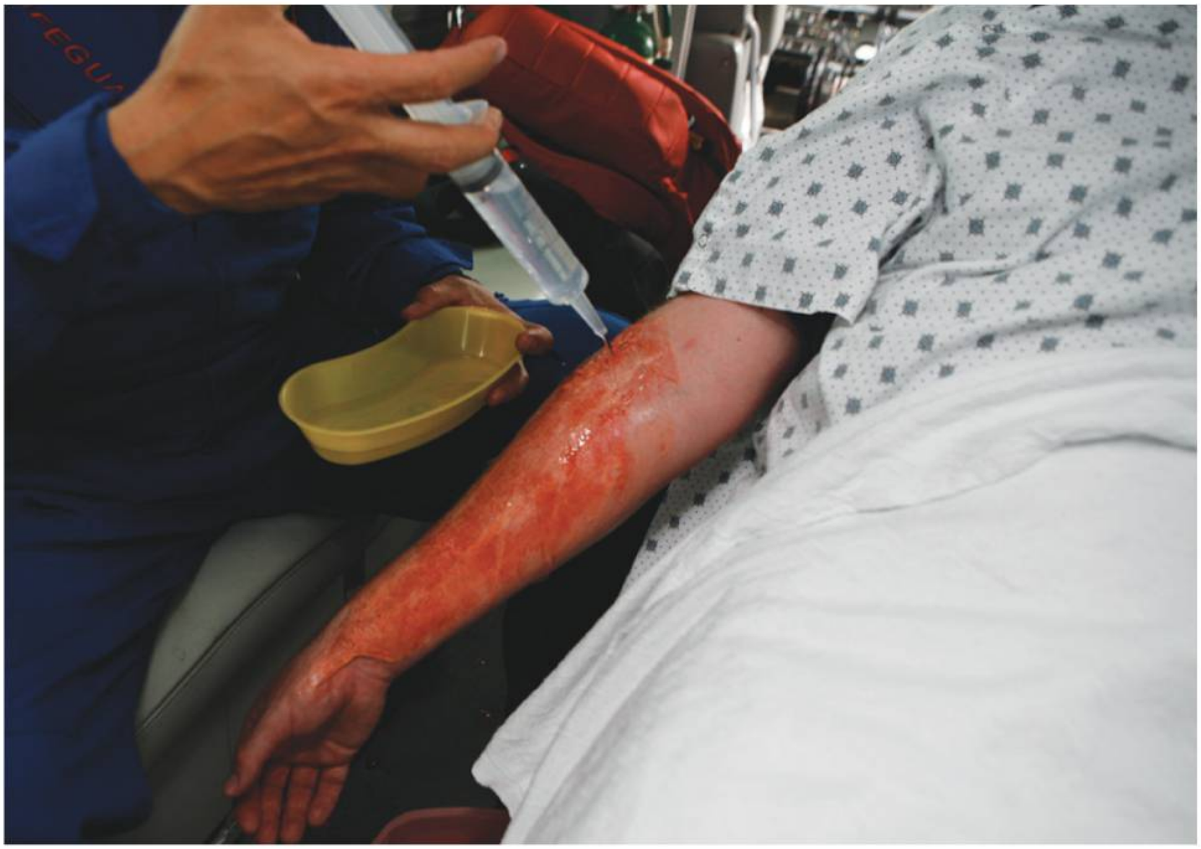

FIGURE 13-8 Management of burn injuries includes irrigation.

© Jones & Bartlett Learning.

All of the patient's clothing and jewelry should be removed because they may trap chemicals. Wet clothing may contribute to heat loss and cause hypothermia. After cooling or decontamination, keep the patient warm and place the patient in clean, dry linens prior to transport.

Airway and Breathing

Managing the burn patient's airway is a difficult challenge. Inhalation injury, cervical spine injury, circumferential chest burns, and poisoning from noxious fumes are all challenging scenarios. The CCTP must assess the patient for the possibility of inhalation injury and manage the airway with endotracheal intubation if stridor, progressive hoarseness, or any other evidence of airway compromise is present. Because inhalation injuries result in airway edema, the CCTP should anticipate a difficult airway and be prepared to perform a surgical airway intervention should endotracheal intubation fail. For patients who require endotracheal intubation, RSI should be performed per local protocol.

If the patient becomes apneic, develops significant respiratory depression, or experiences a drop in oxygen saturation or significantly elevated end-tidal carbon dioxide (ETCO_2) level at any point, the CCTP has no choice except to ventilate the patient (slowly). If the patient is hemodynamically unstable, the CCTP must judge whether sedation is appropriate or whether the risk of profound hypotension is too great to sedate the patient. Many RSI protocols incorporate drugs such as ketamine that increase, rather than lower, blood pressure.

Although succinylcholine is the drug of choice in RSI, it is contraindicated in patients with burn injuries greater than 72 hours old and in patients with known rhabdomyolysis secondary to their burn injuries because it may cause an extremely dangerous rise in potassium level. In these situations, a nondepolarizing agent such as vecuronium or rocuronium should be used instead. Because of the extended time of paralysis when these agents are administered, the CCTP should also carefully weigh the risk of being unable to intubate the patient against the benefits of intubation. Most often the benefits of intubation outweigh the risks associated with paralytic-assisted intubation with a nondepolarizing agent. The CCTP should also consider sedation-only assisted intubation (with a medication such as etomidate) or awake intubation as an alternative in a patient in whom the administration of succinylcholine is contraindicated.

Airway management in the burn patient can be difficult, if not impossible. Not only can airway edema make intubation difficult, but it can also preclude the introduction of airway devices selected for use with failed intubation. Most of these devices rely on the ability to ventilate the patient through an intact glottic opening, which may not be present in the burn patient with inhalation injury. For all these reasons, it is imperative that the CCTP be prepared to surgically manage the airway if orotracheal intubation fails.

Carbon monoxide poisoning, asphyxiation, and cyanide poisoning are major concerns in burn patients; indeed, most early fatalities are a result of carbon monoxide poisoning. Poisoning may be suspected from historical information such as report of a burn injury in an enclosed space. An elevated carboxyhemoglobin level may be diagnosed via an arterial or venous blood gas determination or by using an oximeter capable of measuring carboxyhemoglobin (Spco). Be mindful that conventional pulse oximetry cannot distinguish between carboxyhemoglobin and oxyhemoglobin, leading to significant inaccuracies in estimating oxygen saturation in the setting of elevated carboxyhemoglobin levels. Chapter 21, *Toxicologic Emergencies*, covers the treatment of carbon monoxide poisoning and cyanide poisoning.

Cyanide can be produced from the burning of any substance that contains carbon and nitrogen. Good supportive care in the absence of an antidote can save many cyanide poisoning victims. The treatment for cyanide poisoning is described in detail in Chapter 21, *Toxicologic Emergencies.*

If any of these conditions is suspected, the CCTP should treat the patient with 100% oxygen via nonrebreathing mask. In most burn patients, oxygen, preferably humidified, should be administered immediately.

Signs and Symptoms

Inhalation Injury

- Facial burns
- Stridor or progressive hoarseness
- Carbon deposits and acute inflammatory changes in the oropharynx
- Carbonaceous (black) sputum
- History of impaired mentation and/or confinement in a burning environment
- Explosion with burns to head and torso
- Circumferential neck burns
- Carboxyhemoglobin level greater than 10% if the patient is involved in a confined-space fire
- Soot around the nose and mouth

- Increased mucus production
- Impairment of mucociliary function

Transport Management

Inhalation Injury

- Consider performing early endotracheal intubation using RSI, especially if the transport time is prolonged; if the patient has stridor, progressive hoarseness, or any change in their voice; or for any deterioration in the patient's condition.
- Be prepared to perform surgical intervention should intubation fail.
- Consider administering humidified oxygen (in the absence of wheezing) using a nebulizer with normal saline only and no bronchodilators.

Circulation

In the past, the essentials of circulatory management included early, aggressive, sustained fluid management. This practice is no longer recommended. Judicious fluid management can avoid many of the complications resulting from hypervolemia, primarily those related to hemodilution and hypervolemia. Burns can result in large intravascular fluid losses as a result of the loss of the body's protection against desiccation and evaporation. In addition, circulating inflammatory mediators cause fluid from capillaries to leak into the interstitial space (ie, neither in the vasculature nor in the cell). The inflammatory process at the site of injury results in plasma "weeping" into the burned area. The larger the surface area involved, the greater the fluid loss.

Deep second-degree or larger burns can cause hypotension, so fluid resuscitation should begin within 60 minutes following such an injury. If possible, obtain IV access through unburned skin; however, access through burned skin is acceptable if necessary. Given the delays associated with obtaining access and the lack of early benefit from this intervention, the ABA no longer recommends the administration of prehospital fluids for burn patients whose transport times are less than 60 minutes.

Numerous formulas have been developed to determine the appropriate fluid resuscitation for the first 24 hours after a burn. The most commonly used is the ABA's *Advanced Life Support Course* 2018 guidelines, which recommend resuscitation during the first 24 hours following burn injury with lactated Ringer solution of 2 mL/kg per percentage of TBSA (partial- and full-thickness burns) for adults and 3 mL/kg for children age 14 years or younger and who weigh less than 88 pounds (40 kg). Half of the fluid should be administered over the first 8 hours, 25% should be given over the second 8 hours, and the remaining 25% should be infused over the third 8-hour period.

Urine output is used to monitor fluid status, with goals of 0.5 mL/kg/h output in adults, 1 mL/kg/h output in children weighing less than 88 pounds (40 kg), and 1 to 2 mL/kg/h in neonates. Lactated Ringer solution infusion rates should be increased or decreased by one-third if the urine output declines or increases by more than one-third of these target outputs for more than 2 consecutive hours. The urine output should also serve to guide the subsequent fluid replacement rates beyond the initial 24 hours after injury. If the patient's urine is dark brown or red, indicating it contains hemochromogens, titrate the fluids to maintain a urine output of 1.0 to 2.0 mL/kg/h in adults and 2 mL/kg/h in children, until the pigments have cleared and the urine is straw colored.

CONTROVERSIES

As mentioned previously, the ABA no longer recommends IV fluids in the prehospital environment if transport times are less than 60 minutes. When arrival time at an ED is expected to exceed 60 minutes from the time of burn injury, administer lactated Ringer solution at 500 mL/h for patients age 14 years and older, 250 mL/h for patients ages 6 to 13 years, and 125 mL/h for children age 5 years or younger.

Traditionally, the most commonly used fluid resuscitation method relied on the **Parkland formula**, which recommends resuscitation with lactated Ringer solution (normal saline is an acceptable substitute) of 4 mL/kg per percentage of BSA burned; half of this amount should be given over the first 8 hours (from the time of injury), one-fourth of the total amount should be given over the second 8 hours, and one-fourth of the total amount should be given over the third 8 hours. All calculations are determined from the time of the injury, so fluid boluses may be necessary to correct deficits in fluid resuscitation because of either a delay in presentation or under-resuscitation. It may also be necessary to administer fluids more aggressively if the patient is in shock and has unstable vital signs. The goal for all fluid replacement is to maintain a urine output of 0.5 to 1.0 mL/kg/h.

The formulas used to calculate a burn patient's fluid requirements should serve only as a guide. Monitoring the patient's overall perfusion status, mental status, urine output, and breath sounds is essential. If the patient is too aggressively hydrated, pulmonary or cerebral edema may result. If the patient is not adequately resuscitated, inadequate perfusion of the kidneys or mesentery may worsen organ system damage.

Burn centers often want to participate in the calculation of fluid requirements for children. Ideally, the CCTP should know the preference of the receiving facility or contact it prior to transport to discuss fluid resuscitation strategies. When assuming responsibility for a patient, the CCTP should check all fluids and infusion rates to confirm that they are appropriate, inventory the fluids given already, and reconcile urine output since injury. It is a good idea for the CCTP to empty the indwelling urinary catheter bag when assuming care of any patient to allow for accurate measurement of urine output during transport **FIGURE 13-9**.

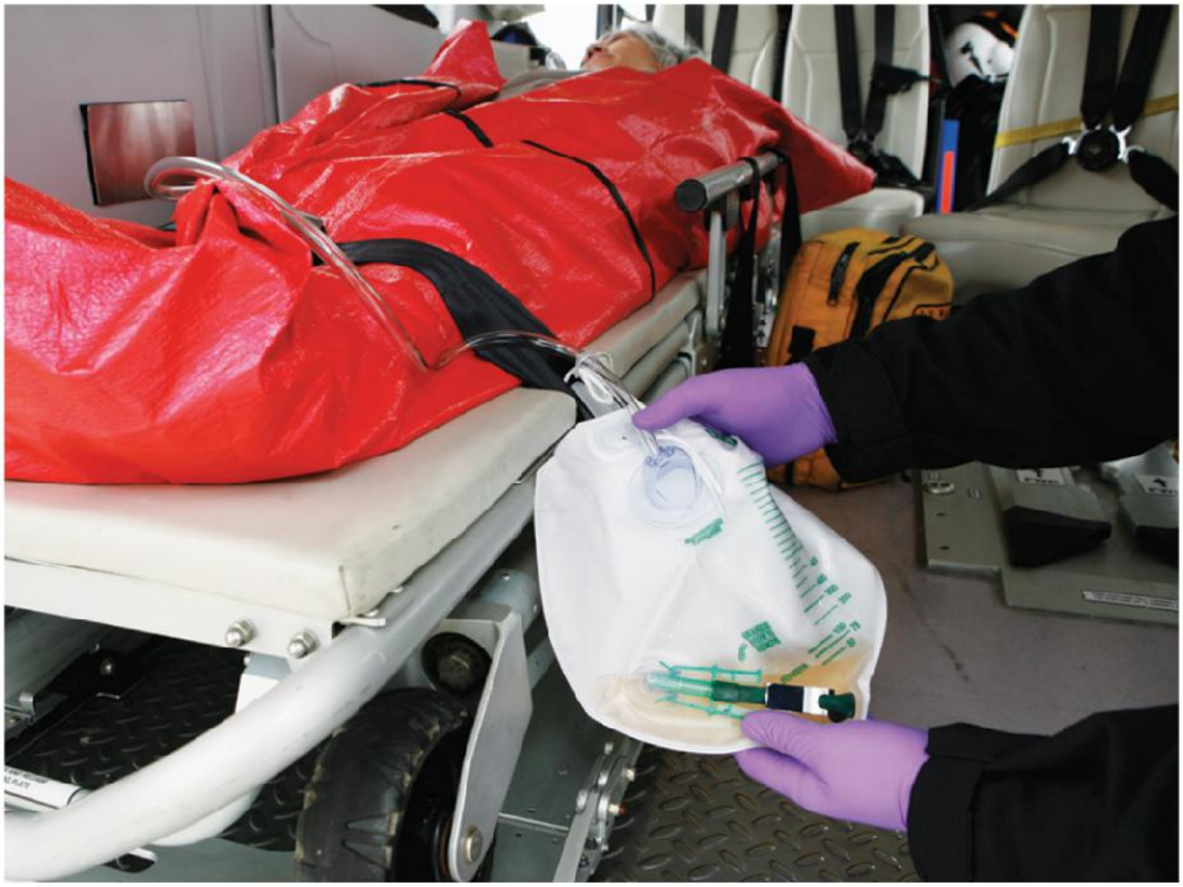

FIGURE 13-9 Empty the indwelling urinary catheter bag when you assume care of any patient to allow for accurate measurement of urine output during transport.

© Jones & Bartlett Learning.

Transport Management

Burn Wounds

- Dry and dress wounds with dry, clean dressings.
- Use bulky dressings to pad pressure points and sensitive areas.
- Do not use ointments or creams. However, if wounds are already dressed with ointments or creams, leave them in place.
- Examine all wounds to confirm that the BSA and the fluid resuscitation calculation are accurate.

Wound Management and Dressings

Wound management is critical, especially when burn injury compromises the skin's ability to act as a barrier to infection and a regulator of the body's temperature. Proper dressings help reduce infection, decrease pain, and prevent heat loss. After cooling, irrigating, and decontaminating, the wounds should be dried and dressed with *dry*, clean dressings **FIGURE 13-10**. A common mistake when caring for burn patients is using wet dressings, which contribute to heat loss and are ineffective barriers to infection. Bulky dressings may be used to pad pressure points and sensitive areas. No ointments or creams are necessary, but if wounds are already dressed with ointments or creams, they may be left in place. All wounds should be examined to confirm that the BSA and the fluid resuscitation calculation are accurate.

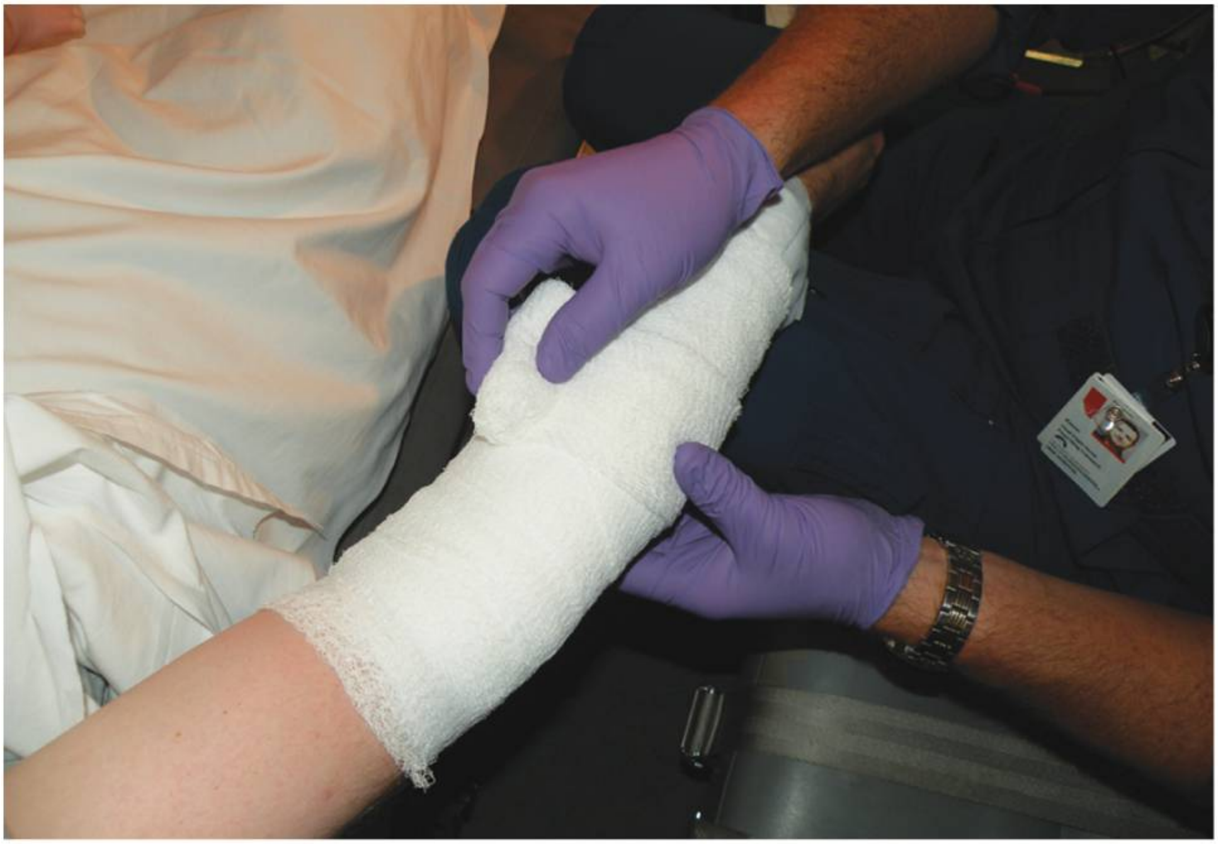

FIGURE 13-10 Dress wounds with dry, clean dressings. Do not use wet dressings.

© Jones & Bartlett Learning.

Wounds must generally be debrided to remove dead skin, which can serve as a source for infection and prevent healthy tissue from repairing the burned area. Wound debridement consists of removing any dead or nonviable tissue from the wound. The debridement of most wounds will be performed at the receiving burn unit. As a general rule, the CCTP should not perform this intervention except in the setting of chemical exposure and blisters formed by chemical agents.

The treatment of blisters is somewhat controversial. On the one hand, exposing a broken blister can result in local wound infection; on the other hand, fluid confined by necrotic skin can result in a closed-space infection. As a general rule, blisters are left intact unless they are caused by a chemical burn. Blisters from chemical burns should be broken during decontamination because they may trap the causative agent and worsen the extent of injury.

Patients with tar and asphalt burns can present a challenge to providers. When tar that is heated to form a liquid comes in contact with skin, heat transfer occurs, causing a burn injury. Asphalt cements become a liquid at lower temperatures (275°F to 300°F [135°C to 148.9°C]) compared with tar, which requires a higher temperature to remain in a liquid state (450°F to 500°F [232.2°C to 260°C]). Therefore, more serious burns occur with tar than with asphalt. As tar and asphalt cool, they solidify and adhere to hair; there is little direct bonding between these substances and skin. The tar or asphalt should be bathed with water until hardened and cool. After the material is cooled, the patient may be transported to the burn center.

If an attempt to remove the tar or asphalt is made prior to transfer to the burn unit, several ointments and solvents may assist in this process. Tar must be removed because it will serve as an occlusive dressing and cause infection. Naphthalene, hexane, and other carbon solvents may be useful for removing asphalts, whereas coal tars respond only to aromatic hydrocarbons (benzene, toluene, or naphthalene). Unfortunately, these solvents can be absorbed, producing toxic side effects; therefore, a specific type called long-chain aliphatic hydrocarbons (hexanes or pentanes) should be used, or removal of coal tars may need to be delayed until the patient reaches the burn center. Sunflower oil, butter, baby oil, and commercial surface-active agents such as polysorbate 80 have been shown to be highly effective and inexpensive means of tar and asphalt removal.

Wound Infections and Treatment

Wound infections do not occur during the first few hours after a burn; consequently, antibiotic prophylaxis by the CCTP is not warranted. Early antibiotic administration without proven infection may select for resistant bacteria, which makes fighting future infections difficult.

Topical antibiotic preparations are generally used to dress wounds. Agents such as bacitracin or a combination preparation of neomycin sulfate and polymyxin B sulfate (Neosporin) are generally used on the face and areas of thin skin, whereas silver sulfadiazine (Silvadene) is commonly used on other parts of the body. Silvadene should never be used on the face, because it can cause skin discoloration.

The exception to the rule about early wound infection is tetanus; its potential for development should be considered in patients without sufficient immunization against this disease. Patients at highest risk for tetanus are immigrants from developing countries and patients who have not had a booster in the previous 5 years. Patients who have not had a tetanus booster in 5 years require 0.5 mL of diphtheria and tetanus toxoids intramuscularly. Patients who have not had the primary series of three immunizations will require tetanus immunoglobulin in addition to starting the primary immunization series.

Pain Control

Burns can be excruciatingly painful, and pain control in the burn patient must be taken seriously. An opioid such as morphine sulfate, in doses of 4 to 8 mg IV (0.1 mg/kg), is the agent of choice in patients who are not allergic, and may be repeated until adequate pain control is achieved. Alternatively, agents such as fentanyl (Sublimaze) or hydromorphone (Dilaudid) may be used. Some burn specialists prefer use of fentanyl over morphine on the theoretical basis that the histamine release seen with morphine administration may promote increased capillary leak, leading to greater edema.

Morphine sulfate may also be used for children. An initial dose of 0.1 mg/kg up to a maximum of 5 mg per dose should be given. Fentanyl is dosed at 1 µg/kg.

Pain should be assessed and treated every 10 minutes until the patient is comfortable. Burn victims may require large doses of opioids for adequate pain control; if patients say they are in pain, treat their pain. Titration of opioids should be based on the patient’s perception of pain, with additional doses withheld in cases of altered level of consciousness, respiratory depression, or hypotension. The patient should be reassessed often and treated as needed. Individual requirements for opioids are different, and the CCTP should ensure that the patient is neither undermedicated nor overmedicated.

CCTPs should also be careful not to confuse sedation and analgesia. Sedatives such as lorazepam (Ativan) do not have analgesic properties, and patients who are receiving ventilation will likely require sedation in addition to analgesia. The CCTP should monitor the patient’s condition closely to prevent oversedation. Oxygenation does not equal ventilation, and patients who are oversedated will experience increased partial pressure of carbon dioxide long before any drop in the partial pressure of oxygen becomes apparent. Therefore, clinical assessment of the patient’s ventilatory status or $ETCO_2$ level must be used as the gauge to assess for oversedation.

All medications for burn patients should be given intravenously—never intramuscularly, unless special circumstances exist. Long transports may require large quantities of medications, and the CCTP should make sure enough medication is available for sedation and pain control during transport. Burns are particularly distressing injuries, and almost any burn patient the CCTP encounters would likely benefit from administration of anxiolytics. Use of anxiolytics also facilitates pain management, often lowering the doses of opioids needed.

Other Issues

Hypothermia

Every effort should be made to maintain a normal body temperature in the patient. The patient’s temperature should be measured prior to transport. Removal of wet clothing, dressings, and linens is essential. Dry sheets and blankets are preferred to cover and warm the patient.

Gastric Decompression

Patients with greater than 20% BSA burned are susceptible to **ileus** (loss of intestinal motility) because of the systemic inflammatory response that occurs with large burns. The administration of opioid pain medications decreases gastric and intestinal motility, which in turn increases the likelihood of an ileus developing. An ileus can cause abdominal distention, discomfort, and vomiting. To avoid these problems, nasogastric tubes should be placed in these patients. Decompression of the stomach with low intermittent suction will reduce distention, discomfort, and vomiting. Any patient who is endotracheally intubated should also have an orogastric tube in place to evacuate the stomach and prevent regurgitation.

Signs and Symptoms

Ileus

- Abdominal distention
- Discomfort
- Vomiting

Transport Management

Ileus

- Perform gastric decompression.
- Use nasogastric tubes.
- Place an orogastric tube in patients who have been intubated.

Special Situations

Burn centers provide care and expertise for many different types of injuries. A basic knowledge of these special situations is important to prevent further injury and provide appropriate treatment during transport.

Renal Failure and Rhabdomyolysis

Despite adequate fluid resuscitation of burn patients, their urine output may not be adequate. Given that urine output is a highly reliable indicator of adequate fluid resuscitation, patients with inadequate urine output can be extremely challenging for any health care provider. Inadequate urine output may occur for any of several reasons. Severe shock may have caused kidney damage, or the patient may have preexisting renal failure. The patient may also have renal dysfunction as a result of the mobilization of muscle proteins impairing filtration, a condition known as **rhabdomyolysis**. Rhabdomyolysis occurs most often with crush injuries, electrical burns, or large full-thickness burns. Treatment of rhabdomyolysis is discussed in more depth in Chapter 11, *Trauma*.

Ocular Burns

Every burned patient should have a thorough eye exam. Corneal abrasions and corneal burns may occur from many mechanisms. Friction burns from auto airbags, blast injuries, thermal burns, and chemical burns are common sources of injury.

In awake and alert patients, eye injuries are rarely overlooked because the patient complains of pain or visual changes. If the patient is sedated, is unconscious, or has distracting injuries, however, clinical suspicion must remain high to avoid missing injuries. Because facial edema may develop quickly, early intervention is important.

After the eyelids swell, it may be difficult to open the patient’s eyes for an exam or treatment **FIGURE 13-11**.

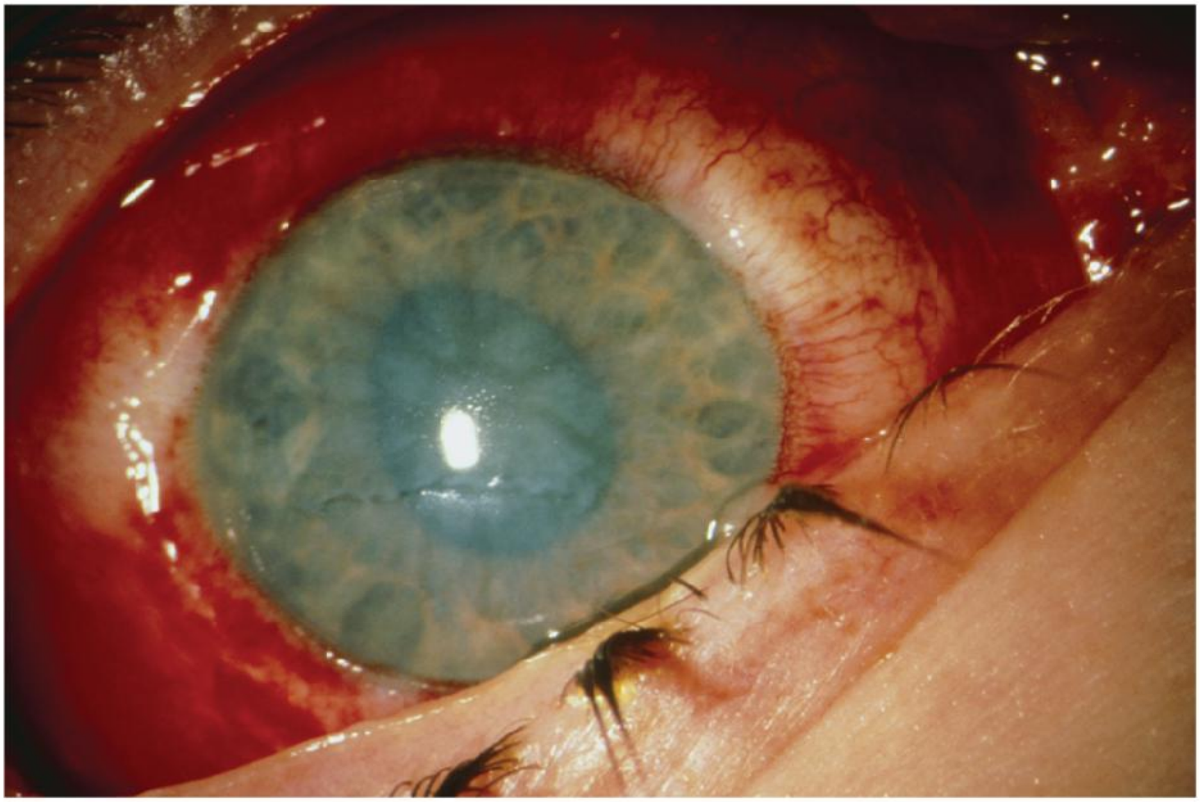

FIGURE 13-11 Examine the burn patient’s eyes early; facial edema may develop quickly and make assessment difficult.

© Western Ophthalmic Hospital/Science Source.

Corneal injuries can be very painful and should be treated with appropriate opioids. Instillation of topical anesthetics such as tetracaine may alleviate the pain from corneal injuries and aid in irrigation, although topical anesthetic drops should not be used repeatedly.

In case of chemical burns of the eyes, the eyes should be irrigated with copious amounts of water for at least 20 minutes or until the conjunctival sac pH has returned to 7. Irrigation of the eyes can be difficult if attempted manually. Morgan lenses—contact lenses with tubing connected to IV fluids—should be placed to facilitate irrigation. Lactated Ringer solution is better tolerated as an irrigation fluid than is normal saline, but either is acceptable. Topical anesthetics should be instilled prior to placement of the Morgan lenses.

Injuries to the eyes caused by an airbag should also be irrigated. Airbags may cause friction burns because the bag deploys faster than the eye can react and close to prevent the injury. In addition, the propellant that inflates the bag can release heat or chemicals that can burn the eyes.

For the critically burned patient with nonchemical burns to the eyes, application of topical ophthalmic preparations (if patient care demands allow for this treatment) will suffice as a short-term remedy until the patient can receive a more definitive examination and treatment at the receiving facility.

Transport Management

Ocular Burns

- Treat corneal injuries with appropriate opioids.
- Chemical burns of the eyes: Irrigate with copious amounts of water for at least 20 minutes or until the pH of the conjunctival sac has returned to 7.
- Nonchemical burns to the eyes: Apply a topical ophthalmic preparation.

Facial Burns

Facial burns require special attention owing to the risk of ocular and airway injuries. Significant facial burns are especially suggestive of accompanying airway injury. Rapid and repeated airway evaluation is crucial, and early intubation should be considered for any airway injury.

The face develops edema quickly. Therefore, an early eye exam is important. To help reduce facial edema, the head of the stretcher should be elevated at a 30° angle if spinal injury is not suspected.

Transport Management

Facial Burns

- If no spinal injury is suspected, elevate the head of the stretcher at a 30° angle to reduce facial edema.

Ear Burns

The ears are also prone to significant swelling when they are burned. The ear canal and eardrum should be examined before edema develops. Discuss this issue with the transporting or receiving physician prior to departure. Prevent additional trauma by avoiding pressure dressings; likewise, do not use a pillow to cushion the ear. Only large, dry, bulky dressings are required.

Transport Management

Ear Burns

- Use large, bulky dressings.
- Avoid pressure dressings.
- Do not use a pillow.

Circumferential Burns and Compartment Syndrome

Burns that encircle the chest, an extremity, or the penis present a difficult challenge. Chest burns can cause respiratory impairment if the development of eschar limits chest excursion. Edema in the extremities and penis may result in vascular compromise. These injuries may require an **escharotomy** to restore mobility to the chest or circulation to an extremity **FIGURE 13-12**. Again, most burn specialists discourage the use of field escharotomy unless absolutely and immediately necessary to preserve life or limb.

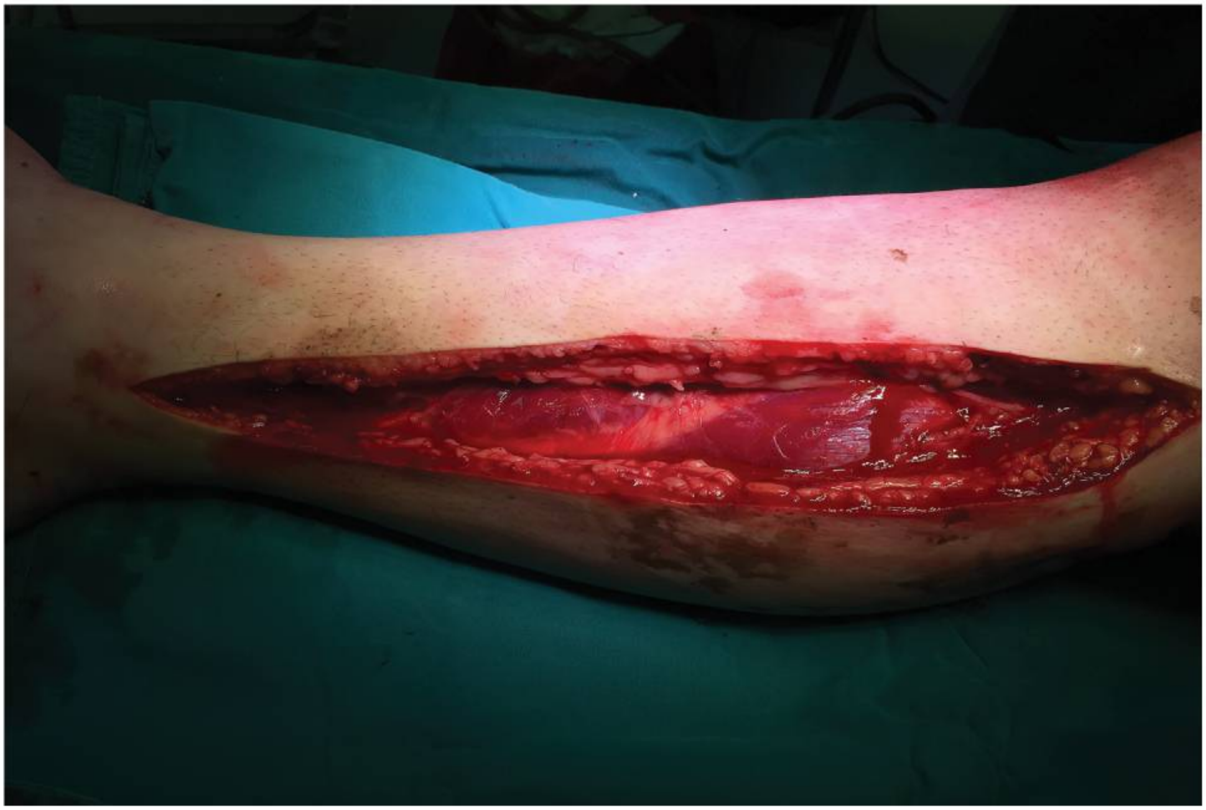

FIGURE 13-12 An escharotomy, in which an incision is made to restore circulation in the context of a circumferential extremity burn.

© Pthawatc/Shutterstock.

The following equipment is needed to perform an escharotomy:

- Scalpel
- Pain medication
- Sedation
- Sterile dressing
- 4-inch × 4-inch (10-cm × 10-cm) gauze pads

An escharotomy may be necessary in the following circumstances:

- Circumferential burns
- Full-thickness burns
- Compartment syndrome (requires fasciotomy)

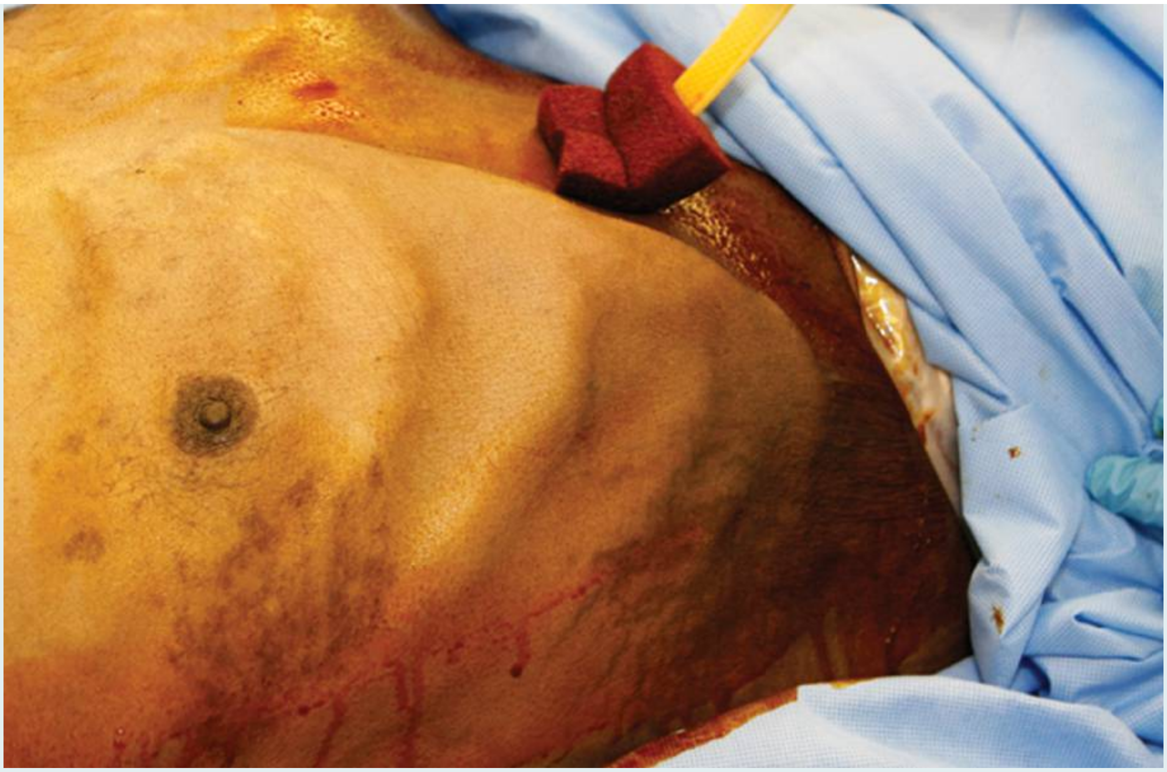
- Thermal burns
- High-voltage electrical burns
- Tissue pressure measurements greater than 35 mm Hg (obtained by placing a needle into the compartment in question, usually done by an orthopaedist)

Complications of an escharotomy may include these conditions:

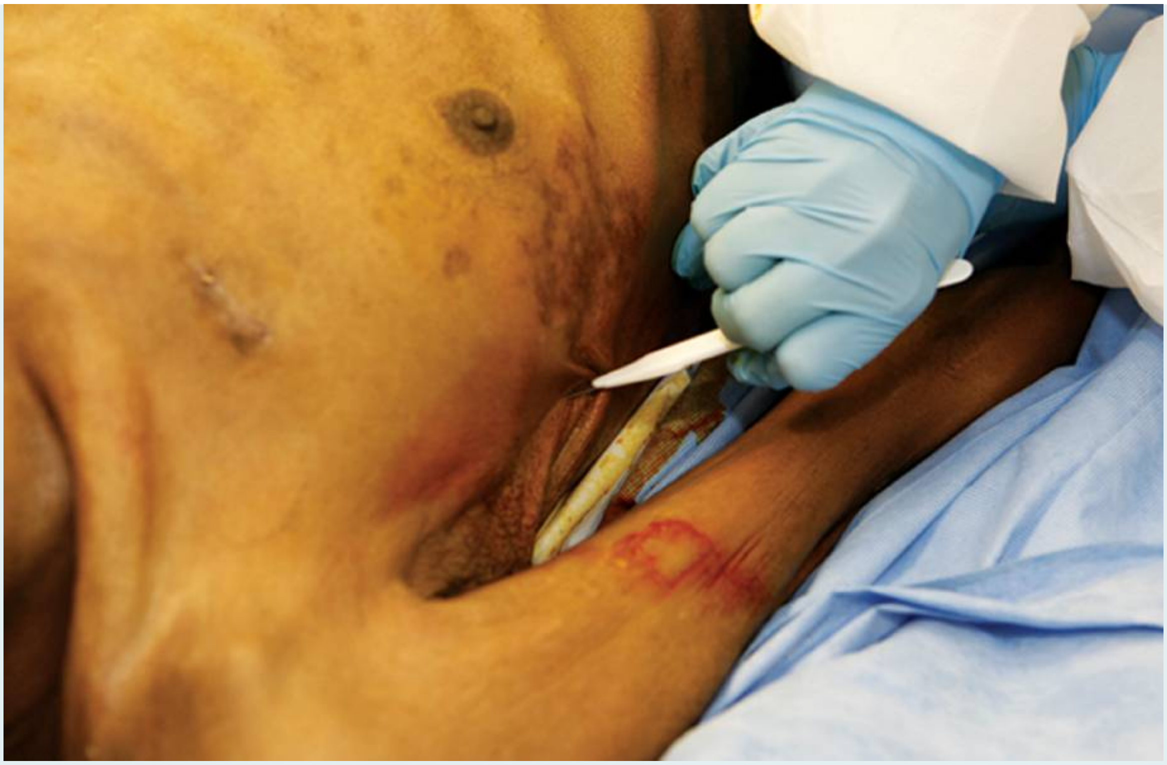
- Bleeding
- Infection
- Nerve damage
- Limited range of motion due to improper technique

Skill Drill 13-1 shows the steps for performing an emergency escharotomy, which are described here:

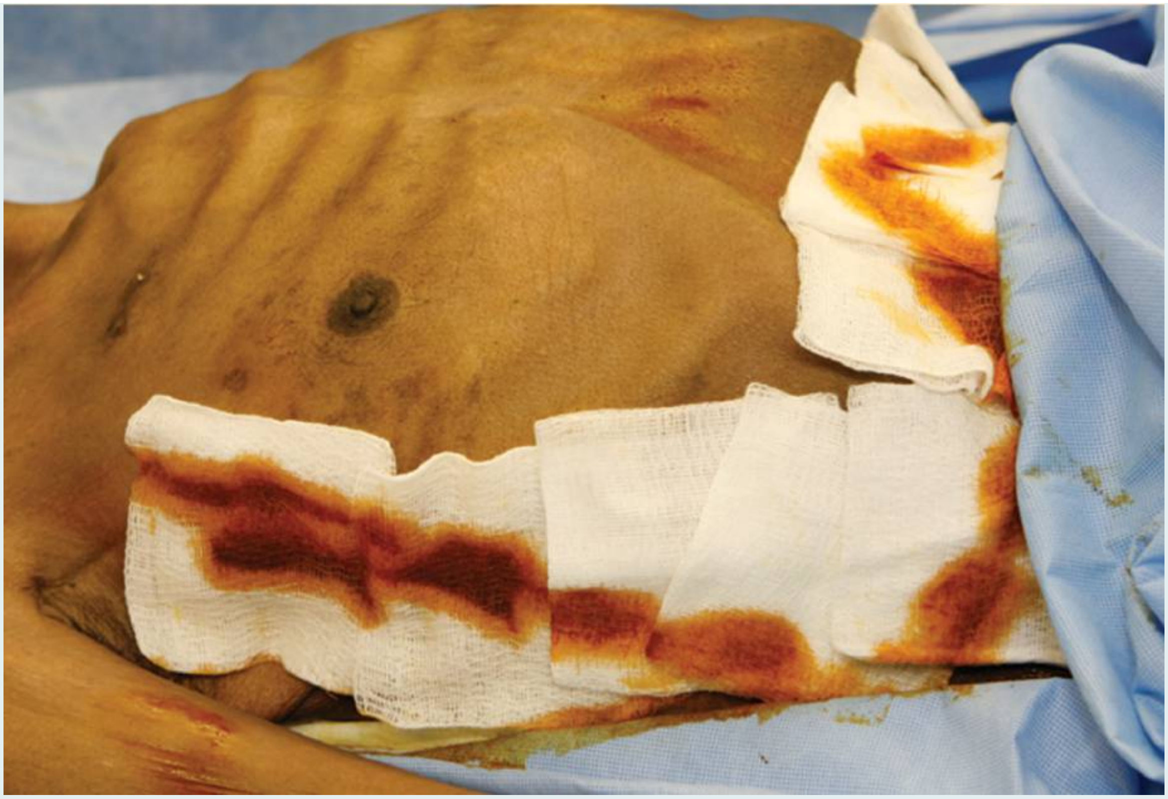
SKILL DRILL 13-1 Performing an Emergency Escharotomy*



Step 1
Prepare your equipment. Administer sedation and pain medications. Maintain an aseptic technique. Determine a well-defined incision pattern.



Step 2
Incise the derma of the burned tissue.



Step 3
Prepare to manage bleeding. Apply a sterile dressing.

*Note: The procedure was performed on a cadaver and does not show the burned tissue associated with this injury.

© Jones & Bartlett Learning.

1. Prepare the equipment.
2. Administer sedation and pain medications. Burns that cause such injuries are deep and destroy nerve endings; therefore, this procedure can be performed without anesthesia.
3. Maintain an aseptic technique **Step 1**.
4. Determine a well-defined incision pattern. For the chest, make an incision along both anterior axillary lines or, alternatively, transversely. For an extremity, make an incision parallel to the bone. A single incision may be sufficient for an extremity. The incision should be of sufficient depth for an obvious release in pressure on the skin and for fat to bulge through the incision. For

the penis, a single dorsal incision is adequate (the dorsum of the penis is the anterior surface if the penis is pointing toward the feet). Hand escharotomies are performed with incisions in the medial and lateral surfaces of each finger and of the palm.

5. Incise the derma of the burned tissue **Step 2**. Built-up pressure should cause the tissue to open even more.
6. Prepare to manage bleeding **Step 3**.
7. Apply a sterile dressing over the incision.

The most qualified person should perform the procedure; however, situations may arise that make escharotomy necessary on an emergent basis to save life or limb. An escharotomy should be performed only after discussion with the receiving burn center or transport service medical direction (if the local scope of practice allows the CCTP to carry out this procedure).

Signs and Symptoms

Circulation Problems Due to Circumferential Burns

- Absence of pulses
- Delayed capillary refill
- Mottling and discoloration of an extremity

Transport Management

Circulation Problems Due to Circumferential Burns

- Escharotomy, if allowed per protocol

CONTROVERSIES

The necessity of prehospital escharotomies is a subject of debate. Many believe that the efficacy of field escharotomies is limited, as revealed by a risk-benefit analysis. With field escharotomies, there is the potential for blood loss, severe hypotension, contamination of the wound, and damage to the nerves. Because of the amount of time it takes for an eschar to form, the likelihood that an escharotomy will be needed in the field is low. However, the CCTP must also consider the potential benefit of performing an escharotomy if the interfacility transport will require an extended length of time. When performed in a facility as opposed to the field, the benefit may outweigh the risk of the procedure.

Hand and Foot Burns

Burns on the hands and feet can cause significant disability and require specialized care. Circulation is the main concern with these injuries, because edema may impair blood flow to the periphery of the extremity, causing extensive damage. Simple interventions such as elevating the injured extremity above the heart and avoiding constricting dressings are important. Loose, dry dressings that allow easy assessment of the patient’s circulation may be used during transport; however, no dressing is required. Do not apply creams or ointments. Likewise, do not apply ice packs because they may cause frostbite.

Transport Management

Hand and Foot Burns

- Elevate the injured extremity above the heart.
- Avoid constricting dressings; use loose, dry dressings or no dressing.
- Do not apply creams or ointments.
- Do not apply ice packs.

Genitalia Burns

Burns on the genitalia and perineum should not distract health care providers from life-threatening injuries. However, certain aspects of the treatment of patients with such injuries require prompt attention. An indwelling urinary catheter should be placed immediately before edema develops. The penis should be examined for circumferential burns and monitored for impaired circulation. A dorsal escharotomy of the penis may be necessary, albeit as a highly unlikely event.

Transport Management

Genitalia Burns

- Immediately place an indwelling urinary catheter.
- If a penis has a circumferential burn, monitor for impaired circulation.

Pediatric Burns and Child Abuse

Children present special challenges when burned because their physiology and composition differ from those of adults. Children have relatively more surface area per kilogram, which necessitates close attention to their fluid resuscitation. Infants also have relatively less glycogen stores than adults, making them susceptible to hypoglycemia if deprived of oral intake for several hours. The CCTP should consider adding glucose to resuscitation fluids in such young patients; however, this treatment should be guided by local burn center preference. Other strategies include frequently checking glucose levels and correcting any hypoglycemia as it occurs, rather than administering glucose-containing fluids. The blood glucose level should be maintained between 60 and 120 mg/dL.

Approximately 25% of all childhood burns result from child abuse; consequently, the CCTP caring for a child should consider this possibility. When children with burns receive care more than 24 hours after the incident, suspect maltreatment. Accidental burns in children most often result from scalding and more commonly occur in the “spill area”—the area of the face and chest that is exposed when children pull a container of hot liquid onto themselves **FIGURE 13-13**. Burns to other areas with well-demarcated edges and in a stocking-glove distribution should raise the suspicion of abuse **FIGURE 13-14**. The CCTP should report any suspicion of child maltreatment to child protection authorities and the receiving facility.

Transport Management

Pediatric Burns

- Consult with a local burn center regarding adding glucose to resuscitation fluids.
- Check blood glucose levels frequently.
- Correct hypoglycemia.

Electrical Burns

Injuries from electricity may result from alternating current or direct current. Alternating current is found in homes and businesses and is the most common source of electrical injury. Direct current is found in motor vehicle electric systems and some lighting systems, and may be found in some industries. Lightning is also direct current.

Electricity releases heat as it travels through or across the body, causing extensive tissue damage. All tissues have a different resistance to current flow, with the nervous system being the least resistant. Bone is the most resistant, but all tissues are susceptible to damage. Electricity may enter and exit the body at any point. The hands are the most common point of entry **FIGURE 13-15A**, and the feet are the most common point of exit **FIGURE 13-15B**. The path that electricity follows between entrance and exit is erratic and unpredictable. Severe charring frequently occurs at the point of entry and may be the only obvious injury. Damage to deeper structures may not be evident if the superficial structure such as the skin is uninjured.

Early evaluation of the extent of electrical injury is difficult. Some common patterns of injury do occur, however. Damage to the cardiac conduction system may present as cardiac arrest, and high voltages may lead to respiratory arrest by paralyzing the diaphragm. Alternating current typically causes ventricular fibrillation and is the most common cause of death. Direct current typically causes asystole. Cardiac arrest in the electrocuted patient is treated with the standard advanced cardiac life support protocol. Other arrhythmias may develop at any time after injury, necessitating continuous cardiac monitoring for the first 24 hours. Notably, a normal electrocardiogram or rhythm soon after the event does not rule out injury.

Skin burns sometimes occur without deeper structures being damaged in electrical injury. Clothing may ignite without an electrical current entering the body. These injuries are treated as other cutaneous burns.

Because the electrical current can travel deep into the skin, structures such as muscle, bone, tendon, blood vessels, and nerves may be severely damaged, despite little evidence appearing on the skin. Massive muscle damage and cell death will release muscle proteins into the bloodstream. In addition, compartment syndrome may develop in the extremities as a result of deep burns; progressive pain, paresthesias, and decreased circulation are clues to this injury. Consult with the transferring and receiving physicians about fasciotomy before transport.

Electric current may also cause violent muscle contractions that break bones or cause joints to dislocate. Spinal motion restriction should be employed and suspected fractures immobilized prior to transport. Care should be taken to protect open fractures from additional contamination.

Lightning injuries are a common source of burns. Patients with lightning injuries may experience any of the injuries already mentioned. In addition, they may experience extensive superficial cutaneous burns in a fern or reticular pattern as electricity passes across the skin **FIGURE 13-16**. The eardrum may rupture as a result of the pressure wave created by the rapid heating of the surrounding air, and the patient may have displacement to the lens of the eye from the pressure gradient produced.

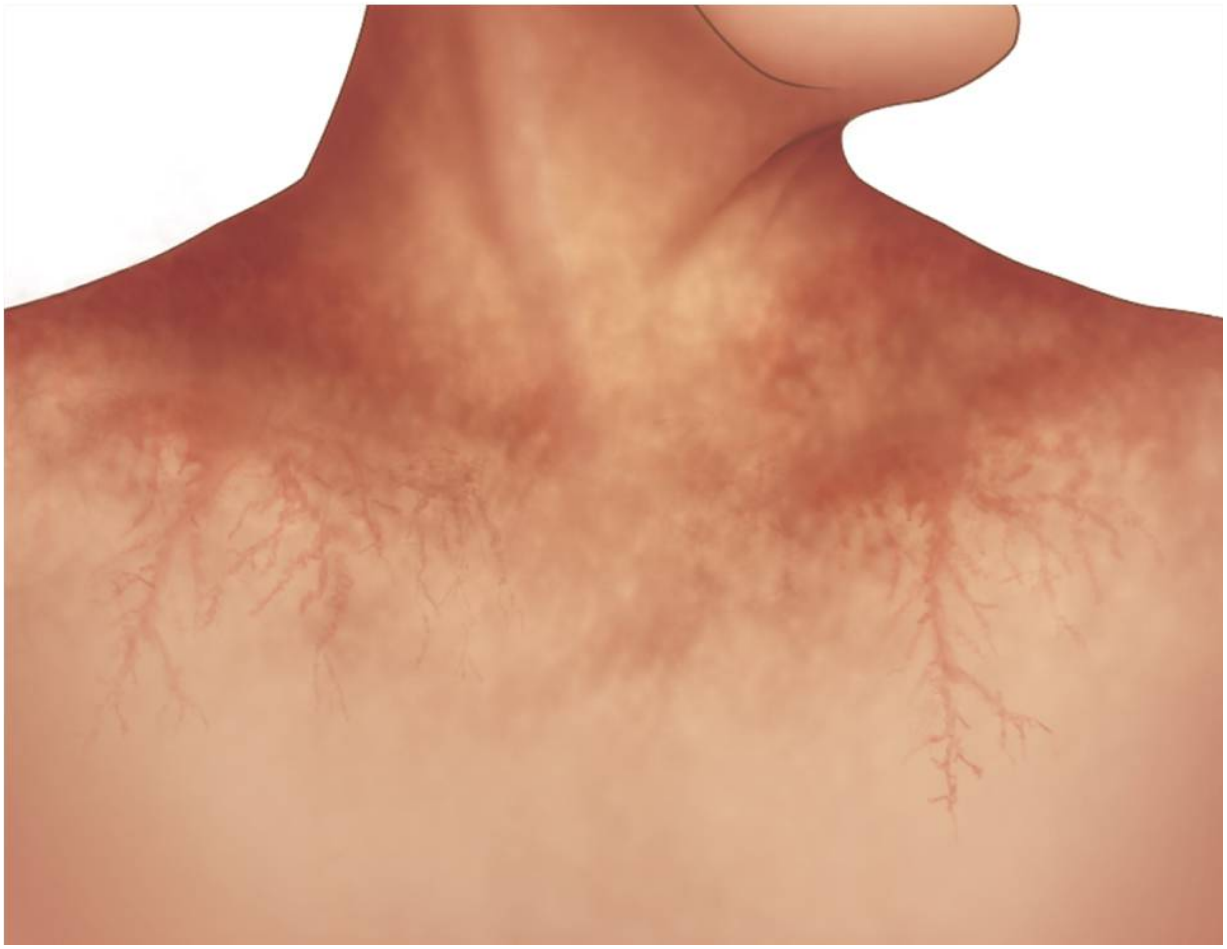

FIGURE 13-16 Fern pattern as a result of a lightning injury.

Transport Management

Electrical Burns

- Treat the same as other cutaneous burns.

Chemical Burns

Common household, industrial, and farm products can be toxic and cause significant burns. The active ingredients responsible for injury are usually acids, alkalis, and a few other organic compounds. The extent of damage depends on the type of agent, its relative strength, and the duration of contact.

Cutaneous burns are not the only risk from chemical exposure; some chemicals may be absorbed systemically, causing organ damage or failure. Such injuries may not become apparent until 6 to 24 hours after exposure. Patients with relatively minor-appearing injuries may require transport for observation at a center for specialized care.

When chemical burns are suspected, it is crucial to decontaminate the patient quickly and thoroughly. Because chemicals can settle in clothing, shoes, linens, and jewelry, the patient should be completely disrobed and then irrigated with copious amounts of water. Attempts to neutralize one chemical with another can produce an exothermic reaction (producing heat) and worsen the burn; therefore, this should not be attempted. After decontamination, the patient should be placed on clean, dry linens. Management of chemical wounds is generally the same as for thermal injuries, with the exception of applying calcium gluconate gel to hydrofluoric acid burns (discussed in the next subsection).

Acid Burns

Acids are found in chemical products such as drain openers, drain cleaners, bathroom cleaners, swimming pool products, and rust removers. They are also found in hair care products such as hair relaxers. Acids are used extensively in industry for production of other compounds and are found in potent industrial cleaning products.

Duration of contact is the main determinant of damage from acids. The initial treatment consists of rapid, copious irrigation with water. Acids tend to cause burns that are more self-limiting than the burns caused by alkalis. When acids come in contact with skin, their damage takes the form of coagulation necrosis. The coagulum, or scar, limits the penetration of the acid, thereby limiting the damage done. This results in a burn with well-demarcated edges and often in a pattern that suggests liquid spilling.

Some acids such as hydrofluoric acid also have other mechanisms of injury and require special attention. Hydrofluoric acid is used in microelectronics, petroleum processing, glass and metal etching, wheel cleaners, rust removal, and many other applications. It is capable of inflicting progressive injury despite irrigation. After this chemical penetrates the skin, fluoride ions are released and cause nerve damage and severe pain. Calcium binds to fluoride and reduces its damage. Therefore, topical calcium gluconate gel should be applied immediately after irrigation. Commercial preparations of calcium gluconate gels are available, but mixing calcium gluconate with a water-based, water-soluble lubricant (such as K-Y Jelly) will suffice if these products are not available. This mixture can be squirted into an exam glove and applied directly to the patient’s hand. Intradermal injection of calcium gluconate and intra-arterial calcium gluconate may also be used to alleviate pain.

Oxalic acid is not as toxic as hydrofluoric acid but may also require calcium gluconate therapy. Calcium *chloride* should not be administered intradermally or intra-arterially.

Alkali Burns

Alkalis are found in many household and industrial products and are capable of producing significant burns. Oven cleaners, drain cleaners, lime, lye, and cement are all commonly encountered alkali substances. These agents, when combined with fat, produce soap; thus, they are able to penetrate deeply and rapidly into the tissues. Alkali exposures continue to burn for extended periods of time and require irrigation for more than 20 minutes. Because there is no coagulum to restrict the penetration of alkalis into the tissues, burns caused by these chemicals typically have poorly defined edges and diffuse spreading of the injury. Special care must be taken during decontamination to avoid unnecessary heat loss.

Dry lime is a commonly used agricultural product. When combined with water, it may also generate an exothermic reaction and cause burns.

With alkali burns, all dry powders should be brushed away to reduce the amount of chemical present before irrigation is performed with flowing water. Fast-flowing water will help dissipate heat, but the higher pressure may cause or worsen tissue damage. When using water under pressure, avoid self-contamination from splashing.

Because of the deep penetration of alkalis, systemic toxicity is also a significant concern with these burns. Care of systemic complications is supportive.

Transport Management

Chemical Burns

- Decontaminate patients quickly and thoroughly.
- Copiously irrigate the burn until the burning has stopped or the material is cool.
- The length of the irrigation process should be guided by the pH of the wound assessed in the base of the wound.
- If you are unable to measure pH, continue copious irrigation for at least 20 minutes.
- After decontamination, place the patient on clean, dry linens.
- Break blisters.
- Remove all clothing and jewelry.
- Do not attempt to neutralize one chemical with another.
- For burns from hydrofluoric acid, apply topical calcium gluconate gel immediately after irrigation.

Hydrocarbon Burns

Hydrocarbons such as petroleum fuels may cause burns after immersion or prolonged contact with these chemicals. They can also cause significant systemic toxicity if absorbed. Treatment is supportive, including copious irrigation and observation.

Hydrocarbons (including most petroleum products such as gasoline) can cause myocardial depression leading to hypotension and cardiovascular collapse. Halogenated hydrocarbons (chlorofluorocarbons, including Freon and those found in many solvents like oven cleaner), such as those used in propellants, are known to cause central nervous system depression or excitability. In particular, the halogenated hydrocarbons may potentially create a fatal arrhythmia.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis Syndrome

Stevens-Johnson syndrome and toxic epidermal necrolysis syndrome are severe mucocutaneous reactions that typically result from certain medications, environmental allergies, infections, and unknown toxins. The medication phenytoin (Dilantin), among others, is well known for causing this reaction. Other medications often implicated include allopurinol, sulfonamides, and certain nonsteroidal anti-inflammatory drugs (NSAIDs). More rarely, other medications such as acetaminophen can be associated with this reaction.

Stevens-Johnson syndrome and toxic epidermal necrolysis are both immune-mediated illnesses that cause sloughing of the skin, mucous membranes, and the cells lining the respiratory system. Both can also present respiratory and wound care challenges that are as difficult to manage as severe burns of other types **FIGURE 13-17**. They are considered to be on the same continuum, with Stevens-Johnson syndrome being the milder of the two. The spectrum of illness from Stevens-Johnson syndrome to toxic epidermal necrolysis is as follows:

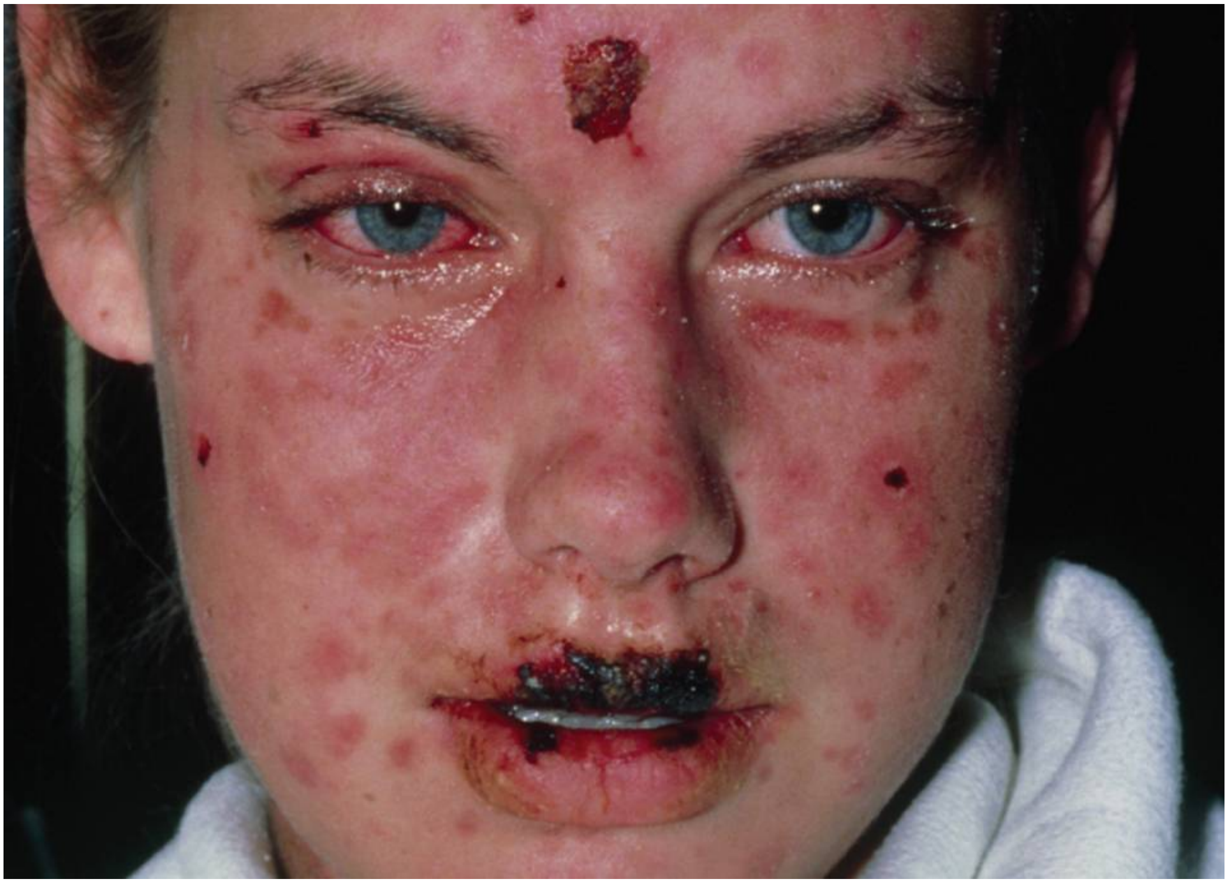

FIGURE 13-17 Patients with toxic epidermal necrolysis or Stevens-Johnson syndrome can present treatment challenges that are similar to those associated with patients with severe burns.

© Dr. P. Marazzi/Science Source.

- In Stevens-Johnson syndrome, epidermal detachment involves less than 10% of the total body skin area. In more than 90% of patients, mucous membranes are involved. Mortality is approximately 10%.
- In Stevens-Johnson syndrome–toxic epidermal necrolysis, overlap is defined by an epidermal detachment between 10% and 30%.
- Toxic epidermal necrolysis is defined by an epidermal detachment of greater than 30%. Its mortality often approaches 30%.

Patients with toxic epidermal necrolysis are frequently treated in burn centers because their wounds are analogous to burn injuries. Treatment is primarily supportive, in addition to the skin care.

Summary

Mastering the care of burn patients is a continuous process. Research is ongoing to discover optimal wound management and resuscitation techniques. Additional training is available from various sources, and most burn centers and units offer educational programs that can be an invaluable resource to local providers.

CASE STUDY

You are dispatched to a rural community hospital for an interfacility transport of a 45-year-old woman who is experiencing dyspnea and pain after being burned in a house explosion secondary to a natural gas leak.

As you enter the treatment room to begin your assessment, you find a woman with multiple partial- and full-thickness burns to her arms, chest, abdomen, and face. She is experiencing severe dyspnea and crying out in pain, having just arrived via EMS. She is conscious, confused, and difficult to understand because of the hoarseness of her voice. You continue your assessment, while your partner sets up equipment for RSI. The patient is complaining of severe pain throughout the burned areas of her body.

Her vital signs include a blood pressure of 118/80 mm Hg; respiratory rate of 38 breaths/min and labored with audible stridor despite three albuterol nebulizer treatments by EMS providers; and a pulse rate of 140 beats/min. You note burns in the mouth; soot around the nose and mouth; partial-thickness burns to the chest, abdomen, and arms; and full-thickness burns to the face. You estimate the patient's partial- and full-thickness burns to be approximately 30% of her TBSA.

Your partner advises you that she is ready to begin RSI. You use an established IV line to administer 2 mg/kg of ketamine and 2 mg/kg of succinylcholine. You insert the laryngoscope, but you are unable to visualize the vocal cords or pass the endotracheal tube because of pronounced edema. You direct your partner to ventilate the patient using a bag-mask device and 100% oxygen while you prepare the surgical airway kit. You are successful in securing a surgical airway. On confirmation of placement using waveform capnography and bilateral breath sounds, you make a note that breath sounds are slightly decreased on the patient's right side as compared to her left side. You quickly cover all burns with dry, sterile dressings and prepare for transport by placing the patient onto your equipment and rapidly performing a hot load (with the engine running and rotors turning) for transport to the closest burn center.

In flight, the patient's vital signs remain stable; you administer 0.1 mg/kg of vecuronium and 1 μg/kg of fentanyl, and you start administering lactated Ringer solution at 100 mL/h. Approximately 2 minutes from the burn center, your partner, who is ventilating the patient, reports that she is meeting resistance. You assess breath sounds and do not hear anything on the right side, although you are uncertain of this finding because of the amount of noise in the helicopter. End-tidal carbon dioxide has remained at 35 mm Hg with a normal waveform. Because of the burns and swelling, you are unable to determine whether jugular vein distention or tracheal deviation is present. You confirm that the surgical airway has not moved and then decide to do a needle decompression, which your partner reports makes ventilating much easier.

On arrival at the burn center, you do a hot off-load of the patient and transport the patient to the trauma bay, where you give a report to the trauma team. You and your partner clean your equipment and get the aircraft back in service.

Once you return to base, you complete your report for the medical record and discover that you miscalculated the initial IV fluid rate according to the Parkland formula. You notify the nursing staff at the burn unit of the error and complete a protocol deviation form. Finally, you notify the referring EMS agency of the outcome.

1. What should the IV fluid rate have been?
2. What is the rationale for the resistance met during ventilation that led to a needle decompression?
3. According to the American Burn Association, which classification of burns did the patient in the case present?

Analysis

Although the Advanced Burn Life Support fluid resuscitation formula is slowly replacing the Parkland formula, many protocols continue to utilize the Parkland formula. The Parkland formula recommends resuscitation with lactated Ringer solution of 4 mL/kg per percentage of BSA burned. In this case, the initial fluid rate should have been 750 mL/h.

Burn patients may experience significant trauma from explosions or motor vehicle crashes resulting in fires. With the presence of such trauma, the possibility exists that you might overlook conditions such as a pneumothorax or hemothorax while treating the obvious burns. Careful repeated examinations should focus on identifying these conditions. Physical assessment is important in such cases, because monitoring devices such as capnography and pulse oximetry may not display appreciable changes until the patient has significantly decompensated.

This patient met several criteria for major burn injuries, including partial-thickness burns involving more than 25% of BSA in an adult, burns involving the face, and burns complicated by inhalation injury or major trauma.

Caring for patients with burn injuries requires the CCTP to deploy aggressive critical thinking, assessment, and intervention skills. The CCTP must use an organized, rapid approach to assess, prioritize, and treat both the burns and any secondary injuries found. Because of the early fluid losses associated with burn injuries, aggressive and sustained fluid management is essential. Determining the severity and extent of burns is important to arrange for transportation to the most appropriate treatment facility.

PREP KIT

Ready for Review

- The initial 24 hours of care after a burn are crucial. The CCTP must have an understanding of the common complications of burns that can develop during the transport of the patient to a burn facility.
- The skin, which is composed of the epidermis and the dermis, is the largest organ of the body and is vital to survival.
- The layers of the epidermis contain pigment cells, immune cells, and capillaries in the lower layers. The epidermis is the first barrier to injury and infection; it is constantly repairing itself, because it is injured more often than the other layers. Its outer layer provides a barrier to prevent water loss from deeper structures.
- The dermis lies beneath the epidermis and contains fibroblasts, macrophages, white blood cells, nerve cells, lymphatic vessels, blood vessels, portions of the hair follicles, and oil and sweat glands.
- Proteins such as collagen and fibronectin, which are produced in the dermis, support the continuously reproducing epidermis and play a major role in wound healing, along with fibroblasts, macrophages, platelets, and endothelial cells. The inflammatory response, which is important in the burn healing process, is also responsible for multiple complications of injuries.
- The skin has multiple functions, including protection from infection, maintaining fluid and electrolyte balance, thermoregulation, and neurosensory functioning, which is important for social interaction.
- Burns occur from a variety of mechanisms, including flame/flash, scald (eg, water, grease), contact, electrical, chemical inhalation, radiation, and any type of thermal source. The agent,

temperature, and duration of exposure determine the size and depth of a burn.

- The zone of coagulation is the most heavily damaged area of a burn and is the area of skin that came into direct contact with the source of heat.
- The zone of stasis encompasses the injured tissue in a burn and may appear red and hyperemic (filled with an increased amount of blood) initially. Within 24 hours after the injury, it has a stagnant blood flow resulting in ischemic tissues, which by the third day become white because they are avascular and necrotic.
- The zone of erythema, which has increased blood flow, is the outermost area surrounding the zone of stasis; it has minimal damage and will recover.
- Burns affecting more than 20% of the total body surface area (TBSA) result in a systemic inflammatory response, which can result in undesirable effects on other tissues and organs, including pulmonary edema, suppression of the immune system, sepsis, and impaired cardiac output.
- The severity of a burn depends on the extent, depth, and location of the burn; the age of the patient; the etiologic agents involved; the presence of inhalation injury; and coexisting injuries or preexisting illnesses.
- The classification of burns includes four categories:
  - Superficial (first-degree) burns, which involve only the epidermis
  - Partial-thickness (second-degree) burns, which involve some of the dermis but not the entire thickness of the skin
  - Full-thickness (third-degree) burns, which involve all layers of the skin and perhaps some subcutaneous tissue and muscle
  - Subdermal (fourth-degree) burns, which involve deep structures such as muscle, bone, large blood vessels, and nerves

- Burn size also influences burn severity. A common approach to determining severity is the rule of nines, which is the method most commonly used in the prehospital environment. The Lund-Browder chart is more accurate than the rule of nines, but is rarely used by prehospital providers.
- The American Burn Association (ABA) classifies burns into three major categories: major, moderate, and minor. Patients who meet the ABA criteria or have a major burn injury should be transferred to a specialized burn center to ensure appropriate acute care, rehabilitation, and long-term care.
- Assessment for burn patients should be similar to assessment for any other patient, with attention paid to each organ system, but especially to the patient’s airway, breathing rate and depth, and cardiac output.
- Burn management includes removing the patient from the source of the burn, cooling, and irrigation.
- Airway management for a burn patient can present difficult challenges because of airway edema resulting from inhalation injuries. The patient must be assessed for the possibility of inhalation injury and the airway managed with endotracheal intubation if stridor, progressive hoarseness, or any other evidence of airway compromise is present.
- Judicious fluid management is important, because burns can result in large intravascular fluid losses due to the loss of the body’s protection against desiccation and evaporation. Formulas to calculate fluid resuscitation for the first 24 hours after a burn include the ABA’s *Advanced Life Support Course* 2018 guidelines (the most commonly used) and the Parkland formula.
- Burn wounds should be dressed with clean, dry dressings (never wet dressings), and blisters should be left intact. In general, the CCTP should not perform wound debridement.
- Antibiotic prophylaxis by the CCTP is not warranted in patients with burns, although deficiencies in tetanus coverage should be remedied.

- Burn victims may require large doses of opioids for adequate pain control, and pain should be assessed and treated every 10 minutes until the patient is comfortable.
- Other issues of burn management include maintaining a normal body temperature to prevent hypothermia and performing gastric decompression if necessary.
- Despite adequate fluid resuscitation of a burn patient, inadequate urine output may occur as a result of severe shock resulting in kidney damage, preexisting renal failure, or rhabdomyolysis.
- Ocular burns can occur from many different sources, including friction burns from auto airbags, blast injury, thermal burns, and chemical burns. A burn patient’s eyes need to be examined early, because edema can develop quickly and make subsequent assessment difficult.
- Treat corneal injuries with appropriate opioids, chemical burns of the eye with irrigation, and nonchemical eye burns with a topical ophthalmic preparation.
- Ocular and airway injuries are the major concerns that arise with facial burns. Airway evaluation is important in such cases, given that early intubation may be necessary.
- Ear burns are susceptible to increased swelling, and an exam should be done before edema develops.
- Circumferential burns (burns that encircle the chest, an extremity, or the penis) and the resultant compartment syndrome present difficult challenges for the CCTP. These injuries may require an escharotomy to restore mobility to the chest or circulation to an extremity.
- Hand and foot burns can cause significant disability. They are treated by elevating the injured extremity above the heart and by using either loose, dry dressings or no dressing.
- Genitalia burns require placement of an indwelling urinary catheter before edema develops. If a penis has a circumferential burn, the CCTP should monitor for impaired circulation.

- Approximately 25% of all childhood burns result from child maltreatment, and the CCTP should consider this possibility when caring for a burned child. Accidental burns in children often result from scalding and frequently occur in the “spill area” (the area of the face and chest that is exposed when children pull a container of hot liquids onto themselves).
- Early evaluation of the extent of injury from an electrical burn is difficult. Damage to the cardiac conduction system may present as cardiac arrest, and high voltages may lead to respiratory arrest by paralyzing the diaphragm.
- Alternating current typically causes ventricular fibrillation and is the most common cause of death, whereas direct current typically causes asystole. Lightning can cause extensive superficial burns in a fern pattern as electricity passes across the skin.
- Patients with chemical burns should be decontaminated quickly and thoroughly, irrigating until the burning has stopped and the material is cooled, or for at least 20 minutes. Take care to avoid unnecessary heat loss when performing irrigation.
- Toxic epidermal necrolysis syndrome, the most severe form of skin reaction to certain medications, environmental allergies, or other unknown toxins, and a milder form, Stevens-Johnson syndrome, can present management challenges similar to those presented by severe burn patients.

Vital Vocabulary

compartment syndrome A condition that develops when edema and swelling result in increased pressure within soft tissues, causing circulation to be compromised, possibly resulting in tissue necrosis.

deep partial-thickness burn A burn in which the skin is blistered but not charred and is painful to the touch; it is usually the result of steam, oil, or flames and involves the deeper layers of the dermis.

dermis The layer of skin that lies beneath the epidermis; it is a dynamic layer of thick connective tissue.

epidermis The outer layer of the skin, which generally consists of four layers (thin skin), except on the palms, fingertips, and soles of the feet, which have five layers (thick skin).

eschar The leathery covering of a burn injury, formed after the burned tissues dry out.

escharotomy A surgical incision in an eschar to lessen constriction; sometimes necessary (although rarely performed in a prehospital setting) to prevent edema from building up, impairing capillary filling and causing ischemia.

fasciotomy A surgical incision into an area of fascia—for example, to relieve pressure between two compartments; not usually performed in a prehospital setting.

full-thickness burn A burn that extends through the epidermis and dermis into the subcutaneous tissues beneath, in which skin is pale, painless, leathery, and charred; also called a third-degree burn.

hyperemic An increase in blood flow into a tissue or organ; congested with blood.

ileus Loss of intestinal motility.

lines of cleavage Regions between interlocking collagen fibers that run in various planes, usually parallel to the skin; they run longitudinally in the skin of the head and limbs and in a circular pattern around the neck and trunk, and are used when deciding where to make incisions for escharotomies and fasciotomies.

Lund-Browder chart A detailed version of the rule of nines chart that takes into consideration the changes in body surface area that occur with growth.

major burn According to the American Burn Association classification system, any of the following: (1) partial-thickness burns involving more than 25% of total body surface area (TBSA) in adults or 20% of TBSA in children younger than 10 years and adults older than 40 years; (2) full-thickness burns involving 10% or more of TBSA; (3) burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment; (4) high-voltage electrical injury; (5) burns complicated by inhalation injury or major trauma; and (6) burns sustained by high-risk or debilitated patients.

minor burn According to the American Burn Association classification system, any of the following: (1) partial-thickness burns involving less than 15% of total body surface area (TBSA) in adults or 10% of TBSA in children younger than 20 years and adults older than 50 years; and (2) full-thickness burns involving 2% or less of TBSA that do not present a serious threat of functional or cosmetic risk to the eyes, ears, face, hands, feet, or perineum.

moderate burn According to the American Burn Association classification system, any of the following: (1) partial-thickness burns involving 15% to 25% of total body surface area (TBSA) in adults or 10% to 20% of TBSA in children younger than 10 years and adults older than 40 years; and (2) full-thickness burns involving 10% or less of TBSA in patients younger than 50 years that do not present a serious threat to functional or cosmetic impairment of the eyes, ears, face, hands, feet, or perineum.

myoglobinuria The presence of myoglobin, a respiratory pigment of muscle tissue, in the urine.

Parkland formula A formula that recommends giving 4 mL of lactated Ringer solution or normal saline for each kilogram of body weight, multiplied by the percentage of body surface area burned; sometimes used to calculate fluid needs during lengthy transport times.

partial-thickness burn A burn that involves the epidermis and part of the dermis, characterized by pain and blistering; also called a second-degree burn.

rhabdomyolysis The destruction of muscle tissue leading to a release of potassium and myoglobin, which then accumulate in the blood and urine and impair filtration; occurs most often with crush injuries, electrical burns, or large full-thickness burns.

rule of nines A system that assigns percentages to sections of the body, allowing calculation of the amount of skin surface involved in the burn area.

Stevens-Johnson syndrome A milder form of toxic epidermal necrolysis, in which epidermal detachment involves less than 10% of the total body surface area; it causes sloughing of the skin, mucous membranes, and cells lining the respiratory system.

subdermal burn A severe, life-threatening burn involving the deep structures of muscle, bone, larger blood vessels, and nerves; also called a fourth-degree burn.

superficial burn A burn involving only the epidermis, producing very red, painful skin; also called a first-degree burn.

superficial partial-thickness burn A burn involving the epidermis and part of the dermis, but not the deeper layers of the dermis; also called a second-degree burn.

thermal burn A burn caused by heat, contact with hot objects, ignited liquids, steam, or hot liquids.

toxic epidermal necrolysis (TEN) syndrome A severe skin reaction to certain medications, environmental allergies, and other unknown toxins, in which epidermal detachment is greater than 30%.

zone of coagulation The center of a burn, which is usually the deepest and most severely affected area.

zone of erythema The outermost area of a burn, which represents the least severely burned area; usually an area of first-degree burn.

zone of stasis The area found just outside the zone of coagulation, which represents a burned area that is less severely damaged.

CHAPTER 14

Electrophysiology, Pacemakers, and Defibrillators

Mike McEvoy, PhD, NRP, RN, CCRN

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the anatomy and physiology of the cardiovascular system (pp 675–681).
2. Describe how to monitor a patient by using electrocardiography (ECG) during a critical care transport (CCT) (p 684).
3. Explain how to correctly place leads from a 12-lead ECG monitor (pp 684–687).
4. Explain how to correctly place additional precordial leads for diagnosing right ventricular and posterior infarctions (p 687).
5. Discuss the step-by-step systematic approach that should be used when interpreting an ECG (pp 688–691).
6. Explain how to determine the heart's electrical axis (p 691).
7. Describe how to identify a bundle branch block on an ECG (pp 695–703).
8. Explain the care for a patient with a bundle branch block during CCT (p 698).
9. Describe how to identify a hemiblock on an ECG (pp 698–700).
10. Explain the care for a patient with a hemiblock during CCT (pp 698–700).
11. Describe the significance of ST-segment and T-wave changes (p 703).
12. Explain how ST-segment and T-wave changes are identified on an ECG (pp 703–704).
13. Identify criteria suggestive of right and left atrial enlargement (pp 704–705).
14. Describe the clinical implications of right and left atrial enlargement (pp 704–705).
15. Identify criteria for determining the presence of left ventricular hypertrophy (LVH), right ventricular hypertrophy (RVH), and the presence of strain (pp 705–707).
16. Describe the clinical significance of LVH, RVH, and the presence of strain (pp 705–707).
17. Describe the ECG changes that indicate the presence of Wolff-Parkinson-White syndrome (pp 707–709).
18. Identify ECG changes that could indicate the presence of pericarditis (p 709).

19. Describe the potential implications of a prolonged QT interval (pp 709–710).
20. Describe how to identify ventricular tachycardia on an ECG, including when it occurs in conjunction with wide complex tachycardia (pp 710–712).
21. Explain the care for a patient with ventricular tachycardia, including when it occurs in conjunction with wide complex tachycardia (pp 711–712).
22. Describe ECG changes associated with electrolyte imbalances, such as hyperkalemia, hypokalemia, hypercalcemia, and hypocalcemia (pp 712–716).
23. Explain the clinical implications of electrolyte imbalances, such as hyperkalemia, hypokalemia, hypercalcemia, and hypocalcemia (pp 712–716).
24. Describe ECG changes associated with digoxin toxicity (pp 716–718).
25. Explain how to diagnose and manage digoxin toxicity (p 718).
26. Discuss the diagnosis and management of coronary artery disease and angina (pp 718–723).
27. Explain the process underlying myocardial infarction, including the actions of cardiac enzymes, changes in blood supply, and the ischemia–injury–infarction pathway (pp 723–738).
28. Describe the ECG changes associated with various types of myocardial infarction (pp 727–738).
29. Summarize the development of heart failure, including the associated signs and symptoms (pp 738–742).
30. Generally describe the field of electrophysiology, including its purpose and capabilities (pp 742–743).
31. Describe the spectrum of therapeutic options for patients with cardiac arrhythmias (pp 743–745).
32. Explain the basic concepts underlying cardiac pacemaker technology (pp 745–752).
33. Describe the general steps in pacemaker troubleshooting and the specifics of identifying and resolving problems with electromagnetic interference (pp 752–754).
34. Recognize single- and dual-chamber pacing systems by their ECG characteristics (pp 754–756).
35. Explain the purpose and function of atriobiventricular pacing devices (p 756).
36. Describe the components and function of implantable cardioverter-defibrillators (ICDs) (pp 756–757).
37. Explain the purpose of atrial tachycardia ICDs, wearable cardioverter-defibrillators, and subcutaneous ICDs (pp 759–760).
38. Briefly identify the special considerations related to external defibrillation when an ICD is present (p 762).

Introduction

Critical care transport professionals (CCTPs) routinely encounter patients with cardiac arrhythmias and need to be familiar with interpretation and monitoring of the 12-lead electrocardiogram (ECG), including the electrophysiology underlying the ECG changes and its implications for the patient. In addition, familiarity with temporary and implanted pacemakers and defibrillators, including transport safety and the ability to troubleshoot problems that may arise with these cardiac devices, is a key skill for CCTPs.

The 12-lead ECG graphically represents electrical activity in cardiac tissue. Cardiac monitoring in the CCT setting typically includes a view of the heart's electrical rhythm in three or more leads and, when indicated, the serial evaluation of 12-lead ECGs. In some cases, additional precordial leads are placed for the diagnosis of right ventricular and posterior infarctions. A key role of the CCT team is to continuously monitor the cardiac rhythm and serial 12-lead ECGs, responding to changes with rapid and appropriate interventions. With that in mind, this chapter provides concise methods and patterns of interpretation to help CCTPs develop a deeper understanding of electrophysiology and of both typical and unusual changes observed in electrical activity as a result of injury or illness.

Traditionally, cardiac arrhythmias have been treated pharmacologically. Unfortunately, cardioactive medications often have side effects that can reduce the patient's quality of life; in some cases, they may be ineffective, even when prescribed appropriately and taken with good compliance. The tremendous evolution of pacing technology has allowed more types of arrhythmias to be treated electrically, with patients often having little to no awareness of the times when electrical therapy is being delivered.

Implanted pacemakers, temporary (transvenous and transcutaneous) pacemakers, wearable defibrillators, and implantable cardioverter-defibrillators (ICDs) vastly broaden the array of therapeutic options for patients with advanced heart failure (HF) and for patients with cardiac arrhythmias. These adjuncts also require care providers, including CCTPs, to have considerable levels of technological expertise in their use. This chapter describes aspects of implantable, temporary, and wearable devices and the electrical therapies that may be important during transport.

Cardiac Anatomy and Physiology

The Heart

Although CCTPs are already familiar with cardiac anatomy and physiology, this section provides a brief review. **FIGURE 14-1** shows the anatomy of the heart.

Description

Myocardial cells require an uninterrupted supply of oxygen and nutrients. Indeed, the cardiac demand for oxygen is particularly unremitting because the heart never stops to rest (without catastrophic consequences). Thus, it is essential that the heart have an absolutely reliable blood supply. Oxygenated blood reaches the heart through the coronary arteries **FIGURE 14-2**, which branch off the aorta at the coronary ostia, just above the leaflets of the aortic valve. The numerous connections (anastomoses) between the arterioles of the various coronary arteries allow for the development of collateral circulation in case of blockage. Unfortunately, the coronary arteries are also vulnerable to narrowing from atherosclerotic heart disease. When the lumen of one of the arteries becomes so narrowed that blood flow through it is impeded, the symptoms of angina occur.

Description

Heart Sounds

The purpose of listening to heart sounds is to identify the “lub-dub” that indicates the cardiac valves are operating properly. The major heart sounds are the two normal sounds, S_1 and S_2 **FIGURE 14-3**, and the two abnormal sounds, S_3 and S_4 **FIGURE 14-4**.

S2 "Dub"
S3 "da"
Abnormal third heart sound
S4 "*bla*"
Abnormal fourth heart sound

FIGURE 14-4 The abnormal S_3 and S_4 heart sounds.

© Jones & Bartlett Learning.

Description

S_1 occurs near the beginning of ventricular contraction (systole), when the tricuspid and mitral valves close. The closing of these two valves should occur simultaneously as the pressure within the ventricles increases, an action that creates the "lub" sound. Any delay in the closing of these two valves, heard as a split sound, is considered abnormal.

S_2 occurs near the end of ventricular contraction (systole), when the pulmonary and aortic valves close. As the ventricles relax, these valves close because of backward flow in the pulmonary artery and aorta. The two valves can close simultaneously or with a slight delay between them under normal physiologic circumstances; this action creates the "dub" sound.

S_3 is the result of the end of the rapid filling period of the ventricle during the beginning of diastole. An S_3 sound should occur 120 to 170 ms after S_2, if it is heard at all. S_3 is generally heard in children and young adults. When it is heard in older adults, it often signifies HF. S_3 is sometimes called a gallop, to help differentiate it from the S_4 sound. When S_3 is present, the heartbeat sounds like "dub-lub-dub" (the second sound is the most pronounced, as in the word "Kentucky").

S_4, if heard, coincides with atrial contraction at the end of ventricular diastole. If heard at any other time, it usually means patients have resistance to ventricular filling, as occurs with a weak left ventricle. S_4 is also normally heard in children and young adults. This sound is sometimes called an S_4 gallop, to help differentiate it from the S_3 sound. When S_4 is present, the heartbeat sounds like "lub-dub-dub" (the first sound is more pronounced than the latter two, as in the word "Tennessee").

TABLE 14-1 lists some of the most common heart sounds, where they are heard, and potential associated causes.

TABLE 14-1 Heart Sounds

Heart Sound	Usual Location	Cause
S_1	Loudest in the mitral area; heard using the diaphragm of the stethoscope	Normal
Split S_1	Between the apex of the heart and the sternum, usually during expiration; heard using the diaphragm	May be normal, nonsynchronous closing of mitral and tricuspid valves or pathologic, such as in a bundle branch block, an atrial septal defect, or pulmonary stenosis
S_2	Loudest in the aortic area; heard using the diaphragm	Normal
Split S_2	Loudest in the pulmonic area, usually on inspiration; heard using the diaphragm	May be normal, nonsynchronous closing of aortic and pulmonic valves or pathologic, such as in hypertension
S_3/ventricular gallop	Heard in early diastole just after the S_2; heard at the apex (left ventricular gallop) or at the left sternal border (right ventricular gallop); loudest on expiration with the patient in the lateral position; heard using the bell of the stethoscope	Always abnormal in older adults; indicates ventricular filling; may be normal in children and young adults or present with diseases such as mitral valve regurgitation, hyperthyroidism, and heart failure
S_4/atrial gallop	Heard late in diastole just before S_1, at the apex or over the suprasternal notch; heard best with the bell	May be normal (children and young adults); indicates increased resistance to ventricular filling after the atrial contraction; often present after a myocardial infarction
Systolic murmur	Turbulent blood flow through the valves of the heart, during systole; heard using the diaphragm; location depends on cause	May be normal or present with aortic or pulmonic stenosis or mitral or tricuspid regurgitation
Diastolic murmur	Turbulent blood flow through the valves of the heart, during diastole; heard using the diaphragm; location depends on cause	Always abnormal; present with mitral or tricuspid stenosis, or aortic or pulmonic regurgitation

Heart Sound	Usual Location	Cause
Pericardial friction rub	Scratchy, high-pitched sound heard throughout the cardiac cycle; best heard with the patient leaning forward, at the third intercostal space to the left of the sternum, using the diaphragm	Often present in pericarditis

© Jones & Bartlett Learning.

The Cardiac Cycle

The cardiac cycle comprises one complete phase of atrial and ventricular relaxation (diastole) followed by one atrial and ventricular contraction (systole).

During the relatively longer relaxation phase (normally 520 ms), the left atrium fills passively with blood, under the influence of venous pressure. Approximately 80% of ventricular filling also occurs during this time as blood flows through the open tricuspid and mitral valves.

With atrial contraction, the contents of each atrium are squeezed into the respective ventricle to complete ventricular filling (atrial kick). Approximately 70% to 90% of the blood in the atria fills the ventricles by gravity; the remaining 10% to 30% comes from atrial contraction or atrial kick. At the beginning of ventricular contraction, the atrioventricular (AV) valves snap shut, the two ventricles contract (ventricular systole), and the semilunar valves are forced open. Blood squeezed out of the right ventricle moves forward, through the pulmonic valve, and into the pulmonary arteries. Blood from the left ventricle is pushed through the aortic valve and out into the aorta. Systole is usually accomplished in a little more than half the time it takes to fill the ventricles, about 280 ms.

Functionally, the heart is actually two pumps: a right pump and a left pump, separated by a thin wall (the interventricular septum). These pumps are, for purposes of efficiency, housed in one organ and work in parallel **FIGURE 14-5**.

Description

The right side of the heart is a low-pressure, thin-walled pump: It pumps against the relatively low resistance of the pulmonary circulation. The right atrium collects oxygen-poor venous blood from the superior and inferior venae cavae and the coronary sinus and delivers it to the right ventricle, which then pumps the blood into the pulmonary artery for distribution to the alveoli and oxygenation.

After the blood's passage through the alveoli, the pulmonary veins collect the now oxygen-rich blood and return it to the left atrium, which delivers it to the more thickly walled left ventricle. The left side of the heart is a high-pressure pump: It drives blood out of the heart against the relatively high resistance of the systemic arteries.

At any given time, a major proportion of the body's blood flow may be shunted into one of the two circulation systems: the systemic circulation or the pulmonary circulation. If the right side of the pump fails or weakens and cannot squeeze out its contents efficiently, blood will back up behind the right atrium into the systemic veins, which then become engorged and distended. Distention of the external jugular veins signals a back pressure from the right side of the heart throughout the systemic circulation. As pressure increases within the systemic veins, fluid leaks into the surrounding tissues, causing edema. When enough fluid has leaked into the interstitial spaces, edema becomes visible in the subcutaneous tissues (particularly the sacrum and lower extremities); it is less readily visible but equally present in the liver, walls of the intestine, and other internal tissues.

By contrast, if the left side of the pump fails or weakens, blood backs up behind the left atrium into the pulmonary circulation. As pressure builds in the pulmonary veins, fluid is squeezed into the alveoli, producing the characteristic signs and symptoms of pulmonary edema: dyspnea, crackles, and pink, frothy sputum.

Description

The arterial walls are highly sensitive to stimulation from the autonomic nervous system. In response to such signals, the arterial diameter may change significantly as arteries contract or relax. Baroreceptors sense changes in blood pressure and, in turn, stimulate the autonomic nervous system. Increased blood pressure activates baroreceptors within the parasympathetic nervous system, resulting in a lowered heart rate and decreased myocardial contractility. Decreased blood pressure activates baroreceptors within the sympathetic nervous system, resulting in an increased heart rate and greater myocardial contractility. Blood pressure is influenced not only by the cardiac output and the fluid volume present in the system, but also by the relative constriction or dilation of the arteries.

Chemoreceptors also play a role in autonomic nervous system activation in response to continual monitoring of the partial pressure of oxygen (PO_2) and pH or the partial pressure of carbon dioxide (PCO_2). Chemoreceptors not only stimulate the autonomic nervous system (thereby affecting heart rate and myocardial contractility), but also promote release of dopamine and ultimately cause the respiratory centers in the brainstem to increase or decrease minute ventilation. For example, when the chemoreceptors sense a hypoxia, acidosis, or hypercarbia condition, they trigger sympathetic stimulation, resulting in an increased heart rate and contractility. In contrast, hyperoxia, alkalosis, and hypocarbia lead to parasympathetic stimulation, which produces a decreased heart rate and lessened contractility.

Functioning of the Pump

The following terms are important to understand how the heart functions as a pump:

- *Cardiac output (CO)* is the amount of blood that is pumped out by either ventricle. The left and right ventricles are approximately equal in interior size, so the two ventricles have relatively equivalent outputs. The normal CO for an average adult is 4 to 6 L/min.
- *Stroke volume (SV)* is the amount of blood pumped out by either ventricle in a single contraction (heartbeat). Normally, the SV is 60 to 100 mL, but the healthy heart has considerable spare capacity and can easily increase the SV by at least 50%.
- *Heart rate (HR)* is the number of cardiac contractions (heartbeats) per minute—in other words, the pulse rate. The normal rate for adults is 60 to 100 beats/min.

The volume of blood that either ventricle pumps out per minute equals the volume of blood it pumps out in a single contraction times the number of contractions per minute:

$$\text{CO} = \text{SV} \times \text{HR}$$

When the body has an increased demand for oxygen, the heart must be able to increase its output several times over. The heart can achieve this feat by increasing SV, increasing HR, or both.

The heart has several ways of increasing SV. One characteristic of cardiac muscle is that, when it is stretched, it contracts with greater force up to a limit, a property called the Frank-Starling mechanism. If an increased volume of blood is returned from the systemic veins to the right side of the heart or from the pulmonary veins to the left side of the heart, the muscle surrounding the cardiac chambers must stretch to accommodate the larger volume. The more the cardiac muscle stretches, the greater the force of its contraction is, the more completely it empties, and, therefore, the greater the SV will be. From the CO equation, it is clear that any increase in SV, with HR held constant, will cause an increase in the overall CO.

The volume of blood returned by the veins to the heart influences preload (the pressure under which a ventricle fills). In situations of increased oxygen demand, the body returns more blood to the heart (preload increases), and CO consequently increases through the Frank-Starling mechanism. In a diseased heart, the same mechanism is used to achieve a normal resting CO (which explains why some diseased hearts become enlarged).

The heart can also vary the degree of contraction of its muscle *without* changing the stretch on the muscle, an ability called contractility. Changes in contractility may be induced by medications that have a positive or negative **inotropic** effect. The ventricles are never completely emptied of blood, however. The percentage of blood actually ejected, called the **ejection fraction**, is a reasonable reflection of overall myocardial function. If the heart is more contractile, a larger percentage of the ventricular blood will be ejected, thereby increasing SV and, hence, CO. The nervous system regulates contractility from beat to beat. When the body requires increased CO, nervous signals increase myocardial contractility, thereby augmenting SV.

The heart can also increase its CO, given a constant SV, by increasing HR (the number of contractions per minute). This change is referred to as a positive **chronotropic** effect.

The Frank-Starling mechanism is an intrinsic property of heart muscle; that is, it is not under nervous system control. By contrast, contractility and changes in HR are regulated by the nervous system.

The Electrical Conduction System of the Heart

Heart muscle can generate its own electrical impulses without nervous system stimulation, a property called automaticity. In addition, the heart is endowed with an electrical conduction system, consisting of specialized conduction tissue that can rapidly propagate electrical impulses to the muscular tissue of the heart. The provider may record these impulses on the ECG; therefore, all CCTPs need to understand the relationship between the activities of the body's electrical conduction system and 12-lead ECG interpretation.

Visualizing the process of impulses traveling in different directions helps to clarify what is happening in the heart. Visualizing the travel of impulses also promotes an understanding of how changes in the structure or function of the heart can alter that travel.

The Dominant Pacemaker: The Sinoatrial Node

Theoretically, any cell within the heart's electrical conduction system can act as a pacemaker. In the normal heart, however, the dominant pacemaker is the sinoatrial (SA) node **FIGURE 14-7**. The SA node receives blood from the right coronary artery (RCA). If the RCA is occluded, as in a myocardial infarction (MI), the SA node may become ischemic. The subsequent death of the conduction cells will prevent the SA node from firing.

Right bundle branch
Left bundle branch
Left posterior fascicle
Purkinje fibers
Left anterior fascicle

FIGURE 14-7 The electrical conduction system.

© Jones & Bartlett Learning.

Description

The SA node initiates the electrical discharge that passes through the **intra-atrial pathways** (or intranodal pathways); in physiology, these are sometimes called atrionodal pathways and include the anterior or Bachman bundle, middle bundle, and posterior internodal system. The SA node is the fastest pacemaker in the heart. Electrical impulses generated in this node spread across the two atria through internodal pathways in the atrial wall in approximately 80 ms, causing the atrial tissue to depolarize as they pass. In 85% to 90% of the population, the blood supply for the SA node comes from a branch of the RCA; in the remaining 10% to 15% of the population, it comes from a branch of the left circumflex artery. The conduction of the impulse is delayed in the AV node for approximately 120 ms so that the atria can empty into the ventricles.

When the atrial rate becomes very rapid, not all atrial impulses can get through the AV junction. Normally, however, impulses pass through it into the bundle of His and then move rapidly into the right and left bundle branches located on either side of the interventricular septum. Next, they spread into the Purkinje fibers, which comprise thousands of fibrils distributed through the ventricular muscle. It takes approximately 80 ms for an electrical impulse to spread across the ventricles, during which time the ventricles contract simultaneously. The effect on the velocity of conduction is referred to as the **dromotropic** effect.

Depolarization and Repolarization

As the electrical impulses travel along these pathways, they come in contact with the cardiac cells, which continue the process of generating electrical impulses or depolarization through the properties of automaticity and conductivity. **Depolarization**, the process by which muscle fibers are stimulated to contract, comes about through changes in the concentration of electrolytes across cell membranes. Myocardial cells, like all cells in the body, are bathed in an electrolyte solution. Chemical pumps inside the cell maintain the concentrations of ions within the cell, in the process creating an electrical gradient across the cell wall. Consequently, a resting (polarized) cell normally has a net charge of –90 mV with respect to the outside of the cell.

When the myocardial cell receives a stimulus from the conduction system, the permeability of the cell wall changes as specialized channels are opened in such a way that sodium ions (Na^+) rush into the cell, causing the inside of the cell to become more positive. Calcium ions (Ca^{+2}) also enter the cell, albeit more slowly and through a different set of specialized channels, helping maintain the depolarized state of the cell membrane and supplying calcium ions for use in contraction of the cardiac muscle tissue. This reversal of electrical charge (ie, depolarization) starts at one spot in the cell and spreads in a wave along the cell until the cell is completely depolarized. The entire process causes a “wave of depolarization” as the electrical charges pass in all directions from one cell to another. The larger the mass of cardiac muscle, the larger this wave of depolarization will be. As each cell depolarizes, it creates a small electrical vector. In the wave of depolarization, the sum of all these small vectors creates the electrical axis, described later in more detail.

As the cells depolarize and calcium ions enter them, mechanical contraction of the cardiac cells occurs. During diastole, the coronary arteries fill and cardiac circulation occurs. As the cells contract from the base of the heart through the apex, blood is pumped through the pulmonary and systemic circulation.

Following depolarization, each cell must recharge by shifting intracellular electrolytes back into place to ready itself for this continual process. The cell is able to recover from depolarization through a process called **repolarization**. Repolarization starts with the closing of the sodium and calcium channels, which stops the rapid inflow of these ions. Next, special potassium channels open, allowing a rapid escape of potassium ions (K^+) from the cell. This process helps restore the inside of the cell to its negative charge; the proper electrolyte distribution is then reestablished by pumping sodium ions out of the cell and potassium ions back in. After the potassium channels close, this sodium–potassium pump helps move sodium and potassium ions back to their respective locations. For every three sodium ions that this pump moves out of the cell, it moves two potassium ions into the cell, thereby maintaining the polarity of the cell membrane. To accomplish this task, the sodium–potassium pump moves ions against the natural gradient through a process called active transport, which requires the expenditure of energy.

TABLE 14-2 summarizes the roles of the various electrolytes in cardiac function.

TABLE 14-2 The Role of Electrolytes in Cardiac Function

Electrolyte	Role in Cardiac Function
Sodium (Na^+)	Flows into the cell to initiate depolarization
Potassium (K^+)	Flows out of the cell to initiate repolarization • Hypokalemia → increased myocardial irritability • Hyperkalemia → decreased automaticity, conduction, and contractility
Calcium (Ca^{+2})	Has a major role in the depolarization of pacemaker cells (maintains depolarization) and in myocardial contractility (involved in contraction of heart muscle tissue) • Hypocalcemia → decreased contractility and increased myocardial irritability • Hypercalcemia → increased contractility
Magnesium (Mg^{+2})	Stabilizes the cell membrane; acts in concert with potassium, and opposes the actions of calcium • Hypomagnesemia → prolonged conduction • Hypermagnesemia → increased myocardial irritability

© Jones & Bartlett Learning.

A myocardial cell cannot respond normally to an electrical stimulus from the conduction system unless it is fully polarized. The period when the cell is depolarized or in the process of repolarizing (the **refractory period**) consists of two phases. In the **absolute refractory period**, the heart muscle has been drained of energy and needs to recharge; it will not contract during this period. In the **relative refractory period**, the heart is partially charged, but not strongly enough to create a full contraction.

Secondary Pacemakers

The SA node normally has the most rapid intrinsic rate of firing (60 to 100 times per minute), so it will literally outpace any slower conduction tissue. If it becomes damaged or is suppressed, any component of the conduction system may act as a secondary pacemaker. The further down the conduction system the pacemaker is, the slower its intrinsic rate of firing will be. Thus, the AV junction will spontaneously fire 40 to 60 times per minute, whereas the ventricular Purkinje system, which is further removed from the SA node, will spontaneously fire only 20 to 40 times per minute.

Measuring the Electrical Conduction Activity of the Heart

The electrical conduction events in the heart can be recorded on an ECG as a series of waves and complexes **FIGURE 14-8**. The depolarization of the atria produces the P wave. It is followed by a brief pause as conduction is momentarily slowed through the AV node or AV junction, which can be seen on the ECG as the **PR interval**. Collectively, the electrical impulses that pass through the right and left bundle branches and Purkinje fibers, representing depolarization of the ventricles, are depicted by the **QRS complex**. Repolarization of the atria and ventricles produces the **T wave**; however, the atrial repolarization wave is small and is buried within the QRS complex, so it is not seen on the ECG. The larger ventricular T wave follows the QRS complex. The **ST segment**, which comprises the section of the complex spanning from the end of the QRS complex to the beginning of the T wave, is important in ECG interpretation and represents the period of inactivity between ventricular depolarization and repolarization. Mechanically, it represents the time that the myocardium is maintaining contraction. Finally, a U wave may be present after the T wave. It is unclear exactly what the U wave represents, but its presence can suggest certain conditions discussed later in this chapter.

Description

Any event that changes the structure or function of the cardiac cells typically results in changes in the normal size and shape (morphologic features) of the complexes recorded on the ECG. The strategically placed ECG leads detect this electrical wave of depolarization in the selected positive lead, and the wave is recorded on the ECG as the familiar P-QRS-T waveform.

Cardiac Monitoring: 12-Lead ECG

Monitoring Versus Assessment

Today's cardiac monitors and defibrillators are typically multiparameter devices that can combine continuous 3-lead ECG monitoring, 12-lead electrocardiography, semiautomatic and manual defibrillation, external pacing, capnography, pulse oximetry, blood pressure monitoring, end-tidal carbon dioxide measurements, invasive pressure monitoring, and other capabilities.

Assessment of the patient's cardiac status takes place before monitoring. This assessment should include an analysis of the cardiac rhythm and 12-lead ECG to determine any underlying electrical disturbances caused by changes in the structure or function of the heart as a result of disease, ischemia, injury, or infarction.

Cardiac monitoring generally refers to the continuous observation of the patient's condition in relation to the cardiac rhythm. Typically, monitoring uses lead configurations for viewing groups of one to three leads simultaneously. If a patient's heart rhythm changes during the monitoring process, it can quickly be verified in multiple leads and the appropriate intervention can be initiated.

Lead Placement

The equipment used to record the ECG may vary widely. Lead placement could also vary when using a machine that derives the 12-lead ECG from a 5- to 6-lead system. Several manufacturers currently produce this equipment, and each has its own proprietary lead set and lead configurations. Major problems can result from using different techniques to acquire the "standard" 12-lead ECG. The gold standard for 12-lead ECG interpretation is the ability to perform serial evaluations for comparison; however, it is important to use consistent lead placements to ensure that all providers compare "apples to apples." Therefore, for simplicity and consistency, in this chapter the discussion of 12-lead ECG will use the “standard” lead placements and the views recorded from them.

The terms *lead*, *electrode*, and *cable* are often used interchangeably, which can be misleading; standard terminology should be used to avoid confusion. The **electrode** is the sensing device that connects directly to the skin; it is usually a self-adhesive pad with some form of conduction media embedded in it to improve the connection of the electrode to the skin, thus improving the quality of the ECG. The **lead** is the designated position of the electrode (ie, limb and precordial/chest leads); it names the electrode placement, which explains why these two terms are often used synonymously. The **cable** is the physical wire that connects the electrode to the ECG monitor.

Before connecting the electrodes to the patient’s chest, the CCTP should prepare the patient’s skin to help improve the quality of the ECG. The skin should be clean and dry, and should be slightly abraded by rubbing with a gauze pad. In addition to drying the skin, the latter step helps remove oils and improves the connection with the electrode. The skin may also be wiped with an alcohol pad to assist in drying the skin and removing oils. In a patient with excessive chest hair (or back hair, when additional nonstandard posterior leads are used), the hair should be clipped with a safety razor before connecting the electrodes. Other unusual conditions affecting the quality of the connection with the electrode to the skin should be corrected as necessary. In patients with extreme diaphoresis, it may be necessary to use topical benzoin or another skin preparation compound to enhance adherence of electrodes to the skin.

The importance of the conduction medium applied to the skin electrode cannot be overemphasized. Because this medium is most often a gel and subject to drying if exposed to air, electrodes applied to the patient should be replaced daily. Additionally, electrodes and pacer/defibrillator pads should remain sealed in their packaging prior to use to prevent drying of the conductive medium, which usually occurs within 24 hours of being exposed to air.

To get an accurate illustration and record the electrical activity of the heart, the leads must be placed so that each provides a unique view **FIGURE 14-9**. The six **limb leads** (I, II, III, aVR, aVL, and aVF [a, augmented; V, voltage; R, right arm; L, left arm; F, foot]) provide a view of the heart in a vertical plane, also called the frontal plane. In contrast, the six **precordial leads** (V_1 to V_6), or chest leads, show a horizontal plane. When the leads are placed in the standard locations, each provides a view of a particular region of the heart. For this reason, it is important to place the leads in the proper location each time. The combination of limb leads and precordial leads provides a three-dimensional view of the heart **FIGURE 14-10** and **FIGURE 14-11**. The six limb leads are created using only four electrodes (right arm, left arm, right leg, and left leg); the four electrodes on the body create six actual readings on the ECG.

Description Description

The average of all electrical impulses generated in the heart can be detected and recorded by the ECG monitor through the combination of leads. These electrical impulses are displayed on the cardiac monitor and can be printed in a standard ECG format.

To better understand the normal waveforms such as P-QRS-T and any additional electrical impulses or changes in the typical presentation, CCTPs should recall that electricity flows from negative toward positive. All ECG leads are considered positive when selected to record the electrical impulse. If the flow of electrical activity proceeds unimpeded toward a positive lead, it will be represented as a positive deflection on the ECG. If the flow of electrical activity flows away from a positive lead, it will be deflected negatively. An electrical impulse that crosses perpendicular to a positive lead is called isoelectric **FIGURE 14-12**.

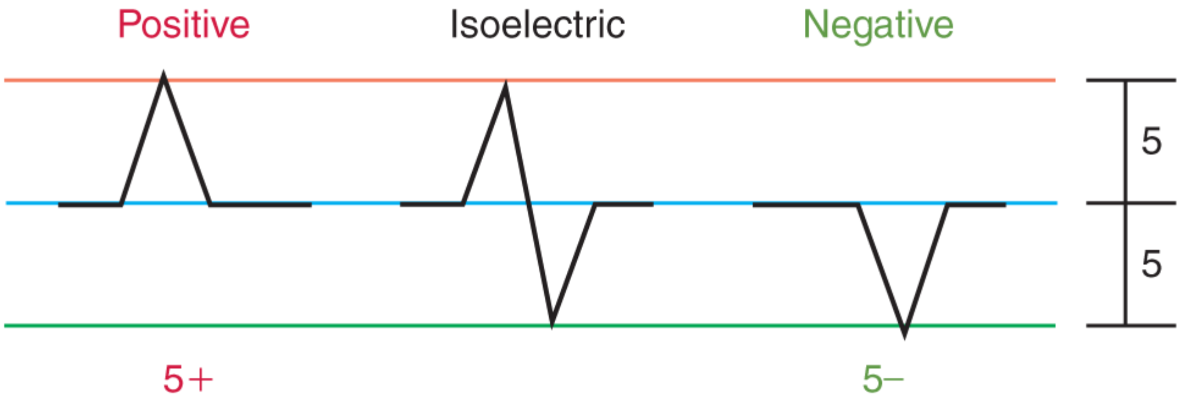

FIGURE 14-12 Representation of positive, isoelectric, and negative QRS deflections.

© Jones & Bartlett Learning.

Description

If the electrical impulse of the heart is deflected by a change in structure or function, it will be less positive, aberrantly conducted, or deflected away from the selected electrode. Because the heart is a three-dimensional organ and the electrical impulses travel through the cardiac tissue in all directions, the leads of the cardiac monitor must be placed in the proper anatomic location to detect these impulses. Traditionally, leads have been categorized as unipolar or bipolar, depending on how they function. The standard limb leads I, II, and III are bipolar leads because they use two leads, a positive and a negative, to measure the electrical potential as it flows from one to the other (negative to positive). The augmented leads (aVR, aVL, and aVF) and the precordial (chest) leads (V_1 through V_6) are unipolar because they use a single positive recording electrode.

As shown in Figure 14-9, the limb leads (extremity leads) include the right arm, left arm, right leg, and left leg, as marked on the lead connectors. Accurate, reproducible ECGs can be obtained by placing these limb leads on the arms or shoulders and lower abdomen as long as they are at least 4 inches (10 cm) from the heart. The precordial (chest) leads must be consistently placed in the proper locations:

- V_1 is placed in the fourth intercostal space to the right side (patient's right) of the sternum.
- V_2 is placed in the fourth intercostal space to the left side (patient's left) of the sternum.
- V_3 is placed between V_2 and V_4.
- V_4 is placed in the fifth intercostal space (patient's left) midclavicular line.
- V_5 is placed between V_4 and V_6.
- V_6 is placed in the fifth intercostal space (patient's left) midaxillary line.

The use of additional or nonstandard right-side heart leads (V_4R, V_5R, and V_6R **FIGURE 14-13**) can provide useful information, as can the posterior heart leads V_7, V_8, and V_9 **FIGURE 14-14**, in patients with suspected right ventricular and posterior MIs. The addition of these leads can increase sensitivity and specificity in the detection and location of the infarct. They are also indicated when a patient has clinical findings suggestive of acute coronary ischemia, but the results of the standard 12-lead ECG are normal or nondiagnostic.

Description

Specialized equipment is available for obtaining a right-side ECG, but such a recording can also be readily obtained using a standard 12-lead ECG machine. The principles and methods of reading the additional-lead ECG remain the same as for the 12-lead ECG, except that the leads are "looking" at a different anatomic location. When switching standard 12-lead ECG leads to conform to the nontraditional right-side and posterior leads, the ECG printout should be labeled to represent the leads recorded.

Prior to running an ECG with right-side leads, a standard 12-lead ECG should be completed. Then, the additional leads are attached as follows, using the precordial (chest) leads (in these descriptions, “right” and “left” refer to the patient’s right and left sides, respectively):

- V_4R is placed in the right midclavicular line, fifth intercostal space, and connected using the V_3 lead. V_4R has the greatest diagnostic accuracy for RV infarct.
- V_5R is placed in the right anterior axillary line, on a straight line from V_4R, and connected using the V_2 lead.
- V_6R is placed in the right midaxillary line, on a straight line from V_5R, and connected using the V_1 lead.
- V_7 is placed in the left posterior axillary line, on a straight line from V_6, and connected using the V_4 lead.
- V_8 is placed in the left midscapular line, on a straight line from V_7, and connected using the V_5 lead.
- V_9 is placed in the left paraspinal line, on a straight line from V_8, and connected using the V_6 lead.

In the past, the bipolar lead MCL_1 (modified chest lead 1) has been used as a substitute for cardiac monitoring when using a 3-lead system. Recent research, however, has shown that QRS morphologic features, when recorded simultaneously with V_1 and MCL_1, are different in a significant number of cases (38%). Thus, this recording is not recommended when it is possible to obtain a true V_1 lead. Given the monitoring systems used in the CCT setting, the 12-lead ECG and multiple-lead monitoring should be the standard of care.

Confirmation of Lead Placement

Confirming lead placement might seem like a redundant act, but in the CCT environment, there are innumerable opportunities for leads to become disconnected. As described later in this chapter, because each lead “looks” at a particular anatomic area of the heart, mixing up the leads will cause erroneous ECG readings, which could result in inappropriate therapeutic interventions. Placement should be confirmed before transport and periodically during transport.

Recording the 12-Lead ECG

The acquisition of a 12-lead ECG is a simple procedure that takes only a few minutes. In the CCT setting, it can be assumed that the patient has already had baseline ECG evaluations and that the ECG monitoring system has been connected to the patient before transport. With interfacility transports, CCTPs must ensure that the monitoring system and lead configuration at the initial facility are consistent with those that will be used during transport. A “new” 12-lead ECG should be recorded and evaluated before transport and then repeated at regular intervals, when any changes in the ECG are noted, and on arrival at the receiving facility. Nevertheless, obtaining additional ECGs should never delay the transport of a patient with an **ST-segment elevation myocardial infarction (STEMI)** to definitive care (STEMI is discussed later in this chapter).

To obtain the best-quality ECG, the patient should remain as still as possible while the ECG is being recorded to minimize artifacts seen on the output. Although the supine position is recommended, an adequate ECG can also be obtained with the patient in a semisitting (semi-Fowler) position. (Any patient position other than supine during ECG acquisition should be noted on the ECG tracing.) The patient’s condition will dictate the position of evaluation during transport. If all required electrodes for 12-lead ECG monitoring have not been applied to the skin, they should be placed before the patient is moved. The skin should be prepared as previously described to provide adequate contact with the electrodes. Following this preparatory phase, with the leads connected to the corresponding electrodes, the 12-lead ECG can be obtained.

Before obtaining a 12-lead ECG, standardization (ie, calibration) is necessary. With the 12-lead ECG, amplitude and duration are important factors, especially in analyzing ST segments and making other measurements. Depending on the equipment, the calibration or standardization should be set so that 1 mV is 10 mm high and 200 ms wide. Some equipment can be set to half-standard calibration. This calibration is usually done when the complexes are so tall that they overlap each other on the ECG paper when recorded. Another calibration on newer machines is the paper speed, which should be set at the standard 25 mm/s, not 50 mm/s, which may have been set as the speed to help evaluate the morphologic features of ECG complexes in a tachycardic rhythm. Be sure to check your machine's calibration. Most newer 12-lead ECG machines can provide a printout of all 12 leads, along with a rhythm strip in lead II or another designated lead.

ECG Paper

ECGs are recorded on graph paper that moves past a stylus at a constant speed (25 mm/s). Thus, the horizontal distance on the graph paper represents a given period. Specifically, one small (1 mm) box is the equivalent of 0.04 second (1/25th of a second), or 40 milliseconds, and one large box (which consists of five small boxes) is the equivalent of 0.20 second, or 200 milliseconds (0.04 × 5 = 0.20). The graph paper's vertical axis represents the amplitude or "gain" of deflection, expressed in mV. The standard calibration for amplitude is 10 mm/mV. A calibration box is printed at the beginning of all 12-lead ECGs. The calibration box informs you of the paper speed and amplitude. It measures 5 mm wide by 10 mm tall, representing the standard 25-mm/s paper speed and 10-mm/mV gain.

Interpretation of the 12-Lead ECG

Acquisition and interpretation of the 12-lead ECG in the CCT setting can pose unique challenges. Typically, time is critical, and using ECG calipers, rulers, axis wheels, and straightedges is particularly difficult in a moving vehicle. These challenges call for greater familiarity with the standard practices and principles of 12-lead ECG interpretation and monitoring. This text emphasizes understanding the electrophysiology underlying ECG changes, which affects how they are depicted on the ECG monitor or printout. Some field-expedient methods of interpretation are discussed to help build the base knowledge expected of the CCTP.

Appearance of the 12-Lead ECG

FIGURE 14-15 provides a graphic representation of what the electrical impulses look like when transmitted to the 12-lead ECG. The configuration of the complexes varies somewhat from lead to lead; therefore, before attempting to identify any abnormalities, CCTPs must know what a typical complex looks like from each lead. In addition, CCTPs must know what a normal 12-lead ECG pattern looks like. If the ECG does not fit this pattern, the CCTP should consider an abnormality to be present.

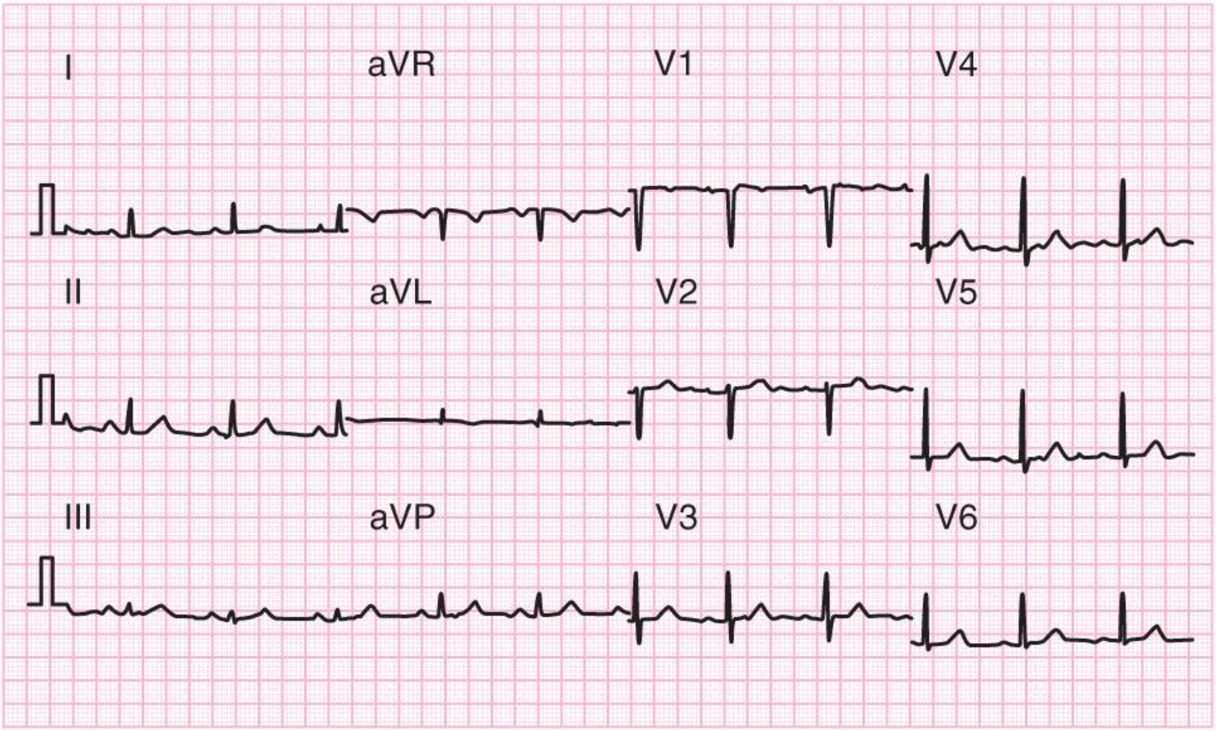

FIGURE 14-15 A normal 12-lead electrocardiogram.

Description

In the limb leads, the P wave is typically upright in leads I, II, aVL, and aVF. It is frequently biphasic in lead III and is purely negatively deflected in lead aVR. In the precordial leads, the P wave is typically upright in leads V_5 and V_6. Lead V_1 is biphasic, and leads V_2 and V_4 are variable. These are the typical presentations for the P wave, although its appearance can vary from person to person. A change in the P-wave morphology suggests an ectopic atrial focus.

The rules for measuring the PR interval remain unchanged from those used in routine cardiac monitoring. The PR interval is a representation of the time from the start of atrial depolarization to the start of ventricular depolarization and includes the delay in conduction that occurs at the AV junction. The PR interval usually lasts from 120 to 200 ms (0.12 to 0.20 s).

The QRS complex is a representation of ventricular depolarization. The septal fascicle delivers the electrical impulse to the interventricular septum, which is the first part of the ventricles to depolarize. Septal depolarization is not always seen on the ECG, but when it is, a small Q wave may be seen in leads I, aVL, V_5, and V_6. **FIGURE 14-16** provides examples of each precordial lead and demonstrates the concept of R-wave progression.

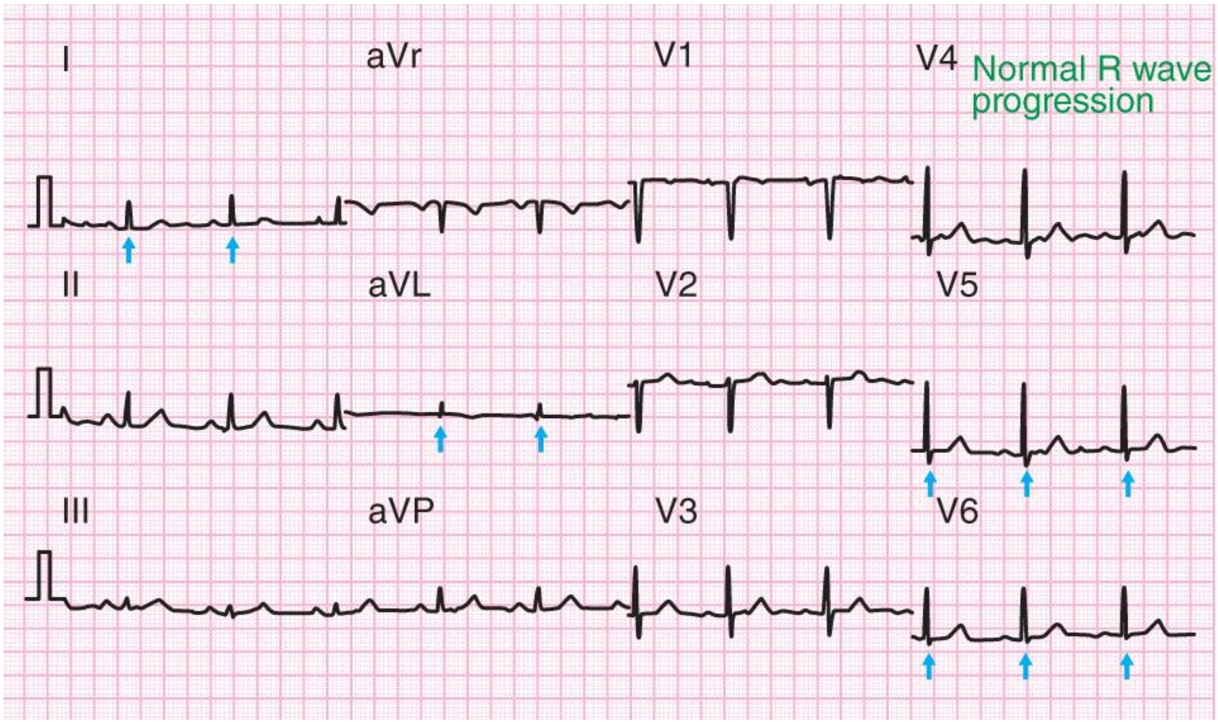

FIGURE 14-16 A small Q wave in leads I, aVL, V_5, and V_6 representing septal depolarization. This electrocardiogram also shows normal R-wave progression.

© Jones & Bartlett Learning.

Description

The T wave will usually be recorded in a positive deflection in the same leads that record a positive deflection of the R wave. In other words, positive T waves are usually found in the same leads that have tall R waves.

As discussed in the lead placement section, each lead provides an enhanced view of a particular region of the heart. The electrical activity picked up by this lead placement is then recorded as complexes from these different perspectives. Understanding that each lead represents a different enhanced view of the heart is the first step in learning to scan the 12-lead ECG by anatomic location **FIGURE 14-17** and **TABLE 14-3**. This skill becomes more relevant as CCTPs begin “localizing” areas of the heart to determine where ischemia, injury, and infarction have occurred. The colors in Table 14-3 will be used to represent these same leads and areas in figures later in this chapter.

It is also useful to know the intrinsic rates of cardiac cells because the CCTP may be able to identify a problem simply by determining the heart rate that is produced **FIGURE 14-18**. The higher the cardiac cell is located in the conduction system in the heart, the faster its "firing rate" will be. The slower pacers found lower in the conduction system will not "normally" fire as long as the higher pacers are functioning properly.

Description

A Systematic Approach to Interpretation of the 12-Lead ECG

A variety of approaches to reading 12-lead ECGs have been recommended by multiple sources. Ultimately, the method used is not as important as consistency in application of that method. Repeatedly using one method ensures reliability, reproducibility, and consistency. The methods described here assume a basic understanding of the elements essential to the fundamentals of ECG interpretation and 12-lead ECGs.

The keys to being able to quickly read an ECG are experience and, as stated, consistency. Interpretation of a 12-lead ECG is a skill that must be practiced repeatedly using a standard method of analysis. However, even specialists can reach widely divergent conclusions when examining a routine ECG tracing. The reason this discrepancy is mentioned is to encourage the use of sound methods of interpretation, documentation of findings, and consideration of every piece of patient information.

During the transport of a critically ill patient, the ECG rhythm must be monitored continuously for changes that require intervention. In this setting, however, monitoring should not be mutually exclusive of serial evaluations of the 12-lead ECG. For systematic analysis of the 12-lead ECG, the interpretation of rhythm and arrhythmias is a fundamental building block. In rhythm and arrhythmia interpretation, there are, in general, 10 key elements that must be assessed.

General

1. Is the rhythm fast or slow?
2. Is the rhythm regular or irregular? If irregular, is it regularly irregular or irregularly irregular?

P waves

3. Are there any P waves?
4. Are all the P waves the same?
5. Does each QRS complex have a P wave?
6. Is the PR interval constant?

QRS complexes

7. Are the P waves and QRS complexes associated with one another?
8. Are the QRS complexes narrow or wide?
9. Are the QRS complexes grouped or not?
10. Are there any dropped beats?

Considering the ever-moving environment of patient transport, a rapid assessment technique should be adapted to consistently review and identify changes seen on the 12-lead ECG. The approach shown in **TABLE 14-4** takes into consideration a variety of situations that must be identified and monitored and/or treated right away.

TABLE 14-4 Rapid 12-Lead ECG Assessment

Verify that aVR is negative (helps to ensure proper lead placement).
Assess rate and rhythm.
Determine the axis (leads I and aVF; also determined by the cardiac monitor's internal diagnostic hardware and printed on the 12-lead ECG).
Identify conduction abnormalities:

- Left bundle branch block
- Hypertrophy
- Aneurysm
- Pericarditis
- Drug or electrolyte imbalance effects
- Early repolarization

Find signs of ischemia, injury, and infarction:

- T-wave inversions
- ST-segment elevation
- Significant Q waves

Identify acute myocardial infarction patterns:

- Anterior
  - ST-segment elevation in V_1, V_2, V_3, and V_4
  - ST-segment depression in II, III, and aVF
- Inferior
  - ST-segment elevation in II, III, and aVF
  - ST-segment depression in V_1, V_2, V_3, or I, and aVL
- Lateral
  - ST-segment elevation in I, aVL, V_5, and V_6
  - ST-segment depression in II, III, and aVF
- Septal
  - ST-segment elevation in I, aVL, V_1, and V_2
- Posterior
  - Tall, wide R waves and ST-segment depression in V_1 and V_2

    - T-wave inversion and ST-segment elevation in alternative posterior leads V_7, V_8, and V_9
- Right ventricular
    - ST-segment elevations in V_4R, V_5R, and V_6R

Consider the patient’s clinical picture.

© Jones & Bartlett Learning.

When examining an ECG tracing, CCTPs should document findings as they are discovered to keep an accurate, complete record of changes for serial evaluations. The ECG is a relatively simple test that can provide information about cardiac anatomy, pathology, and pathophysiology as well as effects of treatment.

The 12-lead ECG shows groupings of complexes that are recorded simultaneously by each lead. The rhythm strip, which typically appears at the bottom of the ECG, records for the entire time that the 12-lead ECG is being obtained. For comparison of cardiac electrical events, the series of complexes viewed in lead I is recorded at the same time as the complexes in the other leads. Their appearances are different because of the angle at which the electrical vectors are viewed.

Axis Determination

As previously mentioned, each cell in the heart can produce its own electrical impulse. Each impulse, in turn, varies in intensity and direction. The term *vector* is used to describe these electrical impulses, and the *axis* is the direction of the wave of depolarization as it passes through the heart. The sum of all of the electrical impulses is called the **mean electrical axis**.

As the electrical impulses or vectors travel through the heart toward the larger muscle mass of the left ventricle, the mean electrical axis should progress in a downward and leftward direction. Because the mean electrical axis is the sum of all vectors traveling in different directions, a change in the patient's normal or preexisting axis indicates that a change has occurred in the structure or function of the heart. For example, in a patient with ventricular hypertrophy, the sum of the electrical vectors will shift toward the enlarged ventricle. If an infarction occurs, the area of myocardium affected will not transmit electrical impulses or will transmit them abnormally, causing a shift away from the infarction. If a section of the electrical conduction system is diseased or blocked, the impulses or vectors will shift away from the affected area.

Although the electrical axis is measured and evaluated by the internal diagnostic software of the cardiac monitor and printed on most standard 12-lead ECGs, any health care provider who reads ECGs must know how these determinations are made. This section explains how to determine the direction of the mean electrical axis.

The Hexaxial System

The **hexaxial system** uses a circular diagram divided into 12 equal segments to describe the frontal plane that is created using the limb leads (I, II, III, aVR, aVL, and aVF) **FIGURE 14-19**. As mentioned earlier, the mean electrical axis is the sum of all vectors generated in the wave of depolarization. To isolate the direction of the axis, two leads are required. To illustrate how this combination of leads is used, the hexaxial circle is divided into four quadrants moving clockwise from 0° to +90°, +90° to 180°, 180° to –90°, and –90° to 0°. A wave of depolarization directed into one of these quadrants will give the general direction of the mean electrical axis.

Description

The QRS complex is a representation of the depolarization of both ventricles. The sum of all the vectors generated creates the mean

QRS vector in a direction downward and to the patient’s left. The mean QRS vector is used to determine the mean electrical axis.

The first lead examined to determine the direction of the mean QRS vector is lead I. Electrical impulses that flow toward the positive electrode create an upright deflection, whereas an electrical impulse that flows away from the positive electrode has a negative deflection. Lead I is the positive lead located at 0°. As the wave of depolarization travels toward lead I, it is shown as a positive deflection on the ECG. If the QRS complex is negatively deflected in lead I, the wave of depolarization shifts away from the left, which means that it is “deviated” toward the right: a right axis deviation (RAD).

The second lead examined to determine the axis is lead aVF. In aVF, the positive electrode is located on the left leg or lower left abdomen at least 4 inches (10 cm) from the heart. Electrically, this placement is at +90°. If the wave of depolarization is downward, it is moving toward the positive electrode in lead aVF and will be shown as a positive deflection of the QRS on the ECG. If the QRS is positive in leads I and aVF, the mean electrical axis is downward (aVF) and toward the patient’s left (lead I). This is the normal axis range **FIGURE 14-20**.

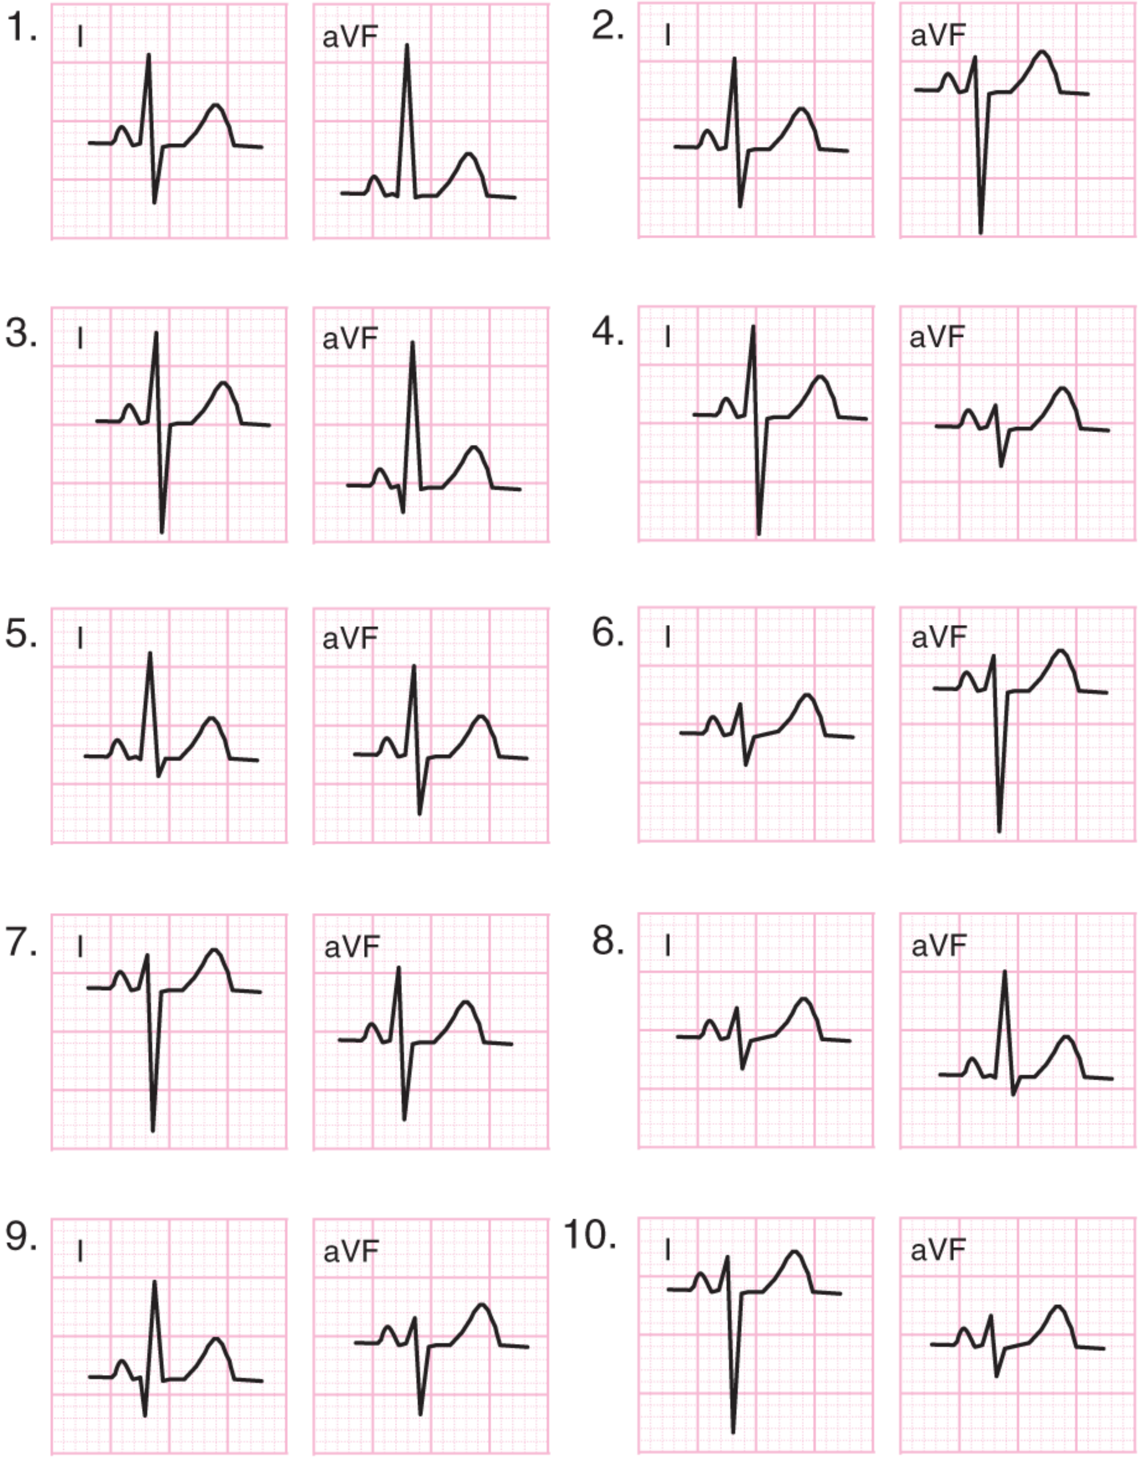
Description

If the QRS complex is deflected positively in lead I, the axis is directed toward the left. A QRS complex that is negatively deflected in lead aVF at the same time that it is positive in lead I indicates that the axis is deflected upward and to the left: a left axis deviation (LAD).

If lead I is deflected negatively, the axis is deviated to the right. If lead aVF is deflected negatively at the same time, the axis is shifted upward and to the right, causing an extreme RAD. Extreme RAD, –90° to 180°, is rare. It occurs when the heart is depolarizing inferiorly to superiorly. Extreme RAD can be seen in ventricular tachycardia (VT), atypical MIs, hyperkalemia, and, occasionally, right ventricular hypertrophy (RVH).

FIGURE 14-21 shows sample ECG waves for practice in determining the quadrant in which the mean electrical axis is located.

The mean QRS axis is in a “quadrant” of normal, RAD, extreme RAD, or LAD. Noting a change in the electrical axis during the transport of a critically ill patient alerts CCTPs to search for the cause of the deviation. Once an abnormal axis is determined, other associated abnormalities can be found. Further evaluation can suggest the appropriate intervention. In the CCT environment, noting the change of axis is more important than calculating the degree of axis. Nevertheless, some rapid assessment techniques can be used to help narrow down the degree of axis.



Remember, use your calipers!

Description

Normal Versus Pathologic Measurements

Before determining the degree of the mean electrical axis, it is important to recognize that the quadrants may overlap to some extent. The methods already discussed provide good approximations of the axis by isolating the quadrant in which it lies. The true pathologic measurements on the hexaxial system are shown in **FIGURE 14-22**.

Description

The normal ranges for the electrical axis extend from –20° to +100°. The 10° overlap from +90° to +100° in the right quadrant is not clinically significant. If the axis lies in either of the two right quadrants, the patient has an RAD.

In determining the left axis, it should be noted that normal extends to –20°. The area from –21° to –29° is considered the "physiologic" left axis and is neither pathologic nor normal. The area from –30° to –

90° is the true pathologic area of the left quadrant, or LAD. The techniques already discussed should be used to isolate the axis in the left quadrant by determining if the QRS is positive in lead I and negative in lead aVF. If lead II is also negatively deflected, the left axis is between –30° and –90° and indicates the presence of a true pathologic LAD.

Calculation of Axis Direction and Intensity

As shown in Figure 14-19, there are a number of ways to calculate the direction and intensity of the electrical axis. An easy way to make this determination is to use the hexaxial system mentioned earlier. This system uses a circular diagram oriented in the frontal (coronal) plane. The diagram is divided into 12 equal segments around the heart, and each division of the diagram is labeled in degrees. The divisions of the lower half of the diagram are given values ranging from 0° to 180°, and the divisions in the upper half of the diagram have values ranging from 0° to –180°. The limb leads (I, II, III, aVR, aVL, and aVF) are overlaid onto this diagram, with each being oriented to its electrical position on the ECG. Lead I is located at 0°, lead II at +60°, lead aVF at +90°, lead III at +120°, lead aVR at –150°, and lead aVL at –30°. On the hexaxial diagram, each lead has a corresponding lead that is 90° away or perpendicular to the other **FIGURE 14-23**.

Description

To use this system to determine the mean electrical axis, first locate the QRS complex that has the lowest amplitude and is the most **isoelectric** in one of the limb leads. Then, find the corresponding perpendicular lead. For example, if the most isoelectric QRS complex is in lead II, located at +60°, the corresponding perpendicular lead would be lead aVL, which runs between +150° and –30°. Next, determine whether the QRS is deflected positively or negatively in the perpendicular lead. If it is positive, the mean electrical axis is +150°. If the QRS is negatively deflected, the mean electrical axis is –30°. **FIGURE 14-24** shows both ends of each limb lead and their corresponding values. Description

Causes of Axis Deviations

Obtaining a baseline ECG on the cardiac monitor to be used during transport is required before transporting a critically ill patient. A complete assessment of the ECG should be made, noting any abnormalities, including the mean electrical axis. An axis that deviates outside the normal range or differs from the patient’s preexisting axis usually has clinical implications. When an axis deviation is detected, CCTPs should always check for corresponding ECG changes that can provide clues to the underlying cause of the deviation.

Common cardiac causes of axis deviation include ischemia and infarction. If the electrical conduction system is affected, the axis will be directed away from the damaged area. One of the areas most commonly affected is the left anterior-superior fascicle of the left bundle branch, an abnormality that results in a left anterior hemiblock (LAH). If an inferior wall MI (IWMI) stops the wave of depolarization, the electrical impulse can be redirected upward and to the left, causing an LAD. With left ventricular hypertrophy (LVH), the enlarged ventricle can draw the electrical axis toward this larger muscle mass, resulting in LAD. Ectopic beats and rhythms can originate anywhere in the heart, directing the wave of depolarization in a right or left direction, causing an axis deviation in the affected area. An RAD is caused by events that redirect the electrical axis toward the right. A congenital cause is **dextrocardia**, which occurs when the heart develops in a right-facing position, creating a mirror image of the normal left-facing heart. Left posterior hemiblock (LPH) occurs with a conduction defect to the left posterior-inferior fascicle of the left bundle branch. Just as an enlarged left ventricle can cause the axis to shift left, an enlarged right ventricle, or RVH, can cause an RAD.

Other conditions that are not cardiac in origin can also contribute to a shift in axis. Any condition that causes the heart to be displaced from the downward leftward position can contribute to this shift. For example, a tall, thin person may have a heart that is displaced (vertically) slightly more downward and away from the left, which can result in a right shift in axis. Children have larger right ventricles compared with adults, so their normal axis points toward the right. Chronic obstructive pulmonary disease (COPD) can lead to RVH, causing an RAD. An LAD can also be caused by mechanical shifts. In patients who are obese or pregnant, the increased intra-abdominal pressure can push up on the diaphragm, displacing the heart into a more horizontal or left position, resulting in an LAD.

TABLE 14-5 summarizes possible causes of various axis deviations.

TABLE 14-5 Possible Causes of Axis Deviation

Axis Deviation	Possible Cause
Right	Right ventricular hypertrophy Left posterior hemiblock Chronic obstructive pulmonary disease Dextrocardia Ectopic beats and rhythms Normal in children
Left	Left anterior hemiblock Left ventricular hemiblock Inferior wall myocardial infarction Ectopic beats and rhythms Obesity Pregnancy

Bundle Branch Blocks and Hemiblocks

When a disruption of the electrical or mechanical response to the wave of depolarization occurs in the heart, bundle branch blocks and hemiblocks may occur. These events may be identified through characteristic changes on the ECG.

Bundle Branch Blocks

A **bundle branch block (BBB)** is a delay or obstruction along the pathway that electrical impulses travel within the heart.

Right BBB

To recognize a block in electrical conduction through the right bundle branch, think of how the wave of depolarization progresses. The electrical impulses that originate in the atria proceed as normal up to the block, with no change in waveforms or intervals. The impulses then continue down the left bundle branch and its fascicles as usual, but are stopped in the right bundle branch **FIGURE 14-25**.

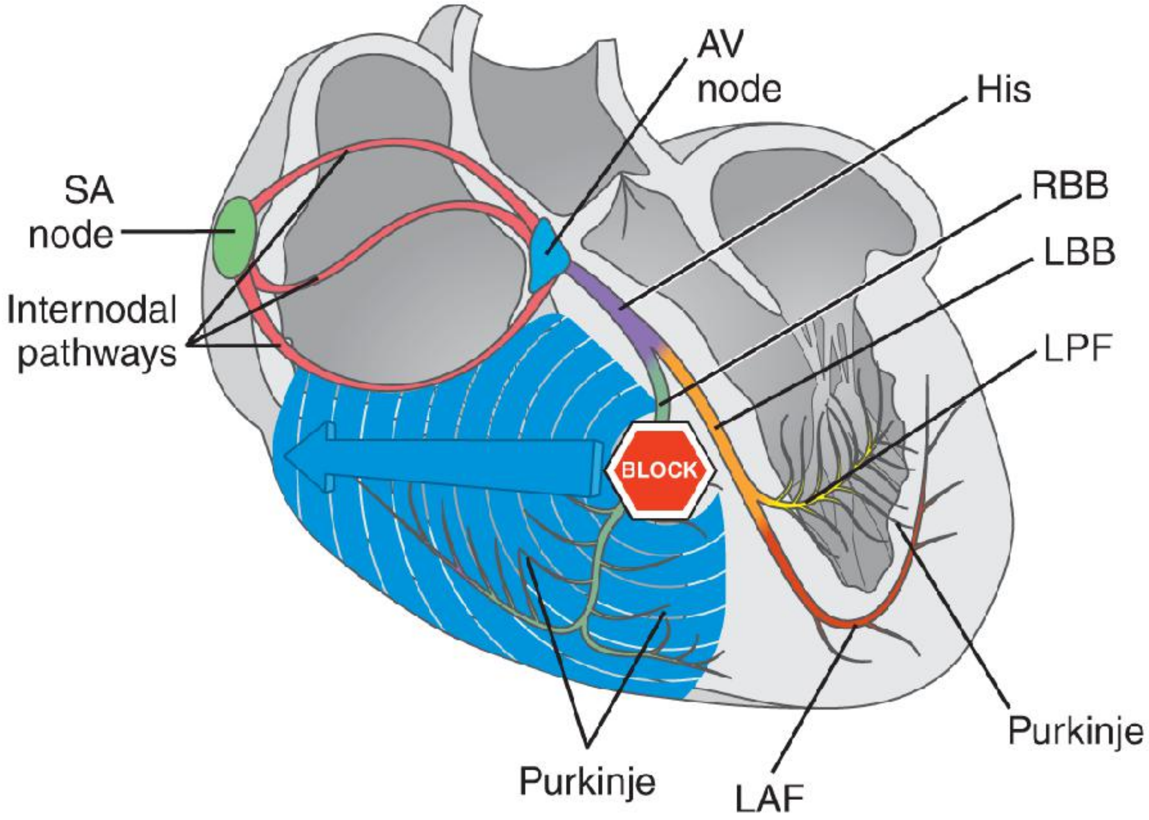

FIGURE 14-25 Right bundle branch (RBB) block.

Abbreviations: AV, atrioventricular; LAF, left anterior fascicle; LBB, left bundle branch; LPF, left posterior fascicle; SA, sinoatrial

© Jones & Bartlett Learning.

Description

Diagnosis

When a block occurs, the wave of depolarization must continue through the right ventricle by cell-to-cell conduction. Because cell-to-cell conduction progresses more slowly than conduction through the normal electrical conduction pathway, the representative complex displayed on the ECG will occur late as well, causing a prolonged QRS interval of 120 ms or more. The ECG initially shows the upstroke of the R wave conducted by the left ventricle and its fascicles. Immediately behind this is the delayed right ventricle depolarization resulting in a second R wave called R′ (R prime). The combination of the normally conducted electrical impulse through the left bundle branch and the delayed conduction through the right bundle branch results in the up and down (“rabbit ear”) appearance of the QRS complex **FIGURE 14-26**.

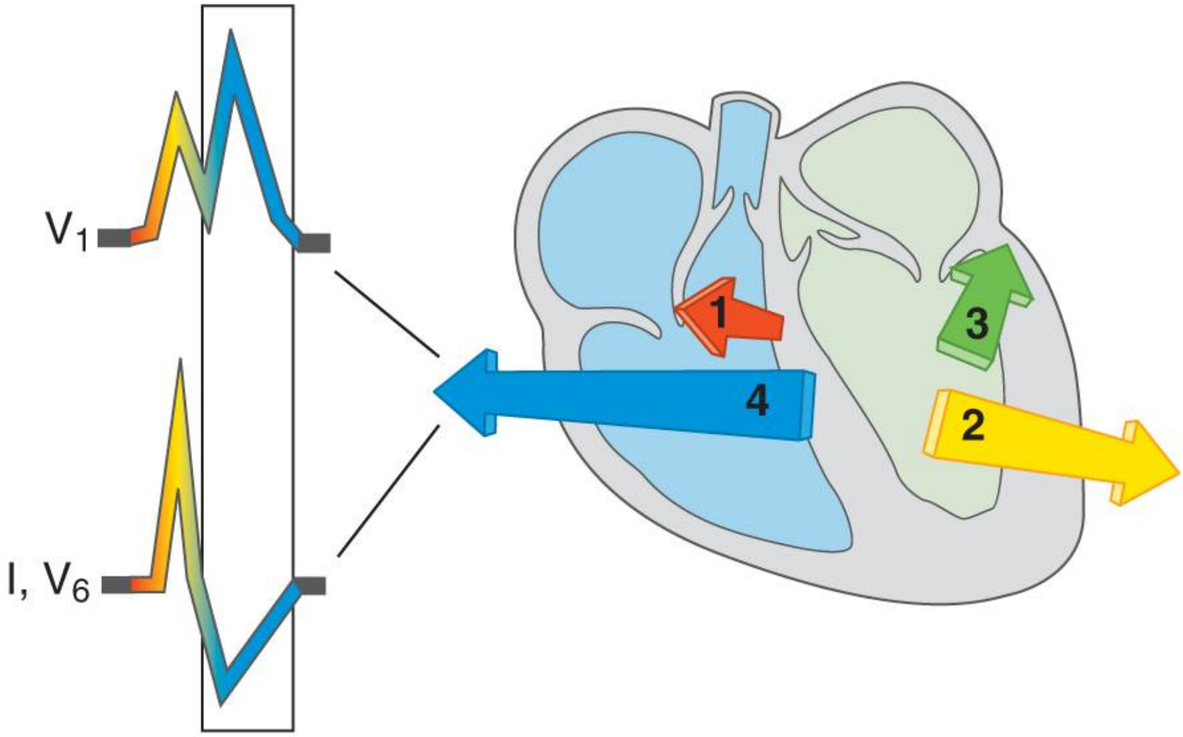

FIGURE 14-26 The effect of a right bundle branch block on the electrocardiogram.

© Jones & Bartlett Learning.

Description

The best lead in which to view the changes associated with a right BBB is the precordial lead, V_1, which shows the rsR′ complex. Lead V_2 can also show the rsR′ complex. The rsR′ complex is one in which a second R wave appears in the second half of the QRS complex. The R′ wave representing the additional vector created by the delayed electrical impulse through the right ventricle will be positively deflected in lead V_1. In addition to the rsR′ complex seen in lead V_1, the delayed conduction through the right ventricle causes a "slurring" of the S wave in the lateral limb lead, lead I, and the left-side precordial lead, V_6. Because other conditions can cause an rsR′ complex (eg, incomplete right BBB, some pulmonary conditions, RVH, and pre-excitation syndromes such as Wolff-Parkinson-White syndrome), the slurred S wave is required for an rsR′ complex to be diagnostic of a right BBB. **FIGURE 14-27** represents the various leads on an ECG and shows relevant areas for a right BBB diagnosis. (Note: This style of illustration is used repeatedly in this chapter.)

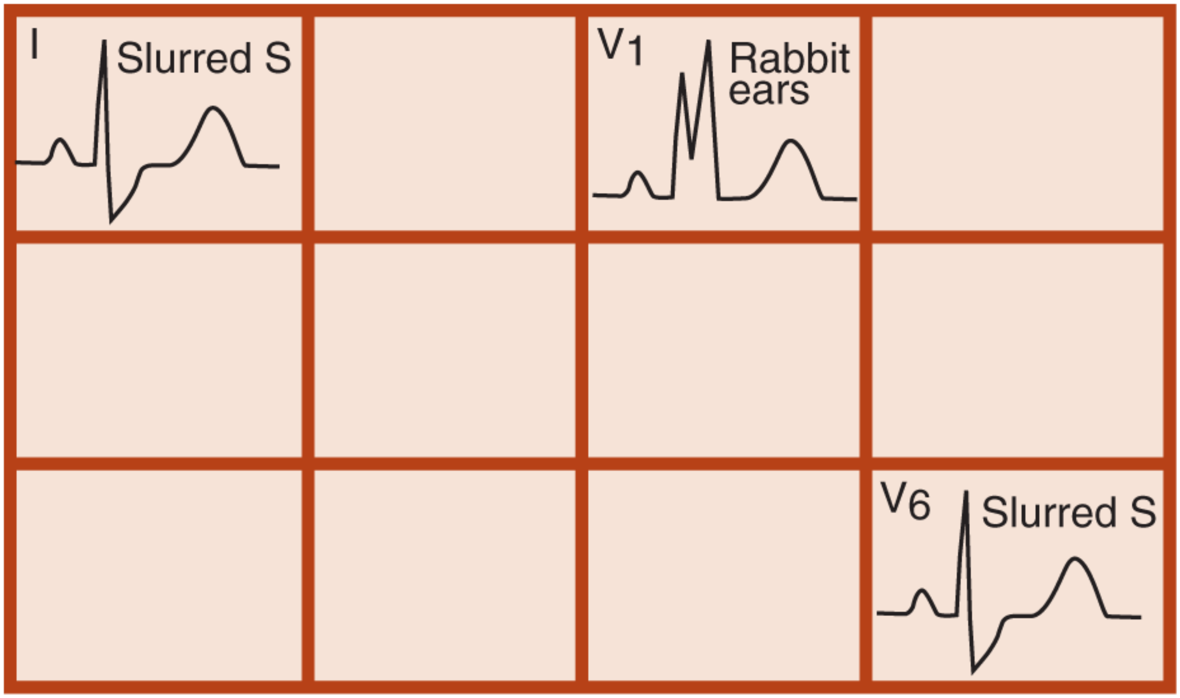

FIGURE 14-27 Electrocardiographic changes seen with a right bundle branch block.

© Jones & Bartlett Learning.

Description

Therefore, the main criteria for the diagnosis of right BBB are as follows:

- QRS prolongation of 120 ms or more

- Slurred S wave in leads I and V_6 (S-wave duration greater than R-wave duration, or S-wave duration greater than 40 ms)
- rsR′ pattern in V_1 and V_2, with the R′ wave taller than the R wave

A right BBB can occur with disruption of the electrical conduction system, and it can be present in a normal healthy heart.

The QR′ Wave

Of the many potential causes of an R′ wave in lead V_1, the one that demands the most attention is the Qr′ or qR′ wave (when their names are written, the larger of the two waves is represented by the uppercase letter) **FIGURE 14-28**.

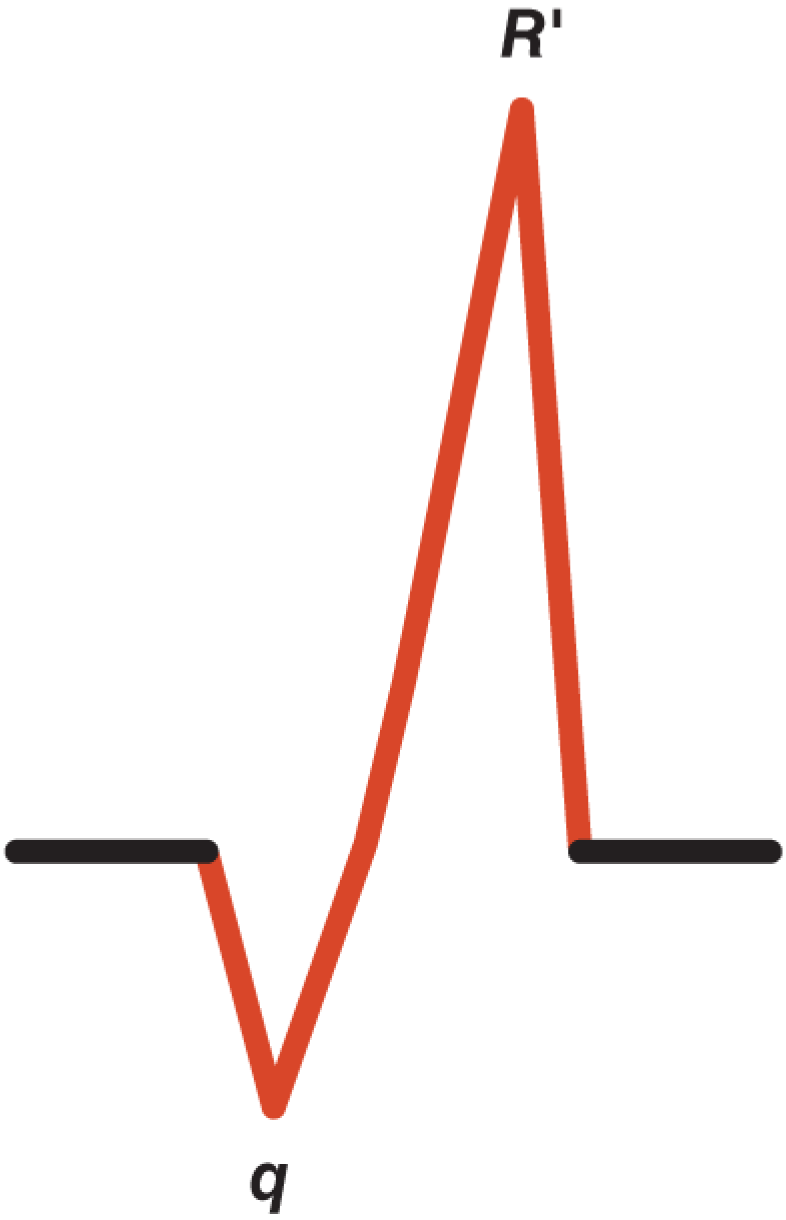

FIGURE 14-28 The qR′ wave.

© Jones & Bartlett Learning.

Description

V_1 is one of the precordial leads that represents the depolarization of the anterior septum (V_2 is the other). A Q wave that occurs in lead V_1 in the presence of a right BBB is evidence of infarction. If this waveform appears during transport of a patient in critical condition, early intervention may prevent ischemia from progressing to infarction.

FIGURE 14-29 provides an example of a right BBB. With practice, by using pattern scanning of the ECG, CCTPs will see the rsR′ complex in the precordial leads that represent septal depolarization. Because the rsR′ complex alone is not sufficient to make a diagnosis of right BBB, the lateral leads, I and V_6, should also be scanned.

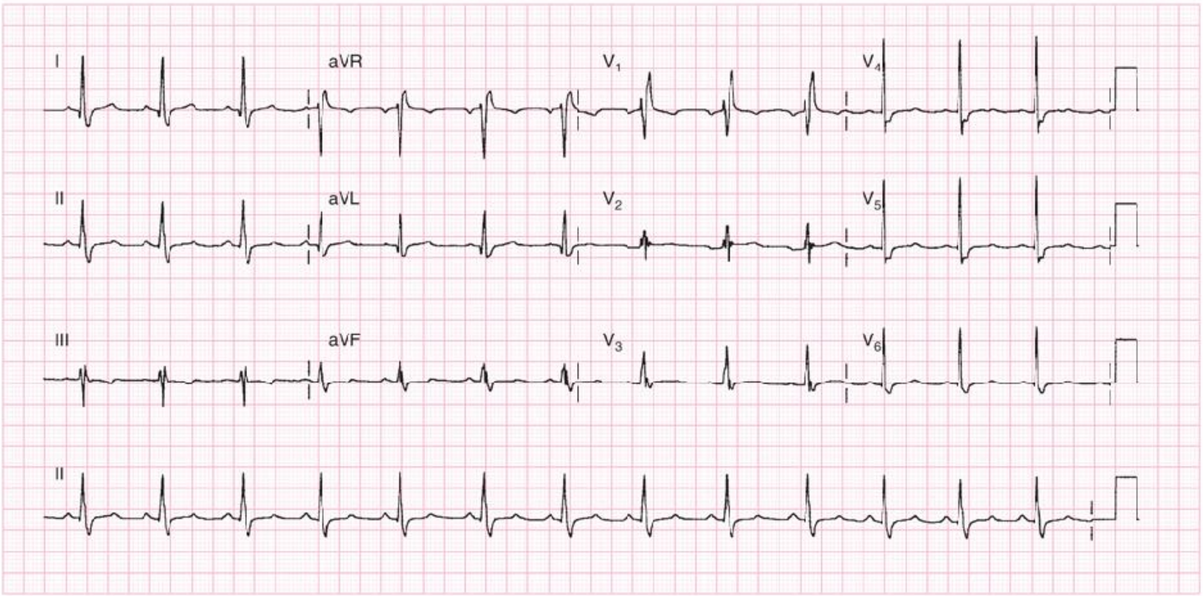

FIGURE 14-29 A 12-lead electrocardiogram showing a right bundle branch block.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

Management

There is no specific treatment required for isolated right BBB. Nevertheless, patients with this condition should have periodic follow-up evaluations.

Left BBB

A left BBB is caused by a disruption of the electrical conduction of the left bundle or both fascicles (the **left anterior fascicle** and the **left posterior fascicle**) of the left bundle. The electrical impulses that originate in the atria proceed as normal, with no change in waveforms or intervals up to the block. The electrical impulses continue to flow unimpeded down the right bundle. With the electrical conduction of the left bundle branch blocked, the wave of depolarization must then proceed by cell-to-cell transmission from right to left **FIGURE 14-30**.

Description

Diagnosis

The delay of electrical conduction in the left bundle branch or its fascicles results in a complex that is 120 ms or longer in duration. Because normal ventricular depolarization proceeds down and to the left, the inferior and lateral leads (I, V_5, and V_6) will show the most direct results of the block. With left BBB, the complexes in these leads will not have Q waves, but rather will typically have tall monomorphic R waves. When the conduction of electrical impulses is delayed, the normal sharp rise of the R wave is replaced with a more gradual or bowed, upward appearance. The peak of the R wave is notched, wide, or both. Reciprocal findings are present in the right-side chest leads in the form of wide, deep, monomorphic S waves. Repolarization is also affected in BBBs. In a left BBB, the T waves should be **discordant**—that is, deflected in the direction opposite to the terminal deflection of the QRS complexes **FIGURE 14-31**.

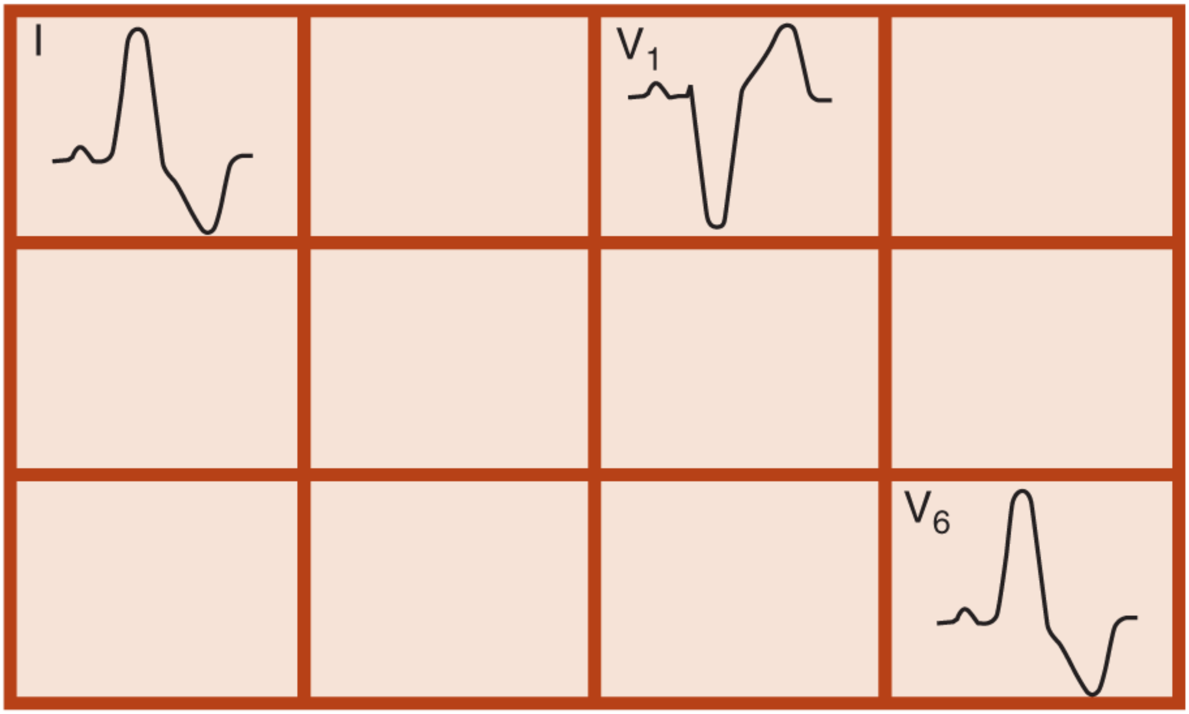

FIGURE 14-31 Electrocardiographic changes seen with a left bundle branch block.

© Jones & Bartlett Learning.

Description

The main criteria for the diagnosis of a left BBB are as follows:

- QRS complex duration of 120 ms or longer
- V_6 should have a notched R wave with no Q wave
- Wide, deep S waves in lead V_1; may also have a small r wave with a large S wave

Lowercase letters are used to represent small waves, whereas capital letters are used to represent large waves. Therefore, “r wave” represents a small wave, whereas “R wave” represents a large wave.

Although a right BBB can be present in a healthy heart, the same is seldom true for a left BBB. Instead, its presence usually means that the patient has a serious problem within the conduction system or ischemia from coronary artery disease. A pacemaker rhythm can also produce wide complexes, so CCTPs should be watchful for pacemaker spikes with a rhythm that has this appearance.

FIGURE 14-32 is an example of a left BBB. The pattern of wide complexes of 120 ms or longer and discordant T waves in every lead indicates that this is a disturbance that affects the ventricular conduction system. The presence of P waves, however, provides assurance that the rhythm originates in the atria and not in the ventricles. The QRS complexes are deflected positively in the lateral leads (I, V_5, and V_6) with corresponding wide, deep S waves in the reciprocal lead, V_1.

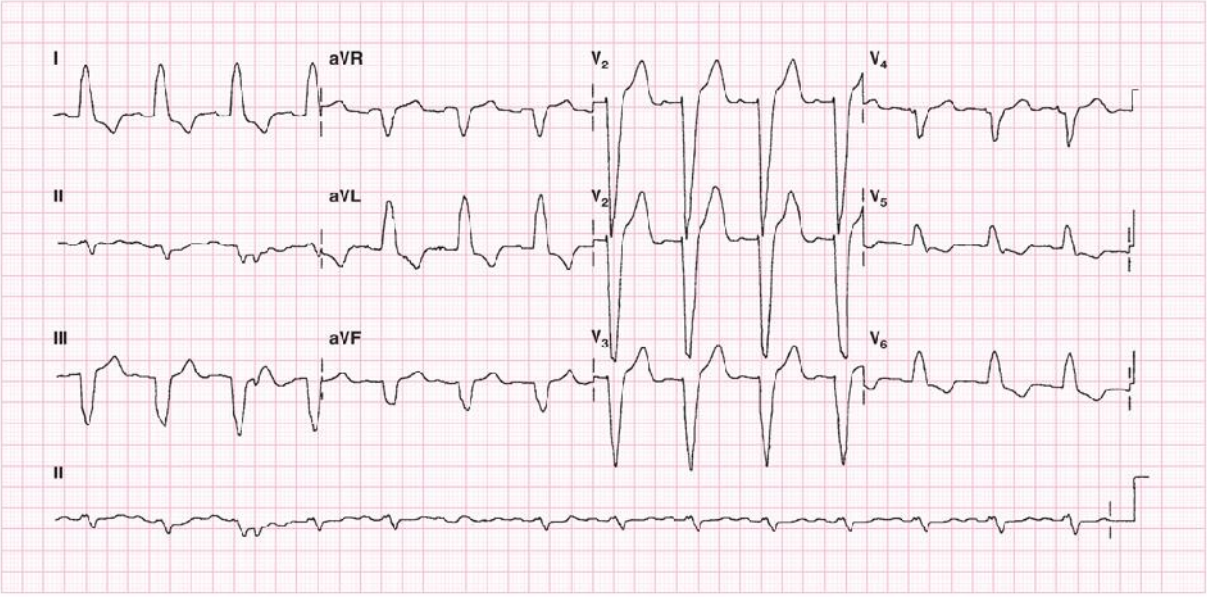

FIGURE 14-32 A 12-lead electrocardiogram showing a left bundle branch block.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

Management

Patients with a left BBB require a thorough cardiac evaluation, and patients with a left BBB and near-syncope or history of syncopal episodes may require a pacemaker. Guidelines for device-based therapy of cardiac rhythm abnormalities have been established and revised by the American College of Cardiology and the American Heart Association. Documentation is key to treatment; hence, any recordings demonstrating left BBB in symptomatic patients should be included in the permanent medical record.

Hemiblocks

A **hemiblock** is a block in the electrical conduction of one of the two fascicles of the left bundle branch. An LAH is the same as a left anterior fascicular block, and an LPH is the same as a left posterior fascicular block. Unlike complete BBBs, hemiblocks cause little to no widening of the QRS complexes because the resultant cell-to-cell transmission of the electrical impulses is much less.

Each fascicle branches off of the left bundle branch. The structures of the two fascicles are quite different, however **FIGURE 14-33**. The left anterior fascicle forms a thin bundle of fibers that conducts electrical impulses to the anterior and lateral walls of the left ventricle. In contrast, the left posterior fascicle forms a broad network of fibers that conducts electrical impulses to the inferior and posterior walls of the left ventricle.

Left bundle branch
Left anterior fascicle
Left posterior fascicle
Right ventricle
Septum
Left ventricle

FIGURE 14-33 Ventricular electrical conduction system.

© Jones & Bartlett Learning.

The structural differences between these two fascicles clarify why a hemiblock occurs more frequently in the left anterior fascicle. Specifically, it would take a smaller area of ischemia or infarction to impede the electrical conduction to a single strand of fibers than to block the conduction to a broad network of fibers. Even though the blood supply to all areas of the heart varies somewhat from person to person, the left posterior fascicle typically receives blood from branches of the left and right coronary arteries, which means that coronary occlusions would have to occur in both sources of blood supply to have a major effect on the left posterior fascicle.

Left Anterior Hemiblock

An LAH occurs when electrical conduction to the left anterior fascicle is blocked **FIGURE 14-34**.

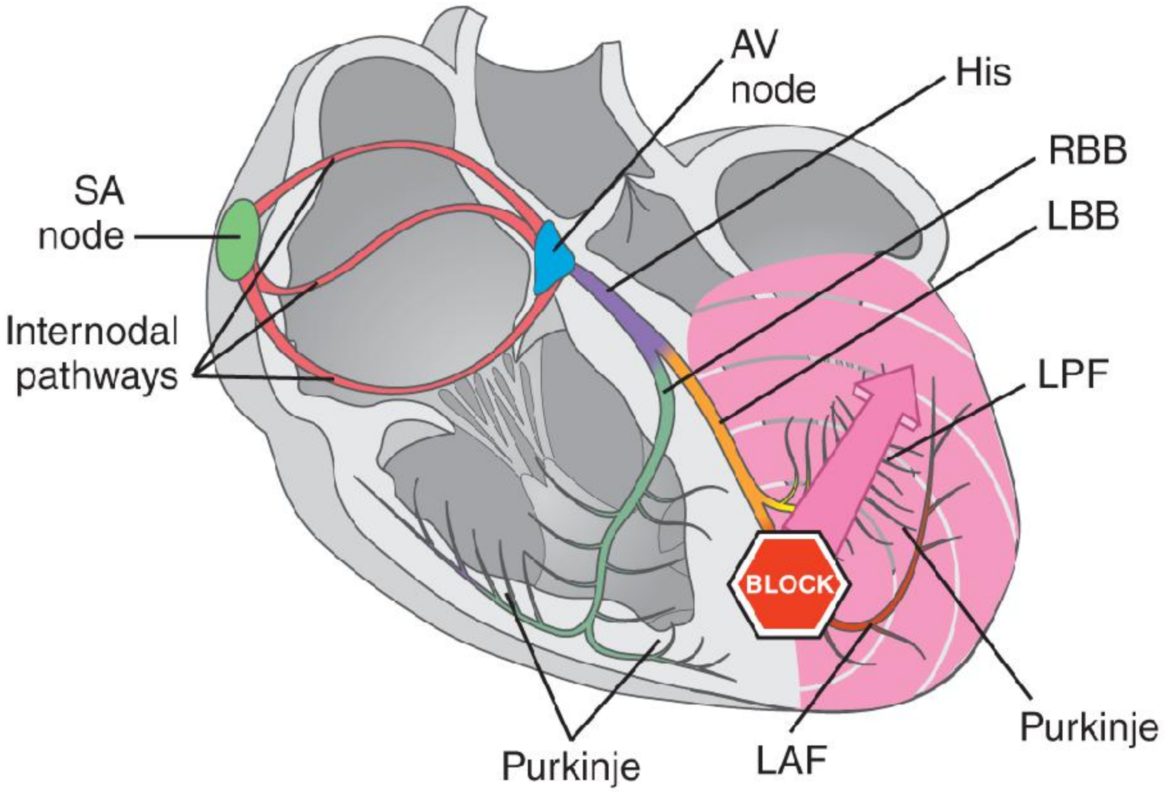

FIGURE 14-34 Left anterior hemiblock.

Abbreviations: AV, atrioventricular; LAF, left anterior fascicle; LBB, left bundle branch; LPF, left posterior fascicle; RBB, right bundle branch; SA, sinoatrial

© Jones & Bartlett Learning.

Description

When conduction to the anterior-superior part of the left ventricle is blocked, depolarization of this area comes from the interventricular septum and retrograde conduction from the inferior and posterior walls. The direction of the wave of depolarization for the blocked area spreads upward and to the left, shifting the electrical axis to the pathologic left, which makes an LAD between –30° and –90° the main criterion for the diagnosis of LAH. Additional findings on the ECG may include a qR complex or a large R wave in lead I. An rS complex also may be found in lead III. These small q and r waves are the result of the interventricular septum depolarizing in an unopposed manner.

The criteria for diagnosing LAH are as follows:

- Left axis deviation within –30° to –90°
- qR complex or large R wave in lead I
- rS complex in lead III (likely to also appear in leads II and aVF)

FIGURE 14-35 is an example of an LAH. The most obvious feature is an LAD. The QRS complex is positively deflected in lead I and negatively deflected in lead aVF. To further isolate this vector to the pathologic range (–30° to –90°), lead II should be examined. Negative deflection, as in this example, confirms the diagnosis of LAD and is presumptive of LAH. Other criteria for LAH are also evident in this example. There is a qR complex in lead I, and there are rS complexes in leads II, III, and aVF. The Q waves that appear in leads I and aVL are insignificant; they are normal and represent the first vector of ventricular depolarization. For a Q wave to be significant and represent an MI, it must be more than one-third the total height of the QRS complex with which it appears and must also be more than 40 ms in duration.

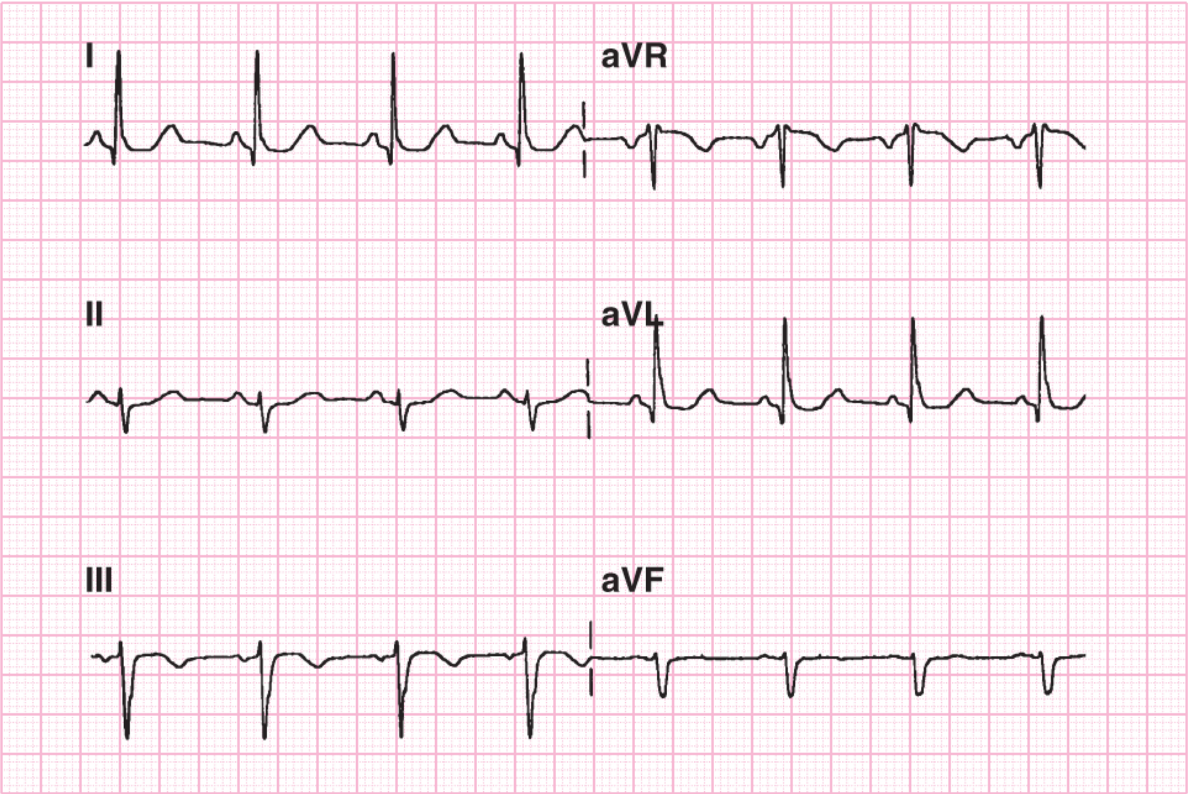

FIGURE 14-35 A 12-lead electrocardiogram showing a left anterior hemiblock.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

Left Posterior Hemiblock

An LPH is exceedingly rare because of the dual blood supply to the area and the broad network of fibers that must be blocked to create this condition **FIGURE 14-36**. In addition to being rare, LPH is more difficult to diagnose. When the depolarization of the inferior and posterior portions of the left ventricle is delayed, the resultant wave of depolarization is directed farther inferior and to the right. This rightward deflection results in an RAD. The electrical impulses conducted up to the block are unopposed and depolarize the interventricular septum and the superior-anterior walls of the left ventricle. This development is shown on the ECG as a small r wave in lead I and a small q wave in lead III.

Description

The criteria for diagnosing LPH are as follows:

- RAD of 190° to 180°
- r wave in lead I and q wave in lead III
- Exclusion of right atrial enlargement and/or RVH

An LPH is a diagnosis of exclusion, which is one reason it is more difficult to diagnose. Other causes of RAD, such as right atrial enlargement and RVH, must be ruled out. Certain chronic lung diseases that cause an overload of the right atrium can be the cause of an RAD. With these additional factors to consider in diagnosing

LPH, when an RAD is found, an r wave in lead I and a q wave in lead III should be sought. With no other evidence of right atrial enlargement or RVH, LPH needs to be considered.

FIGURE 14-37 is an example of an LPH. The figure shows an RAD, as well as an s wave in lead I and an insignificant q wave in lead III. There is no evidence of right atrial enlargement.

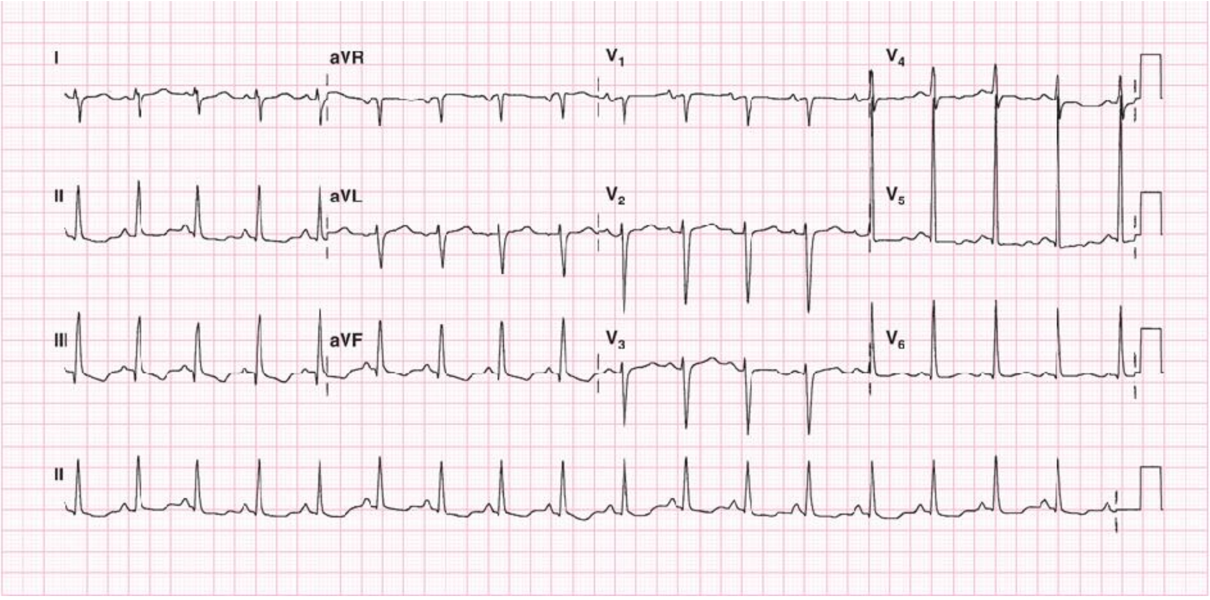

FIGURE 14-37 A 12-lead electrocardiogram showing a left posterior hemiblock.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

A pulmonary condition that makes the diagnosis of LPH impossible in many cases is pulmonary embolism. In 15% to 30% of patients with a pulmonary embolism, there is an ECG pattern of $S_1Q_3T_3$ caused by acute right ventricular strain (S_1Q_3 is also a criterion for LPH). This pattern features an s wave in lead I, and a q wave and an inverted T wave in lead III. In this situation, a clinical history suggestive of pulmonary embolism is important information. A thorough history should be obtained, and the reason for transport should be considered.

Bifascicular Blocks

As its name implies, **bifascicular block** is a condition in which two conduction pathways are blocked at the same time. Such a block includes concurrent findings of right BBB with LAH or LPH.

When right BBB with LAH occurs as a chronic condition, it is considered stable. A new onset of bifascicular block with ischemia, however, is not stable. This presentation will be apparent as a right BBB pattern with a slurred s wave in leads I and V_6 and an up-and-down (rabbit ear) appearance of the RSR′ complex in V_1. The QRS duration will be 120 ms or longer. In addition, with LAH, the typical pattern will include an LAD and rS waves in lead III.

A bifascicular block with a right BBB and an LPH is always considered an unstable rhythm. Owing to the amount of myocardium that must be damaged to cause a true LPH, the defect commonly involves other conduction pathways of the ventricles (right bundle branch). This kind of block often deteriorates into a complete heart block, especially in the presence of an acute MI. Because of the extensive damage it takes to cause an LPH, it does not take much more to progress to a higher degree of block. When a bifascicular block includes a right BBB and an LPH, the typical right BBB pattern with RAD and a small q wave in lead III will be found. **FIGURE 14-38** illustrates two bifascicular block patterns. The right BBB is in black, the LAH is in blue, and the LPH is in green.

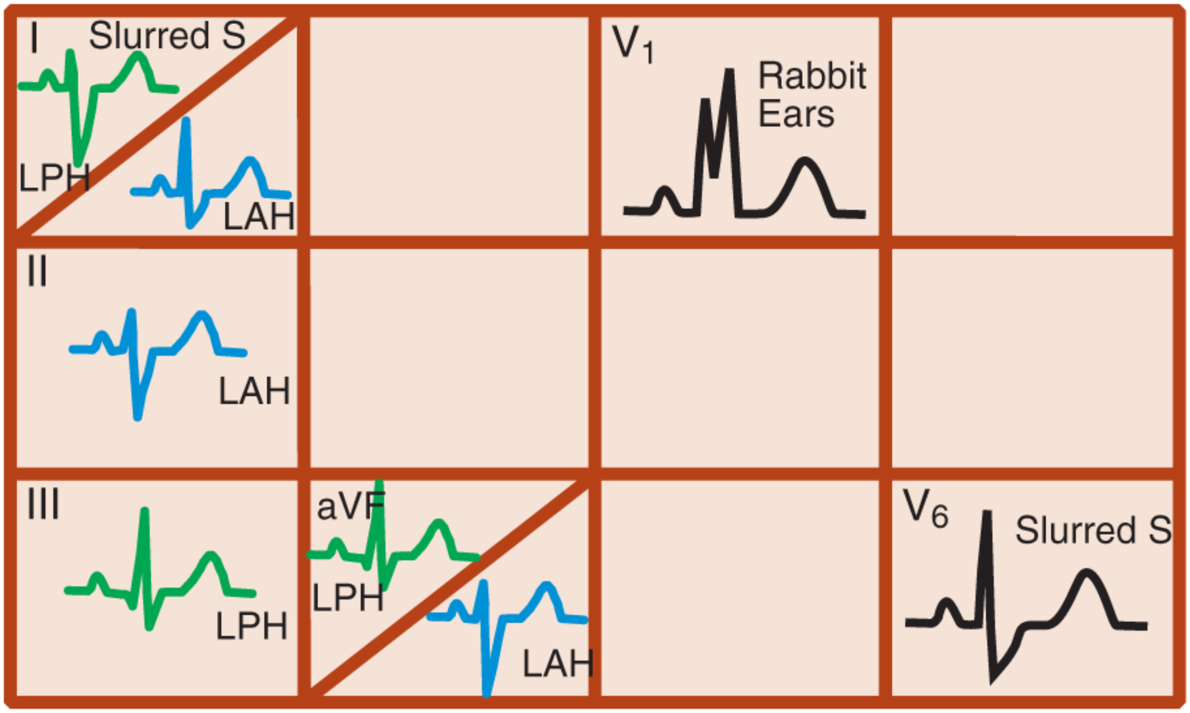

FIGURE 14-38 Electrocardiographic changes seen with a bifascicular block.

© Jones & Bartlett Learning.

Description

FIGURE 14-39 provides an example of a bifascicular block that includes a right BBB with an LAH. To identify it, first scan the ECG for abnormal patterns. In the example, the QRS intervals are 120 ms or more. There is a slurred S wave in leads I and V_6. An RSR′ complex is present in lead V_2. (RSR′ can be found in the septal precordial leads V_1 and/or V_2.) These criteria so far indicate a right BBB. Continue the evaluation, and determine the mean electrical axis. The QRS complex is positively deflected in lead I and negatively deflected in lead aVF, indicating LAD. To further isolate the axis, examine lead II. It is negatively deflected, placing the axis between –30° and –90°, the pathologic left axis. This finding provides the additional criterion necessary to determine that an LAH is present.

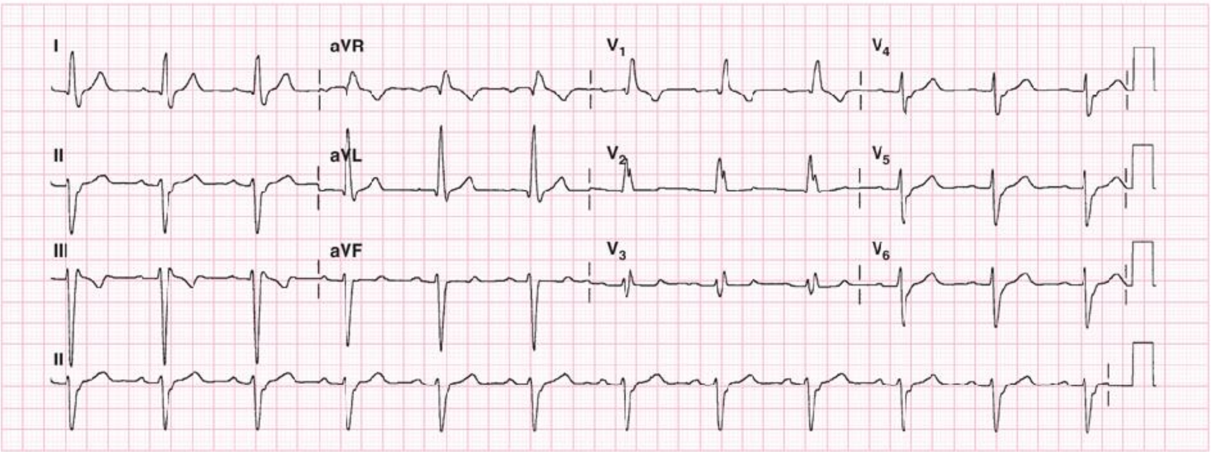

FIGURE 14-39 A 12-lead electrocardiogram showing a bifascicular block with a right bundle branch block and a left anterior hemiblock.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

Bifascicular blocks with a right BBB and an LAH are generally stable unless they occur in the presence of an acute MI. The additional ischemia and tissue death could take out the remaining left posterior fascicle, causing a complete heart block. In a critically ill cardiac patient with an existing bifascicular block consisting of a right BBB and an LAH, signs of ischemia or infarction suggest the need for urgent pacemaker placement, especially in the presence of a second- or third-degree AV block. This procedure will not likely be available in the transport setting, so medical control should be consulted and pads placed for external cardiac pacing. The receiving facility may need to be prepared to place a temporary pacemaker and should be notified of the patient's condition so that a transvenous pacemaker setup is available without delay on arrival. In some cases, depending on the patient's condition and the resources available at the time, a permanent pacer may be implanted immediately.

FIGURE 14-40 provides an example of a bifascicular block with a right BBB and an LPH. To identify it, first scan the ECG for abnormal patterns. Slurred S waves are found in leads I and V_6. There is an RSR′ complex in V_1 consistent with a right BBB. The axis is determined to be in the right quadrant because the rsR is negatively deflected in lead I and positively deflected in lead aVF. To further isolate the axis, find the most isoelectric limb lead with the smallest amplitude. In this example, it is lead aVR. In the hexaxial system, the lead perpendicular (90° away) to aVR is lead III. Assess lead II to determine whether it is positively or negatively deflected. In this case, lead II is positive, placing the mean electrical axis at +120° (RAD). There is also an S wave in lead I and a qS complex in lead III, consistent with an LPH. There are no exclusionary findings to contradict a diagnosis of LPH. Finally, in this example, there is also a first-degree heart block.

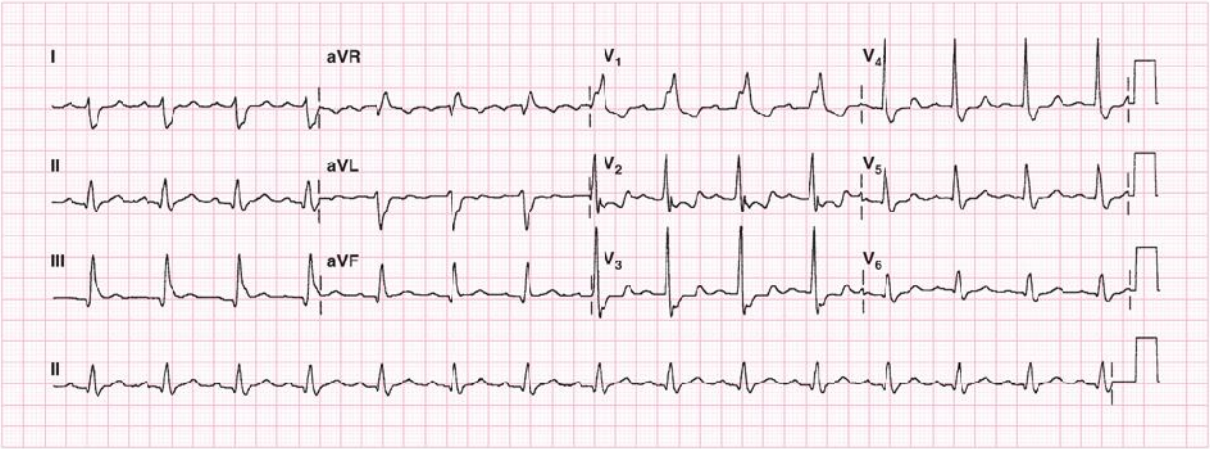

FIGURE 14-40 A 12-lead electrocardiogram showing a bifascicular block with a right bundle branch block and a left posterior hemiblock.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

This pattern of a right BBB with an LPH is an inherently unstable rhythm owing to the extensive myocardial damage necessary to cause the LPH in the first place. Additional ischemia or even a small infarction could extend the conduction defect to include the anterior fascicle as well.

Trifascicular Blocks

The term **trifascicular block** is used to describe the combination of a bifascicular block (right BBB with a block in the left anterior fascicle or left posterior fascicle) with a first-degree heart block (prolonged PR interval). Trifascicular block is important to diagnose because it is difficult to tell if the prolonged PR interval seen with the first-degree heart block component is the result of disease in the AV node or is caused by diffuse distal conduction system damage. If the block at the AV node level becomes a complete heart block, the escape rhythm will originate from the bundle of His. This escape rhythm will produce heart rates in the 40s and lead to symptoms of fatigue, near-syncope, or complete syncopal episodes. If diffuse conduction system damage is present, the escape rhythm may be fascicular or ventricular, which may result in heart rates that are life-threateningly low.

The presence of a trifascicular block after an MI implies the presence of extensive cardiac damage. True trifascicular blocks require immediate temporary pacing, followed by the placement of a permanent pacemaker.

Selected ECG Findings

The ECG findings discussed in this section have been selected for review because they can appear alone or coexist with the conditions already discussed. They may help CCTPs identify the many changes in structure and function that occur with chronic conditions or during an acute cardiac event. Ideally, CCTPs will use these findings to help put the pieces of the clinical puzzle together and recognize how they are reflected in the ECG.

Hyperacute T waves

Within the first few minutes of coronary occlusion, the T wave can become tall and narrow because of the ischemia that is present. This peaking is sometimes referred to as a hyperacute T wave. Such a presentation is transient, beginning within minutes to a few hours before the T wave inverts (flips). The first change that might appear with hyperacute T waves is an upward slanting of the ST segment and a subtle enlargement of the T wave that is disproportionate to the QRS complex. The hyperacute T waves are localized to the area of ischemia and infarction and may be associated with depression of the J point and a prolonged QT interval.

Hyperacute T waves differ from those seen in other conditions. In hyperkalemia, for example, the T wave peaking will be tall and narrow and have a “tenting” appearance. These T-wave changes will appear throughout all leads of the ECG. In contrast, hyperacute T waves that occur as a result of ischemia and infarction appear only in leads that view the area of ischemia and infarction.

ST-Segment Elevation

ST-segment elevation is caused by changes that affect ventricular depolarization and repolarization. Non-MI changes can also cause this condition, including left BBB, ventricular rhythms, LVH, pericarditis, and early repolarization.

As the complete ECG picture of infarction evolves, within a few hours the ST segment usually returns to baseline. A persistent ST-segment elevation may indicate the formation of a ventricular aneurysm.

In addition to myocardial injury, ST-segment elevation can be seen in a number of other conditions, such as early repolarization, and is signaled by elevation of the J point. The J point is where the ST segment "takes off" from the QRS complex, and its elevation in the absence of other findings has no pathologic implications. The way to determine the difference between benign elevation of the J point and elevation caused by myocardial injury is to identify the distinctive configuration seen with myocardial disease. In benign J-point elevation, the T wave is clearly distinguished as a separate wave. With myocardial disease, the elevated J point bows upward and merges with the T wave **FIGURE 14-41**.

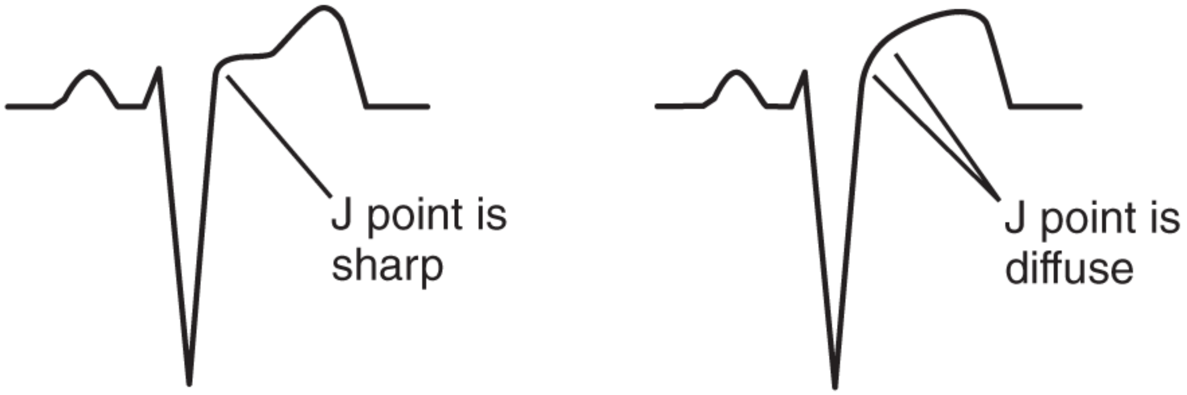

FIGURE 14-41 Sharp and diffuse J points.

Description

Differential Diagnosis

ST-Segment Elevation

- Myocardial disease
- Left BBB
- Ventricular rhythms
- LVH
- Pericarditis
- Early repolarization
- Ventricular aneurysm

Hypertrophy

Hypertrophy is thickening or excessive growth; in this chapter, the term refers to growth of any chamber of the heart. *Hypertrophy* is an increase in muscle mass caused by an increased workload on the heart when it has to pump against resistance; *dilation* is an enlargement of the chamber cavity. These conditions can occur together. The end result is that the heart has a larger mass in the affected area. As discussed in the section on axis determination, the larger the muscle mass, the higher the concentration of electrical impulses or vectors will be.

Left Atrial Enlargement

Left atrial enlargement results in a prolonged electrical conduction time through the left atrium. When normal electrical conduction is initiated by the SA node in the right atrium, the initial impulse is transmitted without delay through this smaller chamber and is recorded on the ECG as the beginning or leading side of the P wave. If the electrical impulse is delayed through an enlarged left atrium, it gives rise to the end or trailing side of the P wave. Overall, the resulting P wave has a notched double-humped appearance.

A P wave that is greater in duration than 120 ms in limb leads I and II and has a notched appearance is known as **P mitrale** **FIGURE 14-42**.

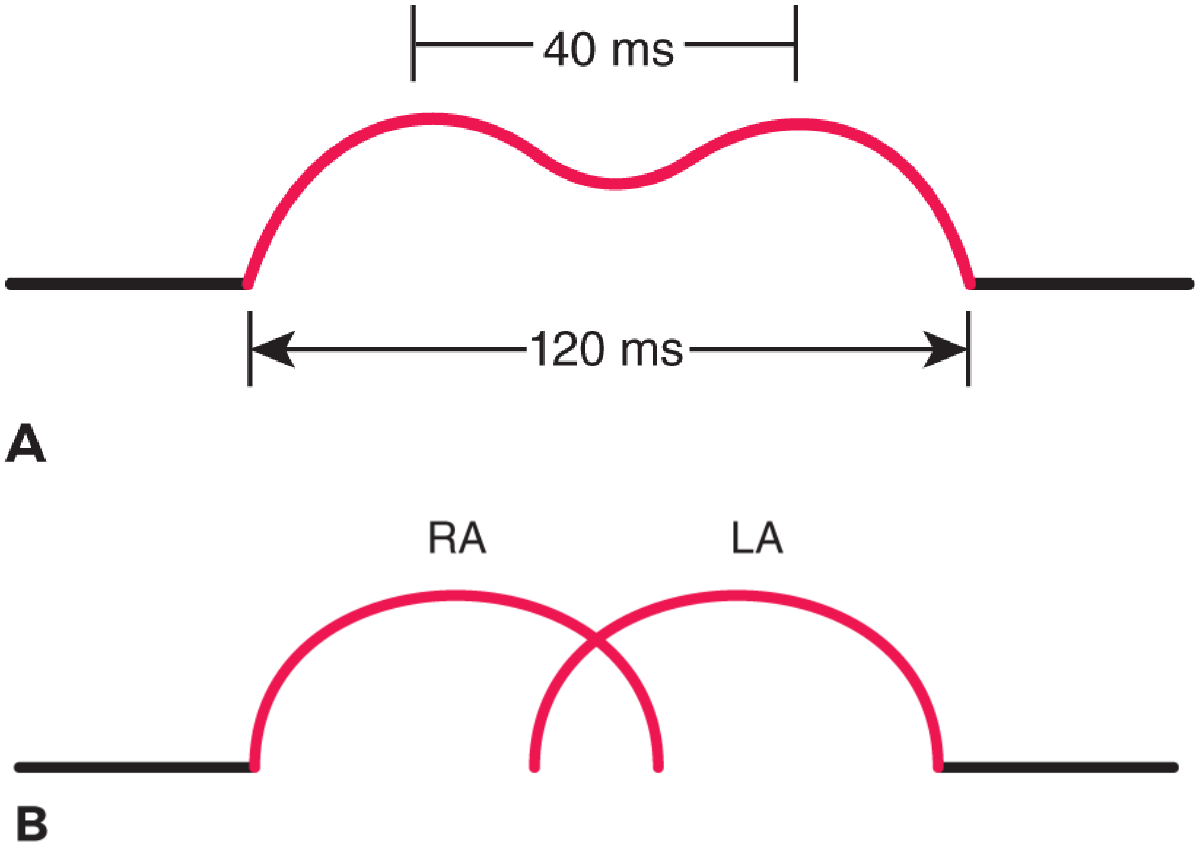

FIGURE 14-42 A. A notched P wave greater than 120 ms in the limb leads shows P mitrale.
B. The cause of a notched P wave.

Abbreviations: LA, left atrium; RA, right atrium

© Jones & Bartlett Learning.

Right Atrial Enlargement

Right atrial enlargement is caused by cardiac and pulmonary conditions affecting the pressures in the right atrium. Causes may include mitral stenosis or regurgitation, COPD, and pulmonary emboli. Right atrial enlargement commonly occurs in conjunction with the pulmonary condition known as **P pulmonale**, which is characterized by tall, peaked P waves in leads II and III that have an amplitude of 2.5 mm (2.5 mV) or more. P waves can be peaked in other conditions, but must be 2.5 mm or higher to make a diagnosis of P pulmonale; if they are less than 2.5 mm, they are not typically associated with right atrial enlargement **FIGURE 14-43**.

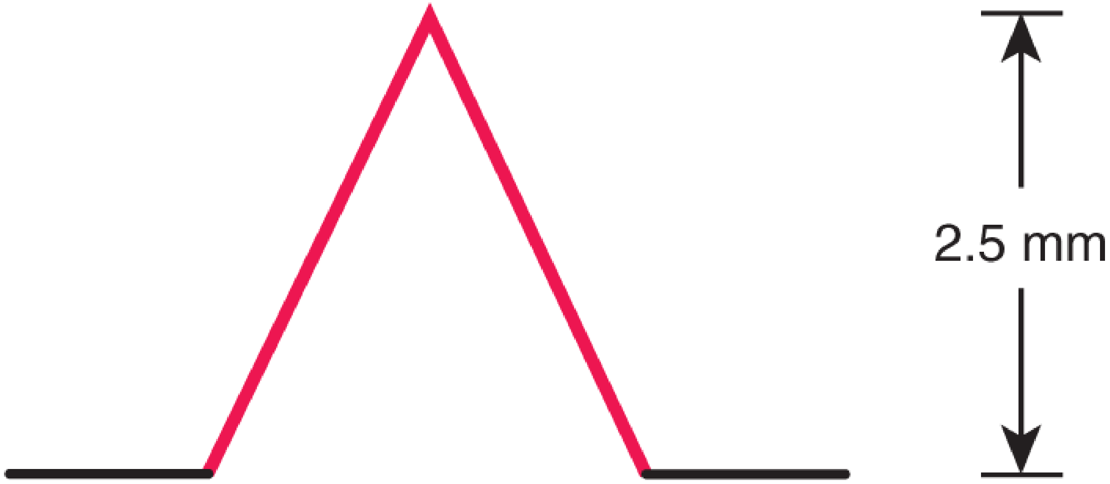

FIGURE 14-43 P pulmonale.

© Jones & Bartlett Learning.

When the evidence suggests atrial enlargement but the measurements are not enough to make the diagnosis, some different P-wave patterns might emerge. **Biphasic** P waves in lead V_1 are common. The biphasic P wave indicates nonspecific **intra-atrial conduction delay (IACD)**. Often, biphasic P waves seen in IACD are related to atrial enlargement, but the wave is not significant enough to be classified as P mitrale or P pulmonale.

Comparing the P waves in leads V_1 and V_6 can be helpful. When the leading half of the P wave is taller and wider in V_1 than it is in V_6, right atrial enlargement is probable. If the trailing half of the P wave is wider and deeper than the leading upright half is in V_1, left atrial enlargement is probable. If the trailing end of the P wave is wider and deeper than one small block on the ECG (1 mm in height by 40 ms in duration), left atrial enlargement is likely.

Both atria can be enlarged at the same time, a condition referred to as biatrial enlargement. To make the determination of biatrial enlargement, any combination of the aforementioned criteria can be applied. For example, in the inferior leads II, III, and aVF, with lead II being the best view for left atrial enlargement, a notched P wave greater than 120 ms in duration or a tall, peaked P wave of 2.5 mm or more in amplitude is found. Then in lead V_1, there is a biphasic P wave meeting the criteria for right or left atrial enlargement. Any combination of right atrial enlargement and left atrial enlargement equals biatrial enlargement **FIGURE 14-44**.

Description

Left Ventricular Hypertrophy

LVH consists of an enlargement or an increase in the muscle mass of the left ventricle. It represents the end-organ response to the increased pressure or overload seen in hypertension. With increased detection and aggressive treatment of hypertension, there has been a relative decrease in the ECG-observed incidence of LVH. Patients who have evidence of LVH on the ECG have a higher risk of developing coronary artery disease, making them more susceptible to the sequelae of that disease. People who have LVH are actually more susceptible to increased mortality than people who experience an MI without LVH.

Although a normal axis is the most common finding with LVH, a physiologic LAD is often present. A pathologic left or right axis deviation can occur with LVH, but the hypertrophy is usually not the cause. In general, the increased R-wave amplitude in the leads that look at the left ventricle is the basis for an ECG diagnosis of LVH. The increased amplitude of waves seen on the ECG—in particular, in the precordial leads—is caused by a two-fold process. First, as the left ventricle enlarges, a greater concentration of vectors occurs, increasing the wave of depolarization toward the precordial leads. Second, the increase in muscle mass typically extends anteriorly, bringing the heart physically closer to the electrodes on the chest. This positioning may be the reason for the finding of a normal axis instead of a pathologic axis deviation.

Several ECG criteria are used to diagnose LVH; however, to simplify the discussion, increased R-wave amplitude in the leads overlying the left ventricle and increased S-wave amplitude in the leads overlying the right ventricle are considered here. To assess for LVH, find the deepest S wave in V_1 or V_2, followed by the tallest amplitude of the R wave in V_5 or V_6. If the sum of the deepest S wave and the tallest R wave is 35 mm or more, LVH is likely.

The following criteria are very useful in making a determination of LVH. The more criteria that are present, the greater the likelihood that the patient has LVH.

- Any precordial lead of 45 mm or more
- An R wave in lead aVL of 11 mm or more
- An R wave in lead I of 12 mm or more

- An R wave in lead aVF of 20 mm or more

FIGURE 14-45 demonstrates several criteria for the diagnosis of LVH.

Description

The ECG in **FIGURE 14-46** also demonstrates several criteria for the diagnosis of LVH. First, the S wave is largest in V_1, which is added to the largest R wave found in V_6; the sum is 45 mm or more. Second, the R wave in lead aVL is well beyond the criterion of being 11 mm or more. In lead I, the R wave is clearly 12 mm or more. More than one of the criteria typically are met on the same ECG, and as many as possible should be found when diagnosing LVH.

Description

Right Ventricular Hypertrophy

The right ventricle can also become enlarged. This growth in size is usually caused by right ventricular overload because of a pulmonary disease such as pulmonary hypertension. The ECG is quite different in RVH than in LVH because the electrical vectors are drawn in the anterior and rightward direction with RVH. Therefore, a right shift in axis in leads I and aVF and in precordial leads V_1 and V_2 for increased R-wave deflection would be expected **FIGURE 14-47**.

V1
V2
Enlarged right ventricle

FIGURE 14-47 Right ventricular hypertrophy.

© Jones & Bartlett Learning.

Description

In RVH, the first finding is often a large R wave in lead V_1 or V_2. This should stand out because during normal conduction, there would be a larger S wave. Owing to the large R waves seen in V_1 or V_2, the normal R-wave progression pattern is altered. The shift of electrical vectors may also create an S wave in V_6 that is larger than the R wave. The other criterion for RVH is the RAD that lies between 100° and 180°.

Strain Pattern

When severe ventricular hypertrophy occurs, the myocardium can become so thick that the coronary blood supply is reduced. As a result, the subendocardium, or innermost layer of the heart, is likely to become ischemic. When hypertrophy is uncomplicated by ischemia, the changes seen in QRS complexes are used to diagnose ischemia. When subendocardial ischemia is present, changes to the ST segment and T wave also appear as a **strain pattern**.

In LVH, the strain pattern in the right precordial leads, V_1 to V_3, is seen as ST-segment elevation with a concave appearance of the upward slope. The T wave is upright and asymmetric in these leads. The precordial leads V_4 to V_6 show a downward-sloping ST-segment depression with an inverted asymmetric T wave. The key to identifying the strain pattern is to note that it is greatest in the lead with the tallest and deepest QRS pattern.

The ECG in **FIGURE 14-48** shows LVH with strain. First, the criteria are met to make the diagnosis of LVH by adding the S wave in V_2 to the R wave in V_5; this sum is 35 mm or more. The strain pattern is demonstrated by the concave upward sloping of the ST segments in the right precordial leads V_1 and V_2 with asymmetric upright T waves. The right precordial leads V_5 and V_6 show the strain pattern as downward-sloping ST segments with asymmetric inverted T waves.

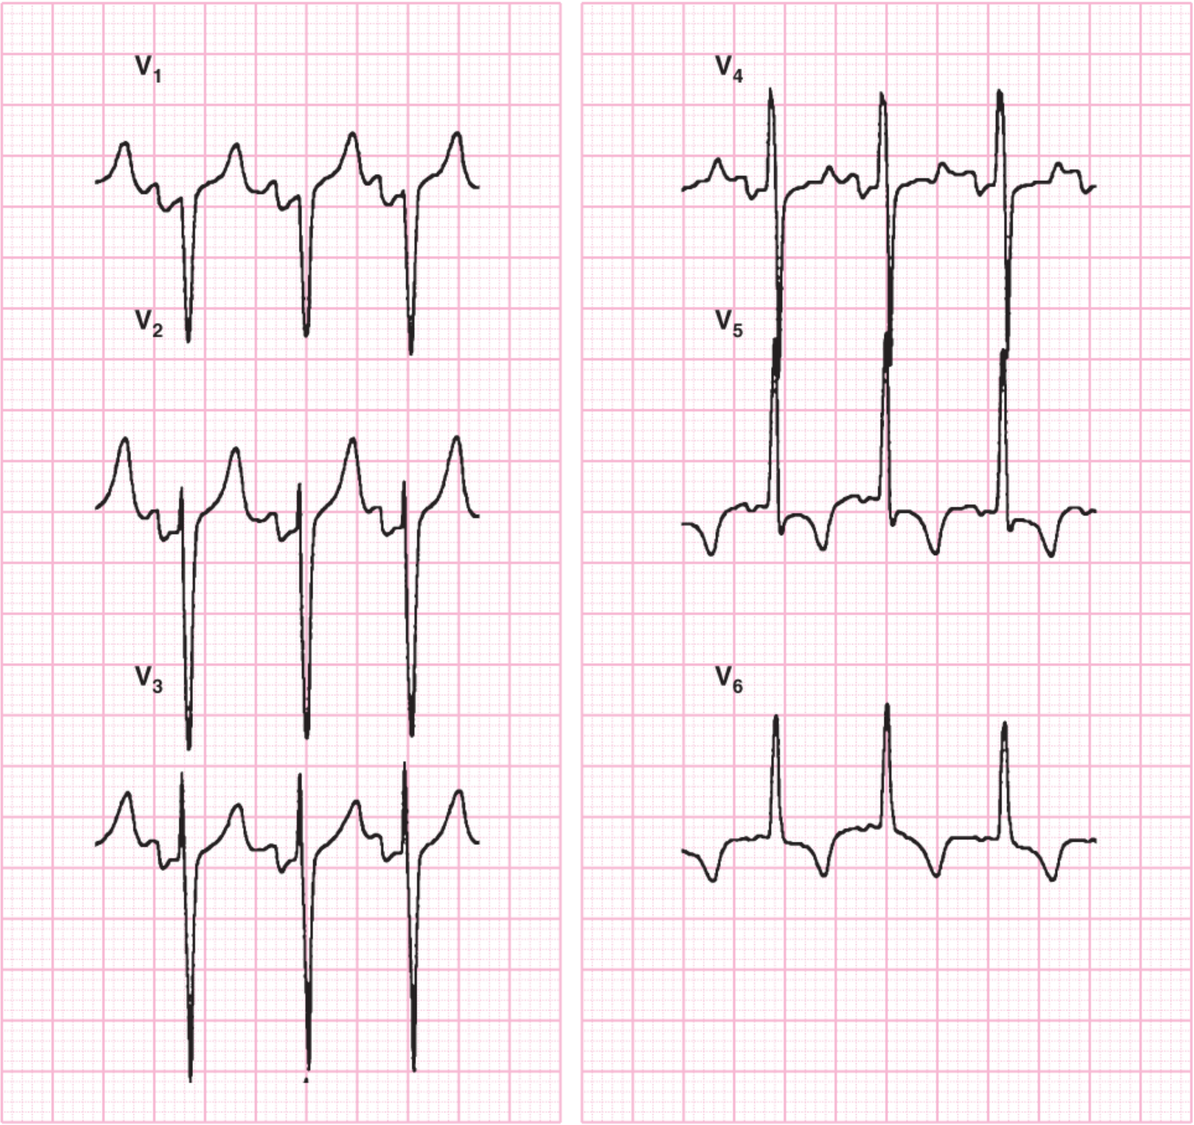

FIGURE 14-48 Precordial leads showing left ventricular hypertrophy with strain.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

Strain patterns also occur in RVH. In such a condition, the mean electrical axis is anterior and to the right, causing an RAD. This situation causes an increased R wave in the right precordial leads V_1 and V_2. The associated strain pattern shows a downward-sloping depressed ST segment and inverted asymmetric T waves. If the T wave is biphasic instead of inverted, the leading half will usually be negatively deflected and the trailing half will be positive in RVH.

It is important to distinguish between the strain pattern and the ST-segment and T-wave changes seen in ischemia and infarction. The strain pattern is problematic, but the ST-segment and T-wave changes can be immediately life threatening. The key to distinguishing between these conditions is to look closely at the shapes of the patterns. The ST-segment elevations or depressions in ischemia are usually flat and not sloping; the T waves are usually symmetric and not asymmetric. Another criterion used to define the two entities is the J point. In ischemia or infarction, the J point is sharper or more clearly defined, and the point at which the T wave takes off from the ST segment is seen. In contrast, in LVH with strain, the J point is usually more diffuse and slopes up or down depending on the lead being viewed. The clinical correlation between ECG findings and other patient information is most important in distinguishing between the strain pattern and ischemia/infarction.

Pre-excitation Syndromes

The pre-excitation syndrome that is of most interest in the CCT setting is **Wolff-Parkinson-White (WPW) syndrome**, which is briefly reviewed here. This condition occurs in less than 1% of the population.

WPW syndrome occurs when an accessory pathway, known as the bundle of Kent, allows electrical current to bypass the AV node and enter (or reenter) the ventricles. This accessory pathway does not have the same ability to slowly conduct electrical impulses as does the AV node, which puts people with WPW syndrome at risk for extremely fast heart rates that may result in significant hemodynamic instability. The accessory pathway can occur on the right side, connecting the right atrium to the right ventricle, or on the left side, connecting the left atrium to the left ventricle.

Two hallmarks are seen when premature ventricular depolarization occurs through an accessory pathway. First, the PR interval is shortened to less than 120 ms. Second, the QRS complex is widened to more than 100 ms. The widening is not the result of a delay in ventricular activation, but rather is attributable to premature activation. Typically in WPW syndrome, most of the ventricular depolarization is activated through the normal conduction pathways. The electrical impulse that passes unobstructed through the bundle of Kent causes early depolarization of a section of the ventricle, resulting in a QRS complex that has a characteristic slurred upstroke called a **delta wave** **FIGURE 14-49**. The delta wave is not seen in all leads, so every lead should be checked to confirm its presence or absence.

Description

In many people with WPW syndrome, the pre-excitation causes few clinical problems. It is well documented, however, that this syndrome can predispose a person to dangerous and even lethal tachyarrhythmias. The two tachyarrhythmias that occur most often in WPW syndrome are **paroxysmal supraventricular tachycardia** (a supraventricular tachycardia [SVT] that starts and ends abruptly) and atrial fibrillation (AF). In the CCT setting, CCTPs should be aware of the potential for development of wide complex tachycardia, which is difficult to distinguish from VT.

In WPW syndrome, when tachycardia is present, the electrical impulses can travel down the normal conduction pathway, through the AV node, and back up the accessory pathway. This condition, which is called orthodromic AV reciprocating tachycardia (AVRT), usually results in narrow complex tachycardia. The abnormal conduction can progress the other way as well, with the electrical impulse traveling through the accessory pathway and back up through the AV node. This condition, which is called antidromic AVRT, causes wide complex tachycardia. The antidromic tachycardias can be very fast if caused by AF or atrial flutter with one-to-one transmission or conduction of impulses.

Treatment of WPW tachyarrhythmias may require electrical cardioversion if these rhythms are unstable. Electrical cardioversion is considered the safest treatment, as management with drug therapy tends to produce unpredictable results. First-line treatment for stable patients with orthodromic AVRT is vagal maneuvers, followed by intravenous (IV) adenosine, followed by an IV calcium channel blocker such as verapamil or diltiazem.

In consultation with a cardiologist, procainamide may also be administered in stable patients, while watching the patient for hypotension and widening of the QRS. Procainamide blocks the accessory pathway but increases conduction through the AV node. Because of the risk of hypotension with too-rapid IV administration of this agent, slow IV infusion is required. Procainamide given slowly has a prolonged onset of action and may not reach therapeutic levels for 40 to 60 minutes. It may control the AF rate through the accessory pathways, but because of the increased conduction through the AV node, it can also create an extremely fast conventional AF. Thus, in any patient with WPW syndrome and AF who is hemodynamically unstable, cardioversion is the treatment of choice.

In stable patients with suspected AVRT where the diagnosis is not certain, as may be the case with wide complex tachycardias, IV procainamide is the recommended first-line therapy, followed by cardioversion if procainamide is ineffective.

The definitive treatment for WPW syndrome is ablation of the accessory pathway.

CONTROVERSIES

Although amiodarone is often thought to be safe in patients with AF and WPW syndrome, it is not. In a case series of 12 patients who received amiodarone, 7 experienced ventricular fibrillation. The safest treatment for unstable WPW tachyarrhythmias is cardioversion.

Pericarditis

Pericarditis is an inflammation of the pericardium, the membrane that surrounds the heart. It can be caused by a number of disorders and conditions, such as infection, MI, autoimmune disorders, chest trauma, cancer, and drugs, among others.

Pericarditis may cause ST-segment elevation and T-wave flattening or even inversion. These ECG findings are consistent with evolving MI, and the signs and symptoms of pericarditis can also mimic an MI. Some features on the ECG can be helpful to distinguish these two possibilities. First, the ST-segment and T-wave changes in pericarditis tend to appear throughout all leads of the ECG. In contrast, the same changes seen with ischemia, injury, and infarction tend to occur only in the leads that are viewing the affected area of the heart. Also, in pericarditis, the T wave usually does not invert until the ST segment has returned to baseline; in infarction, inversion of the T wave occurs after ST-segment elevation. Finally, Q waves do not form in pericarditis.

Another finding on an ECG that is consistent with pericarditis is the appearance of low voltage in all leads because of the pericardial effusion that often accompanies pericarditis. ST-segment and T-wave changes can usually still be seen in this situation. Fluid in the pericardial sac can cause **electrical alternans**, a condition in which the electrical axis varies from beat to beat, because the heart is able to move or rotate. Electrical alternans is most easily recognized on the ECG by the varying amplitude of each complex. Other changes often seen with pericarditis include PR depression, notched J points and, in lead aVR, reciprocal ST depression and PR elevation.

Long QT Syndrome

Long QT syndrome (LQTS) is typically a congenital disorder that can be worsened by a variety of factors, including physical exertion, female sex, electrolyte disturbances (hypokalemia and hypomagnesemia), hypothermia, abnormal thyroid function, structural heart disease, bradycardia, medications, and drug abuse/overdose **TABLE 14-6**. LQTS is characterized by a prolonged QT interval on the ECG; under certain conditions, it has a tendency to deteriorate into ventricular tachyarrhythmias, including **torsades de pointes** (often abbreviated TdP; a very rapid rhythm related to VT), which can lead to syncope or sudden cardiac death. The rhythm is often too fast to maintain effective CO, so the patient loses consciousness, usually without warning. LQTS can also be an acquired syndrome, usually as a result of drug therapy.

It is the deterioration of LQTS that poses a management challenge for CCTPs. Carefully evaluating the ECG, reviewing the patient's medications, and obtaining a medical history will provide clues to the diagnosis and alert CCTPs to the possibility of a tachyarrhythmia developing during transport. For example, CCTPs who will be transporting a cardiac patient who has recently started taking an **antiarrhythmic** agent known to increase the QT interval (eg, amiodarone or sotalol) should be prepared to treat any adverse effects from these medications.

As mentioned, LQTS occurs primarily as a congenital defect but can also be caused by a variety of conditions, medications, and drug abuse/overdoses. The measurement of the QT interval depends on the heart rate: The faster the heart rate, the shorter the QT interval will be; the slower the heart rate, the longer the QT interval will be. Thus, the QT interval must be corrected to account for this factor. The corrected QT interval (QTc), as printed on the 12-lead ECG, has already been corrected for heart rate by the cardiac monitor's diagnostic software.

The QT interval is measured from the start of the Q wave to the end of the T wave. Normal values for the QTc range from 350 to 440 ms for men and from 350 to 460 ms for women. During transport, if the patient's QTc reaches 500 ms and the patient's heart rhythm has not deteriorated into a ventricular tachyarrhythmia such as torsades de pointes, preventive medical intervention may be indicated. Such intervention includes correcting electrolyte imbalances, administering beta blockers (such as metoprolol), and being prepared to treat a developing ventricular tachyarrhythmia.

Typically, LQTS remains asymptomatic until the patient becomes physically active or experiences emotional stress (eg, during CCT). Symptoms usually begin in the preteen to teenage years, but can present anywhere from immediately after birth to middle age. The initial clinical sign of sudden loss of consciousness is often misdiagnosed as a vasovagal event or seizure. To make the correct diagnosis, a health care provider should give close attention to a history of loss of consciousness during physical activity.

Long-term treatment for this condition focuses on beta blockers. These medications should be started for women who have QTc-interval prolongation of greater than 460 ms and for men who have a QTc-interval prolongation of greater than 440 ms. Patients who cannot tolerate or do not respond well to the medication may need a pacemaker, an ICD (discussed later in this chapter), or a surgical procedure called a left cervicothoracic stellectomy.

CCTPs should watch for the prolonged QTc and the tachyarrhythmias that may develop as a result of this condition. Hypokalemia and hypomagnesemia make patients more susceptible to torsades de pointes, which can occur either in short bursts of 15 seconds or less or as a longer hemodynamically unstable rhythm. The treatment for torsades de pointes includes correcting the underlying cause, overdrive pacing, and IV administration of 1 to 2 g of magnesium sulfate. Other therapies for unstable patients may include electrical cardioversion and defibrillation. All treatment should be under direct supervision of a physician or within the standing protocols approved by your agency or jurisdiction.

Transport Management

Long QT Syndrome

Preventive Measures

- Correct the electrolyte imbalance.
- Administer a beta blocker (eg, metoprolol).
- Be prepared to treat a developing ventricular tachyarrhythmia.

Torsades de Pointes

- Consult with a physician or standing protocols.
- Apply basic life support (BLS) and advanced life support (ALS) measures.
- Correct the underlying causes (eg, hypomagnesemia, drug overdose).
- Consider initiating overdrive pacing.
- Consider administering magnesium sulfate.
- Consider initiating electrical cardioversion or defibrillation for patients in unstable condition.

Ventricular and Wide Complex Tachycardia

Wide complex tachycardia in general refers to a cardiac rhythm of more than 100 beats/min with a QRS duration of 120 ms or more. This rhythm can present a diagnostic dilemma for health care providers because it can be of either ventricular or supraventricular origin. Identifying the origin of the arrhythmia can lead to the correct diagnosis and proper therapeutic interventions.

The differential diagnosis for wide complex tachycardia includes the following major categories:

- VT (most common)
- SVT with aberrance
- Pre-excited tachycardias
- Electrographic artifact
- Ventricular paced rhythms

Evaluation of the ECG is critical to make the correct diagnosis of wide complex tachycardia. A variety of diagnostic criteria have been suggested to distinguish the different origins of wide complex tachycardia, and each set of criteria has its own sensitivity and specificity. This section discusses some of the more common methods of making the diagnosis.

Diagnosis

The most useful ECG criterion for establishing the diagnosis of VT is the presence of AV dissociation with more ventricular events than atrial events. This finding practically rules out an SVT origin. An AV dissociation can be implied during wide complex tachycardia by the presence of fusion beats—that is, simultaneous activation of the ventricular myocardium through normal conduction and from an ectopic ventricular focus. In the context of VT, a capture beat or Dressler beat is a narrow QRS complex resulting from an atrial electrical impulse (P wave) that captures the ventricular myocardium through the normal conduction system. A narrow complex beat can also be seen during wide complex tachycardia in a patient with SVT and BBB when a premature ventricular beat originates from or close to the nonconducting bundle branch and fuses with the impulse traveling down the contralateral bundle. This results in a simultaneous ventricular depolarization on both sides of the septum and is demonstrated by a narrow QRS complex.

The QRS duration can also be used to help distinguish between VT and SVT. Studies have shown that nearly 70% of VTs have a QRS duration greater than 140 ms; in contrast, SVTs typically never have a QRS duration greater than 140 ms. To further expand this criterion, in a patient with a right BBB with a QRS duration of greater than 140 ms, VT is the likely diagnosis. In a patient with a left BBB, a QRS duration of greater than 160 ms suggests VT.

The electrical axis seen during wide complex tachycardia is also useful to determine the origin of the arrhythmia. If the axis is 180° to –90° (extreme RAD), the wide complex tachycardia is not likely to be an SVT because this pattern is inconsistent with any type of typical bundle branch or fascicular block. If electrical concordance across the precordium is noted (ie, all QRS complexes point in the same direction in ECG leads V_1 through V_6), the tachycardia is more likely a VT and is rarely consistent with an SVT.

The morphologic features of the QRS complex provide another way to identify the different origins of wide complex tachycardia. The utility of distinguishing VT from SVT in wide complex tachycardia is limited, however, because some measurements are required, making this diagnostic method less accurate and more time consuming when applied in a moving transport vehicle. The following discussion of QRS morphologic features in wide complex tachycardia is provided to help CCTPs better understand the various ECG findings associated with wide complex tachycardia from different origins:

- In a patient with a right BBB, the precordial lead V_1 should be examined. If the left R wave is taller than the R′ wave, or if the QRS complex is biphasic with an Rs or qR pattern, the origin of the wide complex tachycardia is likely VT.
- In a patient with a left BBB, the precordial lead V_1 should also be examined. If the duration of the initial r wave is greater than 30 ms, the time from the beginning of the QRS complex to the nadir

of the S wave is greater than 70 ms, and the downstroke of the S wave is notched, the origin is likely to be VT.

- If the QRS complex in precordial lead V_6 has a monophasic QS or biphasic rS wave with an r to S ratio of less than 1 during a right BBB wide complex tachycardia, VT is likely.
- If the intrinsicoid deflection (from the beginning of the QRS complex to the beginning of the downslope of the R wave) in the precordial lead V_6 is greater than 80 ms, VT is the likely origin of the wide complex tachycardia.

Management

The initial management of wide complex tachycardia primarily depends on the patient's hemodynamic status. Patients who have low blood pressure, pulmonary edema, severe chest pain, or other evidence of poor perfusion associated with the wide complex tachycardia should be promptly treated using synchronized cardioversion.

When a patient with wide complex tachycardia remains in hemodynamically stable condition, more time can be spent reviewing information from the history, physical examination, and ECG findings. As mentioned, the majority of cases of wide complex tachycardia involve VT. Making the correct diagnosis, however, is the safest approach to management.

For a patient in hemodynamically stable condition in whom the cause of wide complex tachycardia is uncertain, vagal maneuvers may be diagnostic, if not therapeutic. If the etiology of a stable wide complex tachycardia is uncertain, a trial of adenosine may terminate some SVTs. This medication works by slowing conduction through the AV node, which serves to cut off the tachycardia circuit in most SVTs. It can sometimes terminate atrial tachycardias and, rarely, VT. Because adenosine has a very short half-life, it rarely causes complications in patients with wide complex tachycardia. An exception is the patient with an irregular wide complex tachycardia as a result of AF and pre-excitation over an accessory pathway. In this case, adenosine can block conduction through the AV node, allowing only conduction through the accessory pathway, and may lead to ventricular fibrillation. Beyond adenosine, other drugs used to treat SVT (eg, calcium channel blockers and beta blockers) may result in significant hemodynamic deterioration if the wide complex tachycardia is actually a stable VT. Additional treatments depend on the response to vagal maneuvers and adenosine, and should be based on expert consultation.

While some experts proceed with elective cardioversion for patients with stable wide complex tachycardias unresponsive to initial therapies, procainamide (class IA), is a reasonable alternative but must be used with caution. Notably, it can cause a sudden drop in blood pressure with rapid IV administration and is contraindicated in patients with complete heart block during wide complex tachycardia because it suppresses the nodal or ventricular pacemakers and can result in asystole. As with all drugs, the indications and contraindications of procainamide should be fully understood before administering it to any patient.

Lidocaine (Xylocaine; class IB) is useful for VT of ischemic origin, but does not terminate SVT. In a patient who is conscious and in a hemodynamically stable condition, higher doses of lidocaine can cause confusion, altered mental status, and even seizures.

Following termination of wide complex tachycardia, preventive treatment aimed at maintaining a stable rhythm should be initiated. This treatment will help prevent recurrent episodes, minimize the patient’s symptoms, and protect the patient from sudden cardiac death. For CCTPs, interventions are generally limited to pharmacologic treatment with antiarrhythmic drugs, usually a continuation of the drug that terminated the wide complex tachycardia. Additional in-hospital treatments may include the use of an ICD and catheter ablation procedures.

Patients whose rhythm converts to wide complex tachycardia rhythm can pose a diagnostic dilemma, especially for a transport team in transit. At times, only minimal information about the patient’s history and clinical and laboratory findings may be known. If wide complex tachycardia develops during transport, a rapid evaluation must be performed and the appropriate treatment must be initiated in a confined environment with relatively limited resources. If the patient is in a hemodynamically unstable condition, wide complex tachycardia should be managed as if it were VT until proven otherwise, and synchronized cardioversion is the initial therapy of choice.

Polymorphic or pulseless VT should be treated as ventricular fibrillation. If it is a witnessed condition that occurs during transport, the patient should already be connected to a cardiac monitor and have a patent IV line. Immediate defibrillation is indicated, and the CCTP should provide cardiopulmonary resuscitation (CPR) if necessary.

Differential Diagnosis

Wide Complex Tachycardia

- VT
- SVT with aberrance
- Pre-excited tachycardias
- Electrographic artifact
- Ventricular paced rhythms

Electrolyte Imbalances and Drug Effects

Electrolytes have an essential role in the proper functioning of cells and are found in both intracellular and extracellular fluids. Important electrolytes are sodium, potassium, calcium, and magnesium. It is the exchange of electrolytes into and out of cells that generates the electrical energy for cellular depolarization and repolarization. As the cells depolarize electrically, they exhibit a mechanical response in the form of contraction; when they repolarize, they relax and expand back to their original states. In the cardiac muscle, this process is repeated continuously over the individual’s entire lifetime. Proper levels of the electrolytes are essential to keep the cells functioning correctly. When changes in electrolytes occur, their effects are often seen on the ECG.

Certain drugs affect the electrolyte channels of the cell membranes, changing how the electrolytes flow into and out of the cells. These drugs can alter conduction patterns and, in turn, their representation on the ECG. Cardiac medications can increase the rate and force of contraction or slow and protect the heart from increased demands. Virtually any function of the heart can be altered by design. Other classes of pharmaceuticals that are not cardiac medications may have expected or unexpected cardiac side effects. It is beyond the scope of any text to address the effects of the countless illicit drugs that are available on the street or even online. Rather, the key point is that an endless number of drug effects may alter what is ultimately seen on the ECG. **TABLE 14-7** provides a brief overview of the cardiac effects associated with a few of these drug classes.

TABLE 14-7 Common Toxic Drug Effects

Drug Class	Possible Toxic Effects
Class I antiarrhythmics	Lengthened QRS and QTc intervals Possible AV blocks Slowed or completely blocked SA node Arrhythmias
Calcium channel blockers	Blocked AV node primarily, but extent of block varies significantly among different drugs in this class
Beta blockers	Slowed automaticity of the SA node and the Purkinje system Blocked AV node
Amiodarone	Slowed conduction everywhere: the SA node, atrium, AV node, Purkinje system, and ventricles
Phenothiazines and tricyclic antidepressants	Widened QRS and QTc intervals T-wave abnormalities Arrhythmias common in overdoses

Abbreviations: AV, atrioventricular; SA, sinoatrial

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

This section discusses ECG effects of two of the most clinically important electrolytes, potassium and calcium, because they produce the most recognizable changes on the ECG. In addition, a more in-depth discussion of digoxin toxicity is provided; this drug is one of the most notorious agents causing ECG changes.

Hyperkalemia

Potassium is the primary intracellular ion (the other is phosphate). An elevation of the potassium level is called **hyperkalemia**. Hyperkalemia is the most dangerous of all electrolyte abnormalities: It can cause death and prevents some drugs used in resuscitation efforts from being effective. On the ECG, hyperkalemia can cause changes in the appearance of all waveforms, indicating that a change has occurred within the cell, and can cause virtually any arrhythmia. Rapid recognition and correction of this electrolyte disturbance is essential to reversing any harmful effects. When hyperkalemia is suspected, a confirmatory potassium level should be obtained. The main ECG changes found in hyperkalemia are the following:

- T-wave abnormalities (tall and peaked)
- Intraventricular conduction delays
- P-wave abnormalities (missing or decreased amplitude)
- ST-segment changes simulating an injury pattern
- Cardiac arrhythmias (predominantly bradycardias)
- Sinusoidal ECG pattern

On the ECG, T-wave abnormalities are typically the first to appear with hyperkalemia. These changes start to appear when the potassium level exceeds 5.5 mEq/L in patients without renal disease and when it exceeds 6 mEq/L in patients with renal disease. The most common changes are tall, narrow, peaked T waves, but these changes are not seen in every patient with hyperkalemia. A prolonged

QT interval may be present. As the potassium level increases, the height of the T wave decreases and widens; the PR, QRS, and QT intervals also widen; and the amplitude decreases.

The ECG in **FIGURE 14-50** represents acute hyperkalemia. Tall, narrow, peaked T waves are visible in leads V_2 through V_4. Tall T waves also appear in the inferior leads II, III, and aVF. When the T wave is two-thirds the height of the R wave, it is considered pathologic.

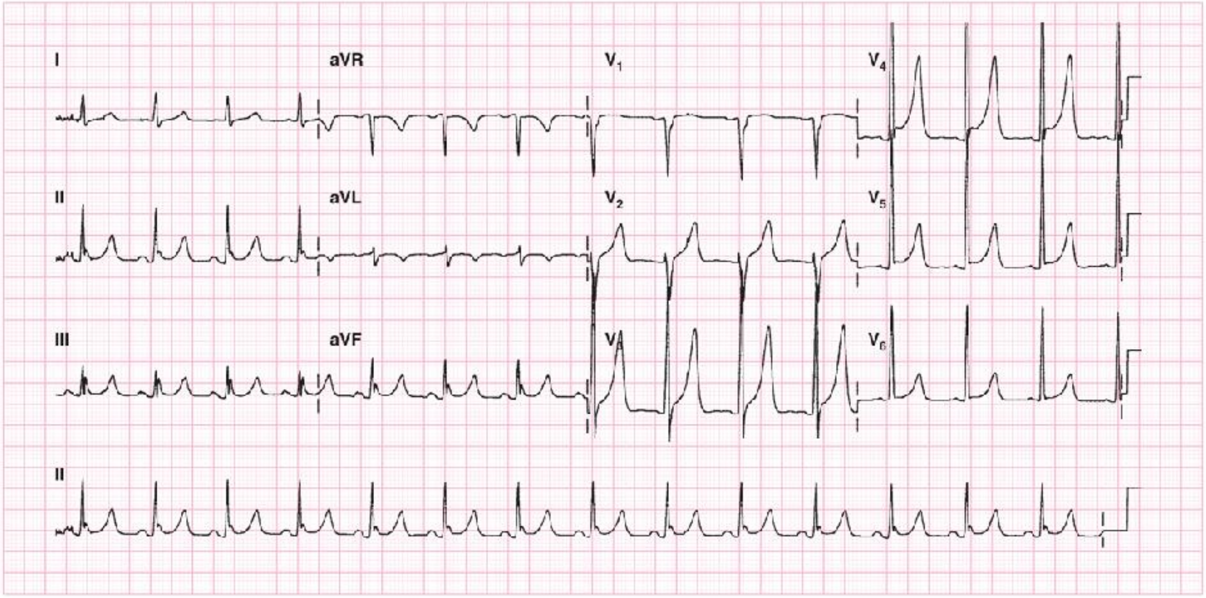

FIGURE 14-50 A 12-lead electrocardiogram showing T-wave changes with acute hyperkalemia.

Description

A patient who has known hyperkalemia or who has renal failure with suspected hyperkalemia should receive supportive treatment including IV access and cardiac monitoring. In the presence of severe hyperkalemia (potassium level ≥ 6.5 mEq/L in patients without renal failure or ≥ 7 mEq/L in patients with renal failure) with marked ECG changes, calcium should be administered initially for cardioprotection. When central access is available, 1 g calcium chloride should be administered over 5 to 10 minutes; for peripheral administration, 1 to 2 g calcium gluconate over 5 to 10 minutes should be given. Dosing can be repeated in 5 minutes if ECG changes persist. Although calcium has no effect on potassium levels, its cardioprotective effects begin within 1 to 2 minutes and last for 10 to 30 minutes. When ECG changes are not present, or following administration of calcium when ECG changes are present, 10 units of regular insulin should be given via IV push with 25 g of dextrose over 1 to 3 minutes. If the serum glucose is greater than 250 mg/dL, consider holding the IV dextrose. Additionally, 10 to 20 mg of albuterol should be administered by nebulizer over 10 minutes. Insulin and albuterol serve to shift potassium into the cells. Providers should attempt to facilitate potassium removal by using a binding resin such as sodium polystyrene sulfonate or sodium zirconium cyclosilicate and, if the patient is hypervolemic, 20 to 40 mg of IV furosemide.

Transport Management

Hyperkalemia

- Provide supportive treatment with IV access and cardiac monitoring.
- In the presence of hypotension or marked QRS widening, give IV calcium, insulin together with 50% dextrose, and albuterol.
- Give magnesium sulfate for digoxin toxicity–related cardiac arrhythmias.
- Give additional medical treatments, such as furosemide and binding resins.

Additional medical treatments include sodium bicarbonate: 50 mEq IV over 2 to 5 minutes or 150 mEq in 1 L of D_5W over 2 to 4 hours, including fluid hydration if the patient is hypovolemic. If severe hyperkalemia does not resolve with medical management, dialysis may be needed.

Hypokalemia

A decrease in the level of potassium is called **hypokalemia**. Hypokalemia does not cause the dramatic changes on the ECG that are seen with hyperkalemia. Some mild, nonspecific changes are apparent, such as ST-segment depression, slightly decreased amplitude of the T waves, and minimal prolongation of the QRS interval. Probably the most common abnormality in hypokalemia is the presence of a prominent U wave. This U wave (shown in Figure 14-8) is usually small and follows the T wave. Hypokalemia does not typically cause arrhythmias by itself.

Differential diagnoses for U waves include the following:

- Hypokalemia
- Bradycardia
- LVH
- Central nervous system events
- Drug use: digoxin, class I antiarrhythmics, phenothiazines

Treatment for hypokalemia is aimed at decreasing potassium losses, replenishing potassium stores, evaluating for potential toxic effects, and determining the cause to prevent additional losses.

In the transport setting, a few steps can be taken to decrease potassium losses. First, if possible, the use of diuretics should be discontinued. If diuretics are required for severe fluid overload, potassium-sparing diuretics should be used, diarrhea and vomiting should be treated, and H_2 blockers should be administered to decrease loss of potassium through nasogastric suction.

Replacing lost potassium is done by measuring the loss and estimating the replacement. IV potassium is not well tolerated peripherally because it can be highly irritating to veins and must be given only in relatively small doses (ie, 10 mEq/h). Potassium supplementation is best administered through a central line. In an emergency situation, in consultation with medical control, as much as 40 mEq/h can be given.

In evaluating patients for the potential toxic effects of hypokalemia, monitoring for cardiac arrhythmias and prompt treatment are essential. Hypokalemia is one condition in which a more aggressive approach to electrolyte replacement is warranted.

Differential Diagnosis

Hypokalemia

- Bradycardia
- LVH
- Central nervous system events
- Drug use: digoxin, class I antiarrhythmics, phenothiazines

Transport Management

Hypokalemia

- Discontinue diuretics (and any laxatives).
- Use potassium-sparing diuretics if required for severe volume overload.
- Treat diarrhea and vomiting.
- Use H_2 blockers to decrease nasogastric suction losses.
- Measure the potassium loss, estimate the replacement, and administer it through a central line.
- Monitor for cardiac arrhythmias, and treat them promptly if they occur.

Hypercalcemia

Hypercalcemia is a disorder that is most commonly caused by malignancy or primary hyperparathyroidism. Other causes of an elevated calcium level are less common and not typically considered until the most common causes are ruled out. ECG changes are minimal with this electrolyte imbalance, with the most significant change being a shortening of the ST segment, which in turn shortens the QT interval. The ST segment may become so short that there appears to be ST elevation. The PR interval may be prolonged; at higher levels, the QRS interval may lengthen and T waves may become flat or even invert. Because hypercalcemia affects conduction times, a variable degree of heart block may develop. Arrhythmias seldom occur as a result of hypercalcemia.

Treatment of hypercalcemia includes supportive management of the ABCs and increased hydration. Often, treatment also includes a loop diuretic (eg, furosemide) to increase calcium excretion and prevent overload from hydration therapy alone.

Transport Management

Hypercalcemia

- Manage the ABCs.
- Provide hydration.
- Administer a loop diuretic.

Hypocalcemia

Hypocalcemia that occurs acutely can be the result of medication or surgical effects. It is recognized as a significant problem in critically ill patients because of depressed myocardial contractility and resultant hypotension. ECG changes seen include a prolongation of the ST segment that produces an apparent lengthening of the QTc interval. The cardiopulmonary effects of hypocalcemia may include wheezing, stridor, bradycardia, and pulmonary crackles (rales), and an S_3 heart sound may be heard. The prolonged QT interval can lead to ventricular arrhythmias (eg, torsades de pointes).

Treatment during interfacility transfer mainly includes supportive measures, including IV fluids, oxygen, and monitoring of vital signs and the ECG. An infusion with calcium gluconate can be given over a period of 5 to 10 minutes. Administration of magnesium may be considered in patients with a prolonged QTc interval to help prevent torsades de pointes.

Signs and Symptoms

Hypocalcemia

- ECG findings: prolonged ST segment and apparent lengthening of the QTc interval

- Wheezing
- Stridor
- Bradycardia
- Pulmonary crackles (rales)
- S_3 heart sound
- Ventricular arrhythmias (eg, torsades de pointes)
- Tetany (carpopedal spasms), paresthesia

Transport Management

Hypocalcemia

- Initiate IV access.
- Administer oxygen to maintain saturation at greater than 92%.
- Monitor vital signs and the ECG.
- Provide an infusion of calcium gluconate.
- Consider administration of magnesium to help prevent torsades de pointes.

Digoxin Toxicity

Among the countless medications on the market that are specifically designed to alter the function of the heart, the most notorious is **digoxin**, a digitalis preparation. According to the American Association of Poison Control Centers, observed mortality rates are high with digoxin toxicity. Understanding the actions of digoxin and treating its adverse effects are essential to decreasing the mortality when toxicity occurs.

Digoxin is a cardiac glycoside that produces positive inotropic and negative chronotropic activity in the heart. It is primarily indicated to treat chronic HF and to control the ventricular rate in atrial tachyarrhythmias (such as AF). The inotropic effects are a result of inhibiting the sodium–potassium adenosine triphosphatase pump. This action causes an increase in intracellular calcium and sodium and a decrease in intracellular potassium. The movement of these intracellular electrolytes results in an increased force of myocardial muscle contraction, thereby causing the positive inotropic effect.

Therapeutic concentrations of digoxin (1.0 to 2.0 ng/mL) cause the desired positive inotropic effect and decreased electrical conduction between the SA and AV nodes. Therapeutic levels of digoxin also decrease automaticity and increase the diastolic resting membrane potential.

The margin between toxic and therapeutic doses is small, however, and many factors influence digoxin levels. One of the most common causes of digoxin toxicity is drug–drug interaction(s). In the CCT setting, patients already taking digoxin may be given other medications that result in digoxin toxicity. Any drug interaction or disease state (eg, hypothyroidism or renal impairment) that can interfere with the absorption or elimination of digoxin can cause an increased serum concentration.

Levels of the electrolytes potassium and calcium must be evaluated in conjunction with suspected digoxin toxicity. If the patient is given diuretic therapy, hypokalemia can develop, resulting in increased automaticity. Hyperkalemia exacerbates the digoxin-induced conduction delays. Also, hypercalcemia increases ventricular automaticity and can increase the effects of digoxin.

At toxic levels, the excessive increase of intracellular calcium elevates the resting potential and predisposes the heart to arrhythmias. Almost any arrhythmia can occur in conjunction with digoxin toxicity, and none is specific to this condition. CCTPs need to be alert to any manifestation of increased automaticity in the face of impaired electrical conduction.

The clinical manifestations of acute digoxin intoxication may not appear for several hours. When they do, they typically include gastrointestinal symptoms of nausea, vomiting, or abdominal pain. Neurologic symptoms may include lethargy, confusion, and weakness. Symptoms associated with chronic digoxin intoxication may be difficult to distinguish from those associated with other medical conditions.

The most common ECG changes in the setting of digoxin toxicity include AV, junctional, or ventricular ectopic beats; first-degree AV block; slow ventricular response in AF; and an accelerated AV or junctional rhythm. More severe arrhythmias may also be seen, including severe bradycardia, high-degree heart blocks, and malignant ventricular rhythms. As this list of potential rhythms suggests, there is no signature arrhythmia that points directly to digoxin toxicity. Instead, to diagnose digoxin toxicity, CCTPs should review the patient’s medications before transport. In a patient known to be taking digoxin, when an arrhythmia occurs, especially in the presence of other clinical findings, digoxin toxicity should be considered as an underlying cause. In general, any accelerated rhythm with conduction delays should raise the level of suspicion for digoxin toxicity.

Any patient taking digoxin who develops an altered level of consciousness or gastrointestinal symptoms with or without ECG changes needs further evaluation for toxicity. CCTPs typically work with data collected before the transport began, however, and new electrolyte values and drug assays are usually not available en route to the receiving facility. The one value that can be obtained before transport that has some prognostic value and can provide clues to the diagnosis of digoxin toxicity (in the presence of other clinical findings that develop during transport) is the potassium level. In a patient with digoxin toxicity, a potassium level greater than 5.5 mEq/L (normal serum potassium level, 3.5–5.0 mEq/L) with normal renal function is associated with higher mortality. Toxicity can occur in a patient with normal therapeutic levels of digoxin if a drug–drug interaction interferes with absorption or elimination of digoxin or in the presence of increased automaticity and impaired conduction.

If the CCTP suspects digoxin toxicity during transport based on ECG changes along with associated signs and symptoms, the initial concern is to manage the ABCs and stabilize the patient’s hemodynamics. Clearing the gastrointestinal tract of very recently ingested digoxin can be beneficial; in the field, this can be accomplished with the administration of activated charcoal. This measure not only helps prevent further absorption of the drug, but also may increase its excretion from the body. Atrioventricular, junctional, or ventricular ectopy; first-degree AV block; slow ventricular response to AF; and accelerated AV or junctional rhythms will typically respond to administration of atropine.

For treatment of severe digoxin toxicity, the standard of care is administration of digoxin-specific antibodies (Fab fragments or digoxin-immune Fab). Fab fragments neutralize free digoxin, decrease potassium levels, and increase renal excretion.

Laboratory tests for electrolyte levels, glomerular filtration rate, creatinine level, and urea level should be obtained as soon as possible. Further treatment includes the administration of insulin and glucose to treat the associated hyperkalemia and to provide the proposed cardioprotective effects. (Insulin may have a cardioprotective effect in digoxin toxicity.) The use of calcium chloride to stabilize the myocardium is controversial. If Fab fragments are used in the treatment of digoxin toxicity, the use of sodium polystyrene sulfonate to treat hyperkalemia is *not* recommended because it will overcorrect the serum potassium level. Fab fragments have also virtually eliminated the need for a pacemaker or cardioversion in patients with digoxin toxicity. Early recognition and aggressive treatment of digoxin toxicity is lifesaving.

Signs and Symptoms

Digoxin Intoxication

- Nausea
- Vomiting
- Anorexia
- Abdominal pain
- Weight loss
- Delirium
- Confusion
- Dizziness
- Disorientation
- Drowsiness
- Headache
- Hallucinations
- Amblyopia (partial or complete loss of vision in one eye)
- Photophobia (painful sensitivity to light)
- Scotoma (area of diminished vision within the visual field)

- Chromatopsia (visual disturbance in which objects appear abnormally colored)
- Xanthopsia (visual yellow discoloration)

Transport Management

Digoxin Intoxication

- Manage the ABCs.
- Stabilize the patient's hemodynamics.
- Administer activated charcoal to clear the gastrointestinal tract in patients who have recently ingested digoxin.
- Administer atropine to address AV, junctional, or ventricular ectopy; first-degree AV block; slow ventricular response to AF; or accelerated AV or junctional rhythms.
- Administer digoxin-specific antibodies (Fab fragments).

Conditions That Mimic Myocardial Infarction

Multiple conditions may mimic the clinical and ECG findings that occur with ischemia, injury, and infarction. The following is a synopsis of these conditions:

- Pericarditis: ST-segment elevation, T-wave inversion (possible)
- Left BBB: ST-segment elevation, QS complexes
- LVH: ST-segment elevation
- Ventricular rhythms: ST-segment elevation, QS complexes
- Early repolarization: ST-segment elevation, tall T waves

Cardiac Disease

Coronary Artery Disease and Angina

Coronary artery disease (CAD) is the most common form of heart disease and is a leading cause of death in US adults. The coronary arteries supply oxygen and nutrients to the myocardium. If one of these blood vessels becomes blocked, the muscle it supplies will be deprived of oxygen (ischemia). If this oxygen supply is not restored quickly, the ischemic area of heart muscle will eventually die (undergo infarction).

Atherosclerosis is of particular concern because it affects the inner lining of the aorta and the cerebral and coronary blood vessels, leading to the narrowing of these vessels and the reduction of blood flow through them. The atherosclerotic process begins, probably in childhood, when small amounts of fatty material are deposited along the inner wall (intima) of arteries, usually at points of turbulent blood flow, such as where the arteries bifurcate or where the arterial wall has been damaged. As the streak of fat enlarges, it becomes a mass of fatty tissue, known as an atheroma, which gradually calcifies and hardens into a plaque. The atheromatous plaque infiltrates the arterial wall and decreases its elasticity. At the same time, the plaque narrows the arterial lumen and interferes with blood flow through the lumen. The narrowed, roughened area of the arterial intima provides a locus for the formation of a fixed blood clot, or **thrombus**, which may then obstruct the artery altogether (in a coronary artery, such a clot is known as a coronary thrombosis). In addition, calcium may precipitate from the bloodstream into the arterial walls, causing arteriosclerosis, which greatly reduces the elasticity of the arteries.

Risk factors for atherosclerosis and CAD include hypertension, cigarette smoking, diabetes, high serum cholesterol levels, lack of exercise, obesity, family history of heart disease or stroke, and male sex.

Peripheral Vascular Disorders

Although atherosclerosis is rarely the primary cause of medical emergencies, it is a major contributor to other conditions that may become medical emergencies. For example, **arterial bruits** (turbulence or “swishing” sounds heard with a stethoscope placed over the carotid arteries) signal the presence of atherosclerosis and increased risk of vascular disease. Atherosclerosis can also contribute to **claudication**, a severe pain in the calf muscle caused by narrowing of the arteries in this muscle and leading to a painful limp. Finally, atherosclerosis may be associated with **phlebitis**: inflammation, swelling, and pain along the veins that can lead to the formation of blood clots and thrombophlebitis, which is venous inflammation associated with a thrombus (blood clot). If dislodged from their original sites, these thrombi become emboli that could travel to the heart and through its right side, lodging in the pulmonary arterial tree and causing a pulmonary embolism.

Signs and Symptoms

Peripheral Vascular Disorders

- Pain, flushing, swelling, warmth, and tenderness in the extremity
- Claudication
- Arterial bruits

Transport Management

Peripheral Vascular Disorders (Suspected Blockage or Embolus)

- Give IV heparin or another anticoagulant, initially as a bolus and then as an infusion.
- Monitor the affected limb with ultrasonography or Doppler imaging, if available.
- Maximize blood flow to the extremity by using warm compresses.
- Keep the affected limb in the position of comfort.
- Minimize movement of the affected limb.

- Apply a cardiac monitor, record a baseline ECG before transport, and perform frequent 12-lead ECG monitoring.

An estimated 10% of Americans are affected by significant peripheral vascular disorders annually. The most dangerous complication of these disorders is pulmonary embolism, which causes approximately 100,000 deaths each year. Risk factors for peripheral vascular disorders include age, oral contraceptive use, smoking, recent surgery, recreational IV drug use, trauma, and extended immobilization. Identification of these risk factors has a significant role in the diagnosis of peripheral vascular occlusions. Signs of peripheral vascular occlusion may include pain, flushing, swelling, warmth, and tenderness in the extremity, although these signs are present in only approximately half of all cases. The presence of claudication indicates a significant narrowing of the peripheral arteries associated with peripheral vascular disorders. Arterial bruits are another sign of vascular narrowing that can contribute to ischemia and stroke.

Unfortunately, a CCT team can do little for a patient with peripheral vascular disease. If a blockage or potential embolus is suspected, IV heparin should be administrated initially as a bolus and then as an infusion. If ultrasonography or Doppler imaging is available on the transport vehicle, the CCTP should frequently assess the affected limb. In addition to administering anticoagulant therapy, apply warm compresses to maximize blood flow to the extremity. It is also helpful to keep the leg in the position of comfort and minimize movement.

In the CCT setting, all patients should undergo cardiac monitoring, but any patient who is being transported for a long distance and has a blood clot with the potential to become a pulmonary embolus should be given a baseline ECG before transport and must undergo frequent 12-lead ECG monitoring. ST-segment depression in the limb leads and the precordial leads accompanied by an increase in right axis deviation may indicate a pulmonary embolus. Historically, the McGinn-White sign—that is, an $S_1Q_3T_3$ pattern (ie, a large S wave in lead I, and a Q wave and inverted T wave in lead III)—was considered a classic indicator of right heart strain. This pattern, however, is seen in only 10% of patients with pulmonary emboli. Anterior-inferior T-wave inversion is now considered a better indicator of pulmonary embolus. Of note, these findings are not unique to pulmonary embolism and could suggest any condition leading to right heart strain or hypertrophy. As a diagnostic tool, the ECG is neither specific nor sensitive for pulmonary embolism.

Acute Coronary Syndrome

The American Heart Association and the American College of Cardiology have published guidelines for the care of patients with STEMI. In these guidelines, the term **acute coronary syndrome (ACS)** is used to describe conditions that cause an episode of ischemic discomfort (chest pain) as the result of disruption of plaque within a coronary artery.

Plaques occur as the natural evolution of atherosclerosis. The plaques that are susceptible to disruption are usually nonobstructive but have a large amount of macrophages and other inflammatory cells associated with them. After the plaques are disrupted within a coronary artery, these substances promote a chain reaction of platelet activation, adhesion, aggregation, thrombin formation, and, ultimately, thrombus formation. The end product is a complete occlusion of the coronary artery or one of its branches. If there is not enough collateral circulation from branches of adjacent coronary arteries, myocardial necrosis begins within 15 minutes and spreads from the endocardium toward the epicardium.

The term ACS is used to describe any group of clinical symptoms consistent with acute myocardial ischemia. ACS represents a sudden deterioration of the condition of a coronary blood vessel. Acute myocardial ischemia typically presents as chest pain stemming from insufficient blood supply to the heart muscle, which itself is a result of CAD. The life-threatening ACS disorders are responsible for much of the emergency medical care and hospitalization in the United States.

The broad term *acute coronary syndrome* includes unstable angina, MI without ST-segment elevation (NSTEMI), and MI with ST-segment elevation (STEMI). Patients with STEMI have a high probability (greater than 90%) of experiencing coronary thrombus occlusion. In comparison, patients with stable angina have only a 1% probability of having a coronary thrombus. Among those patients with unstable angina or NSTEMI, 35% to 75% may have a coronary thrombus. These percentages are not good predictors for identifying those patients in whom MIs with Q waves eventually develop: Not every STEMI leads to the development of Q waves, and Q waves may develop in NSTEMI.

All patients experiencing a possible cardiac event should have a 12-lead ECG performed. Analysis of the 12-lead ECG enables the health care provider to categorize two groups of patients who have experienced ACS: patients with ST-segment elevation and patients without ST-segment elevation. Many patients whose ECG displays ST-segment elevation ultimately will have a STEMI. Patients who have ischemic discomfort (chest pain) without an ST-segment elevation are having unstable angina or an NSTEMI that usually leads to a non–Q-wave MI; these conditions are collectively known as UA/NSTEMI (unstable angina/NSTEMI). Patients with non–ST-segment elevation are ultimately diagnosed as either having or not having unstable angina (depending on whether cardiac enzymes or biomarkers indicate evidence of cardiac injury). Patients who experience angina may also have ST-segment depression. Finally, some patients experiencing angina or MI may have no changes indicated by the ECG.

Early recognition of the signs and symptoms of a STEMI is essential to initiate treatment or to ensure the patient is transported to a facility where the appropriate care can be provided. These signs and symptoms (which are discussed later in this chapter in the section on MI) include chest and arm pain, lower jaw pain, shortness of breath, and diaphoresis. Most deaths resulting from STEMI occur within the first 1 to 2 hours after the onset of symptoms and are usually caused by ventricular fibrillation. To avoid this dire outcome, rapid intervention with the most appropriate reperfusion therapy must start as soon as a diagnosis of STEMI has been confirmed.

The CCTP should perform a 12-lead ECG within 10 minutes of contacting a patient with chest discomfort or other signs and symptoms suggestive of STEMI. If this initial ECG is not diagnostic of

STEMI but the patient remains symptomatic and there is a high degree of suspicion for STEMI, serial 12-lead ECGs should be performed at 5- to 10-minute intervals while maintaining continuous cardiac (ST-segment) monitoring. Newer 12-lead ECG machines are equipped with multiparameter monitoring capabilities that can assess ST-segment deviation every 30 seconds. In patients with IWMI, right-side chest leads should be evaluated for ST-segment elevation suggestive of right ventricular MI (RVMI). The 12-lead ECG in the CCT setting is central to the therapeutic decision pathway because it provides evidence of ST-segment elevation in patients who will benefit from reperfusion therapy. Preemptive defibrillator pad placement on STEMI patients and NSTEMI patients with significantly increased cardiac enzymes should be considered prior to beginning transport.

In patients with STEMI, the more leads that show ST-segment elevation on a 12-lead ECG, the higher the mortality rate is. In other words, if the occlusion occurred high enough in a coronary artery that it has affected a large area of the heart, multiple patterns of ischemia will appear. Other important predictors of mortality are STEMI occurring in conjunction with a left BBB and in a predominantly anterior location. The classic guidelines for the ECG diagnosis of acute MI require at least 1 to 2 mm (0.1 to 0.2 mV) of ST-segment elevation in at least two contiguous leads. (Each small block measured vertically on the ECG paper equals 1 mm.) More detailed consensus criteria can help suggest different categories of AMI.

When no ST-segment elevation is present or the ECG is normal or shows nonspecific changes, there is no evidence to suggest fibrinolytic therapy will provide any benefit; in fact, in such cases, fibrinolytic therapy has been shown to be harmful. If clinical signs and symptoms continue, the 12-lead ECG should be repeated every 5 to 10 minutes and monitored continuously for any ST-segment changes until serologic testing for cardiac enzymes or biomarkers can be done.

All patients with ACS should receive antithrombin and antiplatelet therapy regardless of the presence or absence of ST-segment elevation. Patients with persistent ST-segment elevation are candidates for prompt reperfusion therapy, either pharmacologic or catheter based, to restore blood flow in the occluded artery. Patients without ST-segment elevation should receive anti-ischemic therapy and be considered for catheter-based therapy when indicated. Medications such as heparin or glycoprotein IIb/IIIa inhibitors can be continued in the field, but revascularization will occur in the hospital.

Another situation that warrants fibrinolytic therapy is marked ST-segment depression in leads V_1 through V_4 with tall R waves in the right precordial leads and upright T waves suggestive of a true posterior wall MI (PWMI). In this case, placement of additional electrodes in the posterior position to form leads V_7, V_8, and V_9 is recommended. Primary percutaneous coronary intervention may be appropriate in patients with true PWMI.

Lethal ventricular arrhythmias may develop in patients with STEMI, so continuous ECG monitoring is mandatory. Because many patients with STEMI are transferred to a higher level of care for therapeutic interventions, CCTPs are in a unique position to be able to monitor them during transport and to respond quickly and appropriately if these events occur. The value of setting alarm parameters on the transport monitor to immediately notify the CCTP of acute changes cannot be overstated.

Most patients diagnosed with ACS are experiencing an MI in progress or severe ischemia, which can quickly become an infarction. The gold-standard treatment is prompt arrival at a facility where the location of the blockage can be identified by cardiac catheterization and subsequently alleviated by percutaneous coronary intervention (PCI) such as stenting or angioplasty. Unfortunately, most hospitals do not have this capability.

The role of the CCT team is to transport the patient from a basic-care hospital to a cardiac hospital as expeditiously as possible without deterioration of the patient’s condition en route. Priorities are as follows:

1. Prevent further damage to the heart muscle.
2. Reduce afterload.
3. Prevent a thrombus from getting larger.

4. Reduce myocardial oxygen demand.
5. Maximize oxygen delivery.
6. Reduce or eliminate pain and anxiety.
7. Consider thrombolytic therapy to dissolve the clot(s).

The patient will usually be placed on an anticoagulant heparin drip; in some cases, an IV drip of an antiplatelet medication, such as eptifibatide, may be added to the heparin regimen. These drips must be administered via an infusion pump. The CCTP should monitor the patient en route for signs of serious bleeding. Minor bleeding, especially around the mouth, is common and is not a reason to discontinue or alter the drip rates.

If thrombolytic therapy has not been initiated and is not planned during transport, the CCTP should confer with the transferring provider about administration of 324 mg of aspirin with 180 mg of ticagrelor orally prior to departure. For patients who have previously received or are currently receiving thrombolytics, consider a loading dose of an adenosine diphosphate (ADP) inhibitor such as clopidogrel. Typical ADP inhibitors are administered as oral medications and have been shown to improve PCI outcomes when administered early. The CCTP should also confirm that aspirin administration has occurred or that a contraindication has been clearly documented in the medical record.

Give the patient sufficient oxygen to maintain an oxygen saturation of greater than 92%, but avoid hyperoxia (more than 97% oxygen saturation). Use continuous waveform capnography to monitor patients who require mechanical ventilation, and maintain the carbon dioxide level between 35 and 45 mm Hg.

When transport times will be long or the degree of blockage is severe to the point of being life threatening, administration of a thrombolytic agent may be indicated. Thrombolytics dissolve clots, but their actions are not specific to where these clots might be located. Before administering a thrombolytic, locally determined exclusion criteria need to be met. Such criteria are based on a combination of symptom onset and the estimated delay until PCI can be performed. Examples of thrombolytic exclusion criteria include the following:

- Significant hypertension (eg, systolic blood pressure [SBP] >200 mm Hg and/or diastolic blood pressure [DBP] >110 mm Hg)
- Right versus left SBP difference greater than 15 mm Hg (suggests potential dissection)
- Significant closed head or facial trauma in the previous 3 months
- Stroke in the previous 3 months
- Any history of intracranial hemorrhage
- Recent (2–4 weeks) history of major trauma, surgery, or gastrointestinal/genitourinary bleed
- Pregnant female
- Bleeding disorder, coagulopathy, or anticoagulated state
- Serious systemic disease
- Shock states (eg, hypotension, pulmonary edema)

Reperfusion arrhythmias are commonly seen in patients following thrombolytic therapy or after PCIs such as stent placement or angioplasty. When cardiac tissue becomes ischemic, potassium leaves the intracellular space. With reperfusion, the potassium rapidly returns to the intracellular spaces, resulting in rhythm disturbances. Usually these disturbances are short-lived, but serious rhythm disturbances, including cardiac arrest, have occurred. Patients also should be monitored for signs of bleeding (eg, femoral or retroperitoneal hematomas, rigid abdomen, hypotension, unexplained tachycardia) and a headache with an altered level of consciousness. If severe bleeding occurs, the CCTP should turn off the heparin drip. Hypotension is managed with fluids or pressors, and the transport may need to be diverted to the closest hospital for stabilization and treatment of the patient, possibly including a blood transfusion.

Transport Management

Acute Coronary Syndrome (Interfacility Transport)

- Control blood pressure.
- Provide analgesia.
- Provide anxiolytics, if indicated.
- Collaborate with the sending provider to assure an ADP inhibitor has been administered, if indicated.
- Assess for and treat pulmonary edema.
- Monitor the heparin (anticoagulant) and/or eptifibatide (antiplatelet) drips.
- Monitor the patient for signs of bleeding and headache with altered level of consciousness.
- Give sufficient oxygen to maintain an oxygen saturation of 92% to 97%.
- If the patient required mechanical ventilation, monitor with continuous waveform capnography, and maintain the carbon dioxide level between 35 and 45 mm Hg.
- Monitor the cardiac rhythm.
- Administer thrombolytics, if indicated.
- If severe bleeding occurs, discontinue any anticoagulant, thrombolytic, or antiplatelet infusions; manage hypotension with fluids or pressors; and consider diversion to the closest hospital for stabilization and further treatment.

Angina Pectoris

The principal symptom of CAD is angina pectoris. Angina occurs when the supply of oxygen to the myocardium is insufficient to meet the demand. As a result, the cardiac muscle becomes ischemic, and a switch to anaerobic metabolism leads to an accumulation of lactic acid and carbon dioxide. A person who experiences angina caused by CAD while at rest, when oxygen needs are minimal, has more severe CAD than a person who experiences angina only with vigorous exercise.

When obtaining the medical history from a patient with chest pain, it is important to distinguish between stable angina and unstable angina. Stable angina follows a recurrent pattern: A person with stable angina experiences pain after a certain, predictable amount of exertion, such as climbing one flight of stairs or walking for three blocks. The pain also has a predictable location, intensity, and duration.

Chronic, stable angina is the result of an atherosclerotic lesion that diminishes the myocardial oxygen supply available during exertion. Patients with this type of angina often take nitroglycerin or some other form of nitrate for relief of anginal pain. In the CCT environment, nitroglycerin should be given intravenously, especially for long transports. IV nitroglycerin is better able to control anginal pain compared to other forms of nitroglycerin. When IV nitroglycerin is given, it is advisable to discontinue all other forms of nitroglycerin. If a patient who is being transported is not taking nitroglycerin and suddenly develops chest pain, a sublingual nitroglycerin tablet or spray may be used initially to reduce the discomfort while delivery of IV nitroglycerin is being established or titrated upward.

Unstable angina is much more serious than stable angina and indicates a greater degree of obstruction of the coronary arteries. In many cases, it is caused by a thrombus or plaque rupture. This condition is characterized by noticeable changes in the frequency, severity, and duration of pain, and often occurs when the patient is not experiencing predictable stress. The patient may report that the anginal attacks have grown more frequent and severe during the past several days or weeks, that they awaken the individual from sleep, or that they occur when the individual is otherwise at rest. Nitroglycerin is often not effective with this type of angina. Such attacks are often warning signs of an impending MI.

Finally, silent ischemia refers to the presence of angina without clinical manifestations, which is detected only when ST-segment elevation is noted on the ECG.

Myocardial Infarction

An MI can occur as a result of the cardiac muscle being deprived of coronary blood flow long enough for myocardial tissue death to ensue. Narrowed vessels (eg, from atherosclerotic disease), coronary artery occlusion (eg, by a thrombus), spasm of a coronary artery, and reduction of overall blood flow (eg, from shock, arrhythmias, or pulmonary embolism) are all potential causes of an MI.

The location and size of an MI depend on which coronary artery is blocked and where along its course the blockage occurred. The majority of infarcts involve the left ventricle. When the anterior, lateral, or septal walls of the left ventricle are infarcted, the source is usually occlusion of the left coronary artery or one of its branches. In most cases, IWMIs are the result of an RCA occlusion. When the ischemic process affects only the inner layer of muscle, the infarct is referred to as a subendocardial MI. By comparison, an infarct that extends through the entire wall of the ventricle is described as a transmural MI. The infarcted tissue is invariably surrounded by a ring of ischemic tissue—an area that is relatively deprived of oxygen but still viable. That ischemic tissue tends to be electrically unstable and is often the source of cardiac arrhythmias.

Acute MI is a leading cause of death in the United States, and more than 800,000 people experience MI each year in this country. Given that more than 70% of sudden cardiac arrests occur outside the hospital, emergency medical services (EMS) providers clearly have a crucial role in recognizing and promptly managing this condition. Patients at risk for sudden cardiac death include those with the following characteristics:

- Prior sudden cardiac arrest
- Prior MI
- HF, class II to IV
- Ejection fraction of less than 40%
- Family history of sudden cardiac arrest
- Prolonged QT interval

Of all deaths from acute MI, 90% are due to arrhythmias, usually ventricular fibrillation, which typically occur during the early hours of the infarct. Arrhythmias can be prevented or treated, so most deaths from acute MI are considered preventable.

Infarct Recognition and Localization

Many cardiac patients are transported from one facility to another where they can receive specialized procedures that are not available at the sending hospital. The physical and emotional stressors of the transport itself can place an additional burden on a patient in already critical condition. CCTPs must always remain acutely aware of the patient's cardiac status and ensure rapid identification of both new findings, including MI, and evolving and changing events.

The diagnosis of an MI relies on three initial components: the history and physical examination, testing for cardiac enzymes, and interpretation of ECG changes associated with an MI. An MI evolves from a normal state to ischemia, injury, and, ultimately, infarction when an event occludes vessels and limits the supply of oxygen-enriched blood reaching the cells. Ischemia and injury are reversible conditions that must be identified and treated to help prevent death of cardiac muscle.

As soon as a chief complaint of a cardiac nature has been noted, start treatment of the patient; obtaining a focused history and performing a physical examination can wait. However, for purposes of discussion, this section proceeds through the history and physical examination.

Cardiac Enzymes

In the past, serum testing for cardiac enzymes was not typically done during transport. Today, however, point-of-care testing devices are increasingly available, and CCTPs should be familiar with these assessment tools. Moreover, such test results are frequently available in the patient's chart and may help put the patient's cardiac status into perspective.

Although the ECG does not directly represent levels of cardiac enzymes that are released as cells are damaged, ECG changes are seen as an aftermath of cell damage because of the change in cell function. When myocardial cells die during an infarction, their internal contents leak into the bloodstream. Troponins T and I are contractile proteins of the myofibril that are specific for detecting myocardial cell injury; although not specific to STEMI/NSTEMI, they are the forms most commonly measured in testing. The levels of these proteins rise during the first 2 to 6 hours after injury, then peak from 12 to 16 hours after the MI. The cardiac troponin I level can remain elevated for 5 to 10 days, and the cardiac troponin T level can stay elevated for 5 to

14 days. Recently, high-sensitivity troponin assays are being used for faster diagnosis of MI.

Creatine kinase (creatine phosphokinase) is an enzyme found in heart (MB fraction) and skeletal (MM fraction) muscle as well as in the brain (BB fraction). The creatine kinase level increases in more than 90% of MIs. Because it is also found in skeletal muscle and the brain, this enzyme can be elevated during trauma and physical exertion, in postoperative patients, in patients with seizures, and in patients with other conditions in which cells are damaged. In an MI, the creatine kinase level begins to rise in 4 to 6 hours, peaks in 24 hours, and returns to normal in 3 to 4 days.

The creatine kinase isoenzyme MB fraction is specific to cardiac muscle. It rises and returns to normal sooner than the total creatine kinase level; that is, the MB fraction rises in 3 to 4 hours and returns to normal in 2 days.

Myoglobin is an oxygen-transport protein. Damage to skeletal or cardiac muscle causes its release into the circulation. After an MI, the myoglobin level rises in the first 2 hours, peaks in 6 to 8 hours, and finally returns to normal in 20 to 36 hours. An increased myoglobin level can also be found in skeletal muscle injury and renal failure, which explains why these values are no longer utilized in evaluation of ACS.

Because levels of several of these markers can be elevated in other medical conditions, they must be used in conjunction with other clinical and laboratory findings when a cardiac event is suspected. Current national and international guidelines for diagnosis of ACS suggest that when the troponin level is available, neither creatine kinase nor myoglobin measurement is useful for diagnosis of ACS.

Blood Supply

Before proceeding further, it is important to review how blood circulates throughout the heart, so as to better understand the ECG changes seen in an MI. The heart is a muscle and, like any muscle, requires an oxygen-enriched blood supply to survive. The blood supply to the heart is delivered through two main coronary arteries and their branches during diastole. Areas that are supplied by more than one source are said to have collateral circulation.

The right and left coronary arteries originate at the base of the aorta just above the aortic valve. The major branches of the right coronary artery are the marginal, posterior (descending) interventricular, and SA nodal branches. The RCA supplies blood to the right atrium, the right ventricle, and portions of the left atrium and left ventricle. The sinus node branch supplies blood to the sinus node, and the AV nodal branch supplies blood to the AV node.

The major branches of the left coronary artery are the anterior interventricular (also known as the left anterior descending) and left circumflex branches. The left coronary artery supplies both ventricles, the interventricular septum, and the left atrium. The left anterior descending artery supplies the right and left bundle branches.

The deoxygenated blood is returned to the venous circulation through the coronary sinus.

By understanding the coronary blood flow and the areas of the heart represented by the ECG, CCTPs can use ECG changes to identify which branch of the blood supply is affected during an MI. Be aware, however, that coronary artery distribution may vary slightly from patient to patient.

Ischemia, Injury, and Infarction

Decreased blood flow to the heart can result from a chronic condition, called coronary vascular disease, or from an acute injury, in which a coronary artery or one of its branches becomes occluded by an embolus. The heart begins in a normal state in which it is receiving an adequate blood supply. Increased oxygen demand caused by an increased workload or a decrease in supply caused by coronary vascular disease or a blocked artery can lead to ischemia, injury, and, ultimately, infarction. Ischemia and injury are reversible, and when evidence of either is present, rapid intervention can often prevent infarction.

When ischemia develops, the tissue becomes more electrically negative compared with the unaffected surrounding tissue. This change causes a pattern of ST-segment depression. The T wave is also inverted (flipped) because of repolarization occurring along abnormal pathways **FIGURE 14-51**.

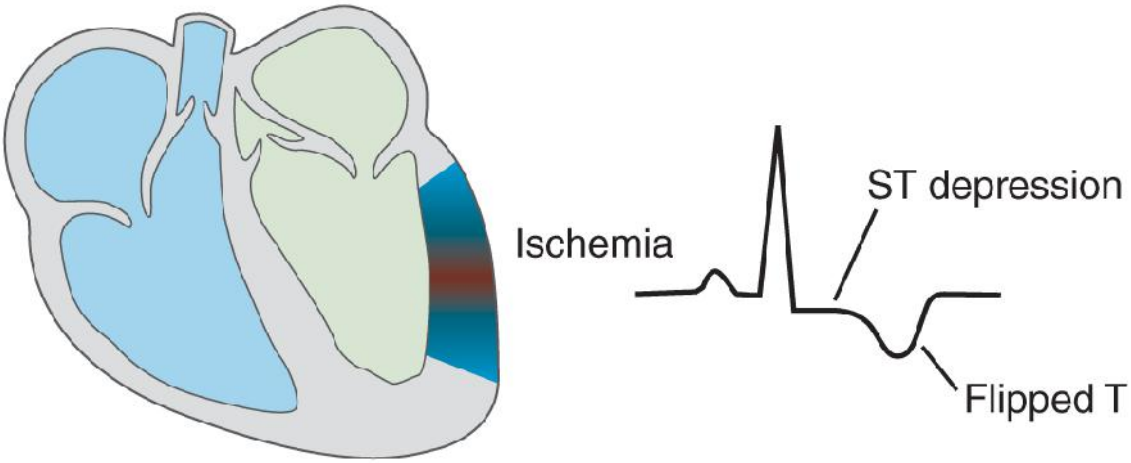

FIGURE 14-51 Ischemia.

© Jones & Bartlett Learning.

Description

Other causes of T-wave inversion are also possible, including ventricular hypertrophy with strain, BBB, and cerebral hemorrhage. To help distinguish ischemia from one of the other causes of T-wave inversion, examining the shape of the T wave may be helpful. With myocardial ischemia, the T wave inverts symmetrically. With other causes, the T-wave inversion is often asymmetric or "slurred."

As ischemia continues uninterrupted, injury develops. The injured area does not repolarize completely, causing it to become more electrically positive than the unaffected area surrounding it. This change causes the ST segment to become elevated. The T wave remains inverted because it continues to repolarize through abnormal pathways. As the injury progresses, the elevation of the ST segment can increase **FIGURE 14-52**.

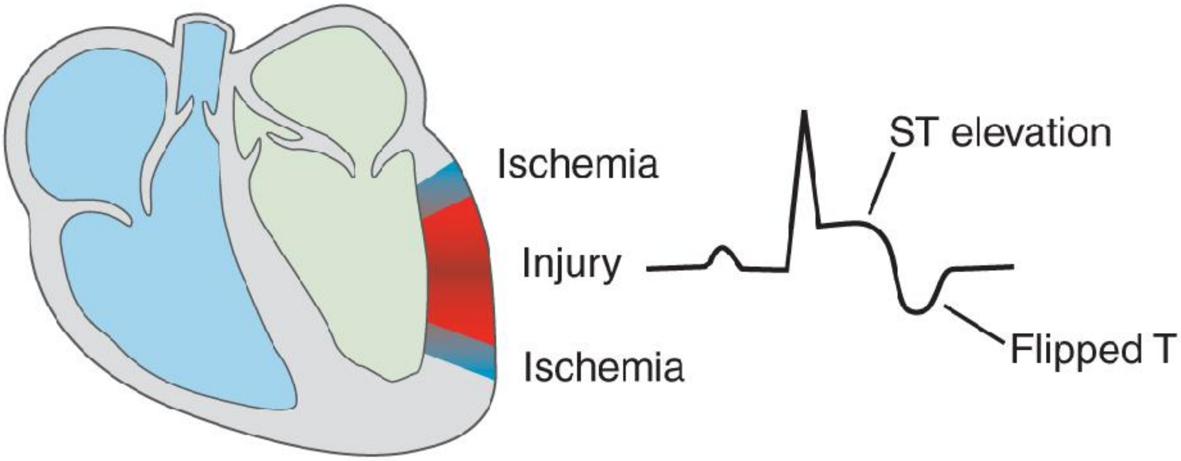

FIGURE 14-52 Ischemia and injury.

© Jones & Bartlett Learning.

Description

If ischemia and injury continue uninterrupted, infarction can occur. The infarcted tissue no longer generates or transmits electrical impulses, so the area becomes “electrically neutral.” Because this tissue can no longer generate or transmit electrical impulses, no direct wave is recorded on the ECG. Electrical impulses are deflected away from the area of infarct and are represented by Q waves. Another way of looking at Q-wave formation is as the result of electrical impulses being generated by the other wall of the ventricle and passing unopposed away from the positive electrode. Because ischemia and injury continue to be present until the infarct process is completed, ST-segment elevation and inverted T waves will still be noted on the ECG **FIGURE 14-53**.

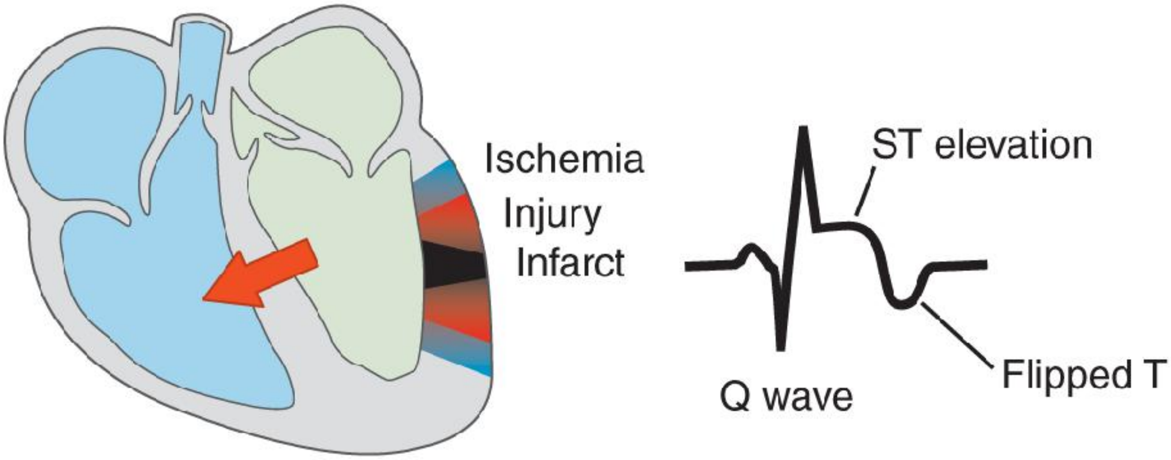

FIGURE 14-53 Ischemia, injury, and infarction.

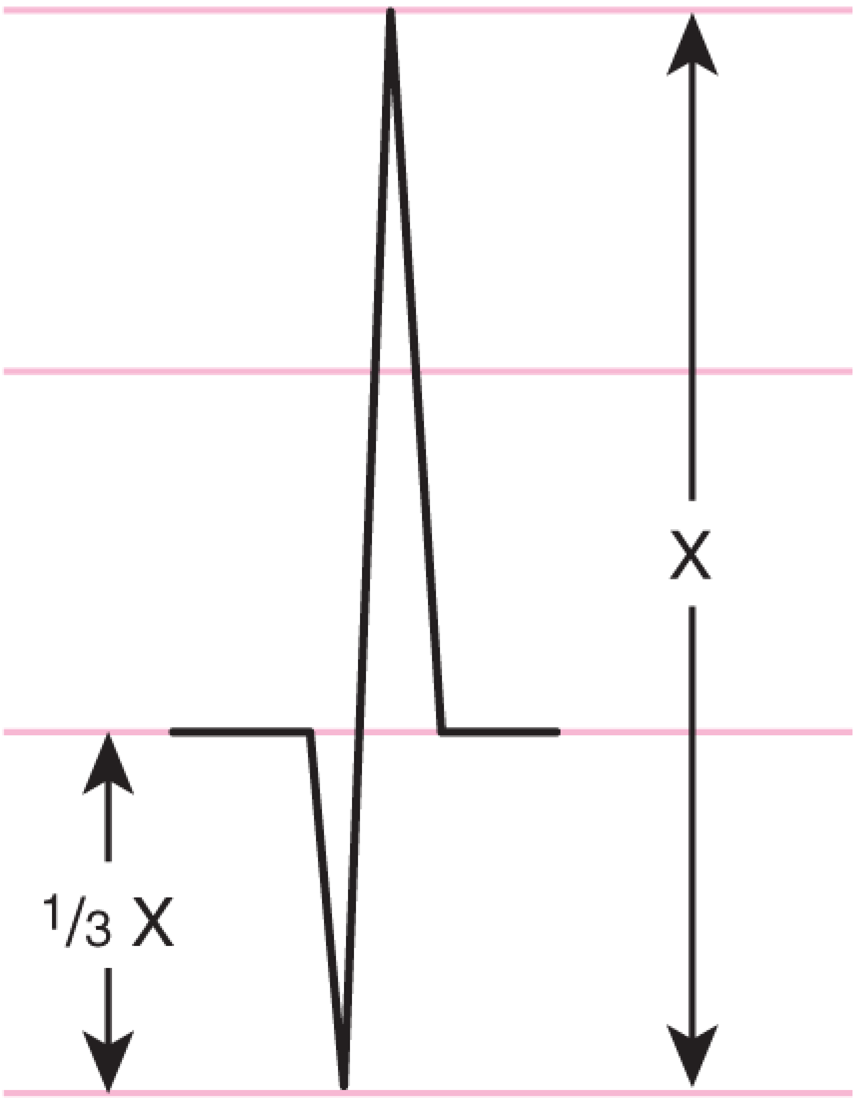
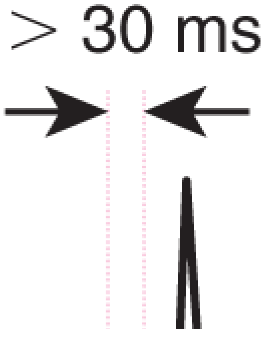
© Jones & Bartlett Learning.

Description

Sometimes small Q waves are seen in the left lateral leads (I, aVL, V_5, and V_6) and occasionally in the inferior leads (especially II and III) in patients with normal hearts. The normal small Q waves occur as a result of early left-to-right depolarization of the interventricular septum. For Q waves to be significant, indicating pathology, they must be more than one-third the total height of the QRS complex with which they appear and wider than 40 ms in duration **FIGURE 14-54**.



A



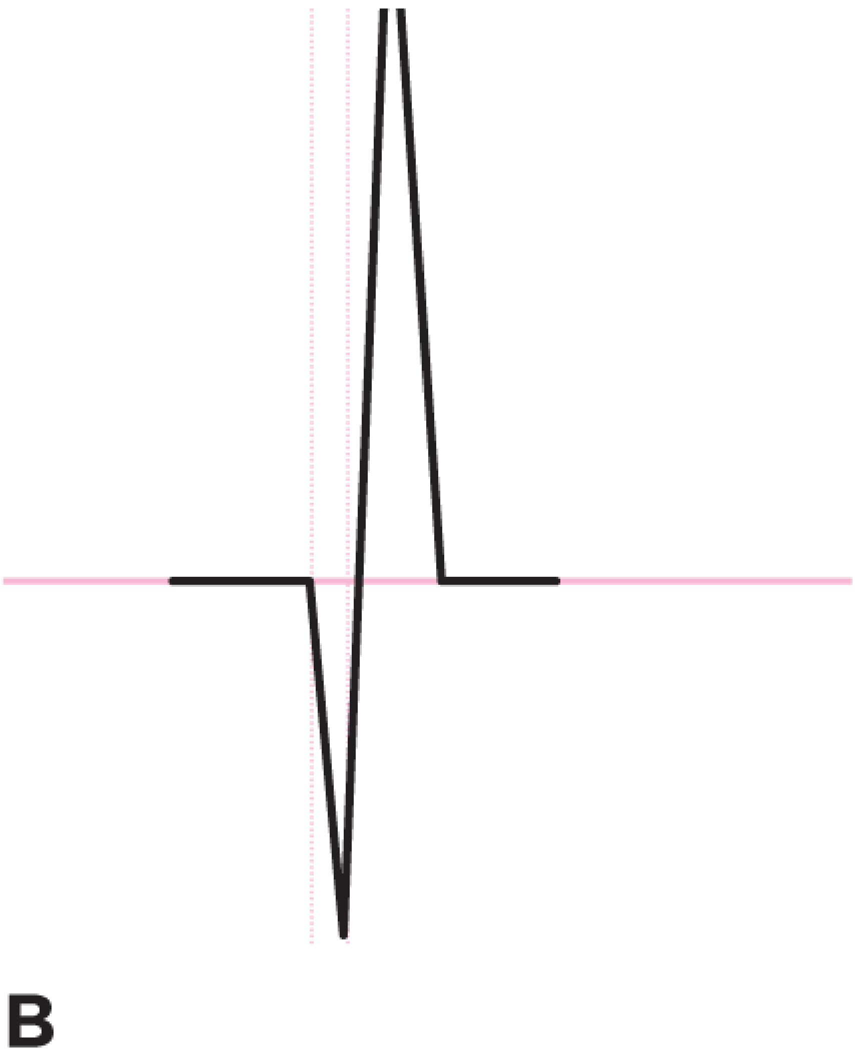


FIGURE 14-54 Q-wave significance. **A.** If the Q wave is more than one-third the total height of the QRS complex, it is a pathologic Q. **B.** If the Q wave is more than 30 ms wide, it is a pathologic Q.

© Jones & Bartlett Learning.

An MI can occur with or without Q waves. Q waves can develop as discussed, especially when larger areas of myocardium are affected. With a smaller infarct, the cell-to-cell conduction of electrical impulses can hide the smaller resulting Q wave. Because ischemia and injury are always present in the setting of MI, ST-segment and T-wave abnormalities will still be present. When a patient has a history, signs and symptoms, and ECG changes suggestive of a cardiac event, a full workup is indicated. In this case, evaluation of cardiac enzymes can be the key to making the correct diagnosis.

Generally, STEMIs are associated with a higher incidence of HF and death because of the larger area of heart tissue damaged. NSTEMIs tend to lead to a higher incidence of long-term mortality because of life-threatening arrhythmias that arise from the area of infarction. Quick recognition of ischemia, injury, and infarction, followed by rapid intervention, can reduce the area of infarction and decrease the incidence of subsequent cardiac events that might lead to death.

As mentioned earlier in this section, the infarcted myocardial tissue becomes electrically neutral. As a result, the electrical current will be directed away from the area of infarction. The electrode that lies over the area of infarction will record a deep negative deflection, a Q wave. The electrical current that is directed away from the area of infarction causes **reciprocal changes** in leads located 180° from the site of infarction. Reciprocal leads must be 180° from the lead in question and lie in the same plane. Limb leads and precordial leads cannot be reciprocal, because limb leads lie in the frontal or vertical plane, whereas precordial leads lie in the horizontal plane. The apparent increase in electrical force moving toward the opposite lead will be recorded as tall, positive R waves. This applies not only to Q waves, but also to ST-segment and T-wave changes. For example, a Q wave, an ST-segment elevation, and a T-wave inversion recorded in leads II, III, and aVF will be recorded as a tall R wave, ST-segment depression, and an upright T wave in the reciprocal leads I and aVL **FIGURE 14-55** and **TABLE 14-8**.

Localizing the Infarction

The area of myocardium that infarcts depends on which coronary arteries are occluded and the extent of the collateral blood flow. It is important to localize where an infarction has occurred because the prognostic and therapeutic implications are determined largely by which area of the heart has died. Each of the coronary arteries perfuses more than one area in the heart. Thus, if one coronary artery becomes blocked, more than one region of the heart can become ischemic and develop injury and, ultimately, infarction. ECG findings, therefore, do not always fall neatly into one anatomic area of infarction.

Acute MIs often involve more than one region of the heart. For example, an inferior MI is often an inferoposterior MI, an anterior MI can become anteroseptal or anterolateral, lateral MIs are often posterolateral, and so forth **FIGURE 14-56**. Q waves from old infarctions can be present with findings of a new MI and can obfuscate the process of making the correct diagnosis from the ECG. In the CCT setting, the patient by definition is in serious condition and will likely have evidence of one or more underlying conditions. This makes it even more important to review an "old" ECG from the patient's chart, acquire a new 12-lead ECG before transport, and make serial evaluations along the way. To be sure an ECG change has occurred, CCTPs must know what was there before they came in contact with the patient.

Description

With all this in mind, in general, infarctions can be grouped into several general anatomic categories **TABLE 14-9**.

TABLE 14-9 Coronary Artery Relationships to Area Perfused

Area of the Heart	Main Arteries That Perfuse the Area
Inferior	RCA (90%), LCx (10%)
Inferior right ventricle	Proximal RCA
Inferoposterior	RCA (90%), LCx (10%)
Isolated right ventricle	LCx

Area of the Heart	Main Arteries That Perfuse the Area
Isolated posterior	RCA (90%), LCx (10%)
Anterior	Left anterior descending
Anteroseptal	Left anterior descending
Anteroseptal-lateral	Proximal left anterior descending
Anterolateral, inferolateral, or posterolateral	LCx

Abbreviations: LCx, left circumflex artery; RCA, right coronary artery
© Jones & Bartlett Learning.

Acute Anterior Myocardial Infarction

An anterior wall MI seldom occurs alone. It involves the anterior surface of the left ventricle and is usually caused by occlusion of the left anterior descending artery **FIGURE 14-57**. Leads V_3 and V_4 are considered the anterior leads **FIGURE 14-58**. In an anterior MI, the normal pattern of R-wave progression may not occur, a situation called **poor R-wave progression**.

Description

Even without significant Q-wave formation, poor R-wave progression may signify an anterior MI. Poor R-wave progression can also be seen in patients with RVH and chronic lung disease and with improper lead placement. By itself, it is not specific for the diagnosis of anterior MI.

Acute Anteroseptal Myocardial Infarction

An anteroseptal MI is common with an occlusion of the left anterior descending artery. As with all anterior MIs, this presentation is often associated with hemodynamic compromise and cardiogenic shock. The leads that offer the best view of this MI pattern are the septal leads V_1 and V_2 and the anterior leads V_3 and V_4 **FIGURE 14-59** and **FIGURE 14-60**.

Description

The ECG in **FIGURE 14-61** represents an acute anteroseptal MI. The anterior and septal leads, V_1 through V_4, show marked elevation and flattening of the ST segment, which is typical of this pattern of infarction. Further evaluation of the ECG shows some minimal elevation of the ST segment in lead aVL. The left anterior descending artery perfuses all three areas. ST-segment depression is found in the reciprocal leads, II, III, and aVF.

Description

Acute Anteroseptal Myocardial Infarction With Lateral Wall Extension

If the proximal left anterior descending artery is occluded, an acute anteroseptal MI with lateral wall extension may result. Changes can be seen in all precordial leads (specifically, V_5 and V_6 for the lateral extension) and in leads I and aVL. With the loss of electrical impulses in the anterior infarcted tissue, there is not always significant Q-wave formation. Reciprocal changes can be found in leads II, III, and aVF **FIGURE 14-62** and **FIGURE 14-63**.

Description

The ECG in **FIGURE 14-64** represents an acute anteroseptal MI with lateral wall extension. The ST-segment elevation in leads V_2 through V_6 extends to leads I and aVL. Reciprocal changes are seen in leads III and aVF. In addition to the signs of ischemia and injury, Q waves are forming in leads V_3 to V_6 and in leads I and aVL. In this ECG, the ST segments are very elevated and the T waves are tall and peaked; this phenomenon, often referred to as hyperacute T-wave changes, indicates an early acute MI. The hyperacute T-wave changes occur only during the first 15 to 30 minutes of an acute MI. When they occur outside the hospital, they are seldom seen because responders usually arrive after the period when these changes are visible. If these changes are found during transport, CCTPs are in a unique position to initiate care, even if it is only to notify the receiving facility to decrease the door-to-treatment time. Early revascularization has a good outcome because the period of ischemia has been relatively short and less permanent damage has been done.

Description

Acute Lateral Wall Myocardial Infarction

An acute lateral wall MI involves the left lateral wall of the heart. It can occur alone or with other patterns of infarction. This type of MI is often the result of occlusion of the left circumflex artery. ECG changes may occur in the lateral leads (I, aVL, V_5, and V_6), while reciprocal changes may be seen in the inferior leads (II, III, and aVF) **FIGURE 14-65** and **FIGURE 14-66**.

Description

The ECG in **FIGURE 14-67** represents an acute lateral wall MI. There is ST-segment elevation in the lateral leads I and aVL, and reciprocal changes are apparent in the inferior leads II, III, and aVF. Further evaluation shows T-wave inversions in the lateral precordial leads V_5 and V_6. Because the inverted T waves are symmetric, they are related to the acute lateral wall MI and not associated with LVH with strain. An LVH pattern shows an asymmetric inverted T wave.

Description

Acute Inferior Wall Myocardial Infarction

An IWMI involves the diaphragmatic surface of the heart. It is caused by occlusion of the right coronary artery in 90% of patients and by occlusion in its descending branch or the left circumflex artery in 10% of patients. The characteristic ECG changes of infarction can be seen in the inferior leads II, III, and aVF. Reciprocal changes are seen as ST-segment depression in leads I and aVL, unless the high lateral wall is included in the infarction. An IWMI is commonly seen with patterns involving the lateral wall, the posterior wall, and RVMIs. Q waves persist for the lifetime of the patient in most cases, though not necessarily in inferior infarctions. Nearly 50% of inferior infarctions fail to meet the criteria for significant Q waves within 6 months. Small Q waves in the inferior leads may suggest an old inferior infarction. Small inferior Q waves may be present in healthy hearts, so it is important to use the patient's clinical history in decision making **FIGURE 14-68** and **FIGURE 14-69**.

Description

The ECG in **FIGURE 14-70** represents an acute IWMI. Pathologic Q waves appear in leads II and aVF. There are no acute ST-segment or T-wave changes present that would be consistent with an acute infarction. There are also no reciprocal changes found in leads I or aVL. Without signs of acute infarction, pathologic Q waves are considered age indeterminate; without a good patient history, there is no other way to know how old they are. There are also two premature ventricular ectopic beats present that are not necessarily related to the other findings.

Description

Acute Inferolateral Myocardial Infarction

ECG changes found in acute inferolateral MIs are seen in inferior leads II, III, and aVF and in lateral leads I, aVL, V_5, and V_6. ST-segment changes may occur and will be found in leads V_2 to V_4 if the infarct extends anteriorly. When anterior extension is present, classic ST-segment and T-wave changes will always be seen in the lateral precordial leads, V_5 and V_6 **FIGURE 14-71** and **FIGURE 14-72**.

Description

Acute Apical Myocardial Infarction

An apical MI is an extension of an inferolateral MI. It covers a large area of the inferior part of the heart and extends further anteriorly and laterally. The acute apical MI occurs in a patient with RCA dominance. Direct ECG changes can be found in inferior leads II, III, and aVF; lateral leads I and aVL; and precordial leads V_2 through V_6. Because of the diffuse ECG changes, an acute apical MI may be confused with pericarditis **FIGURE 14-74** and **FIGURE 14-75**.

Description

The ECG in **FIGURE 14-76** represents an acute apical MI. Because of the large area affected, the ECG changes are diffuse and can take the form of ST-segment elevation in limb leads I, II, III, and aVF and precordial leads V_2 to V_6. This widespread pattern of ECG changes must be distinguished from those seen in other conditions such as pericarditis. In pericarditis, there are no Q waves or reciprocal changes, and the T-wave inversion usually does not occur until the ST segment returns to baseline. In an infarction, the ST segment is elevated and the T wave is inverted at the same time. A very rare condition that also demonstrates diffuse ECG changes is aortic dissection, which occludes the coronary ostea (the origin of the coronary arteries) on the aorta just distal to the aortic valve. This blockage, among other things, causes a global infarction of the heart because it occludes the source of both main coronary arteries.

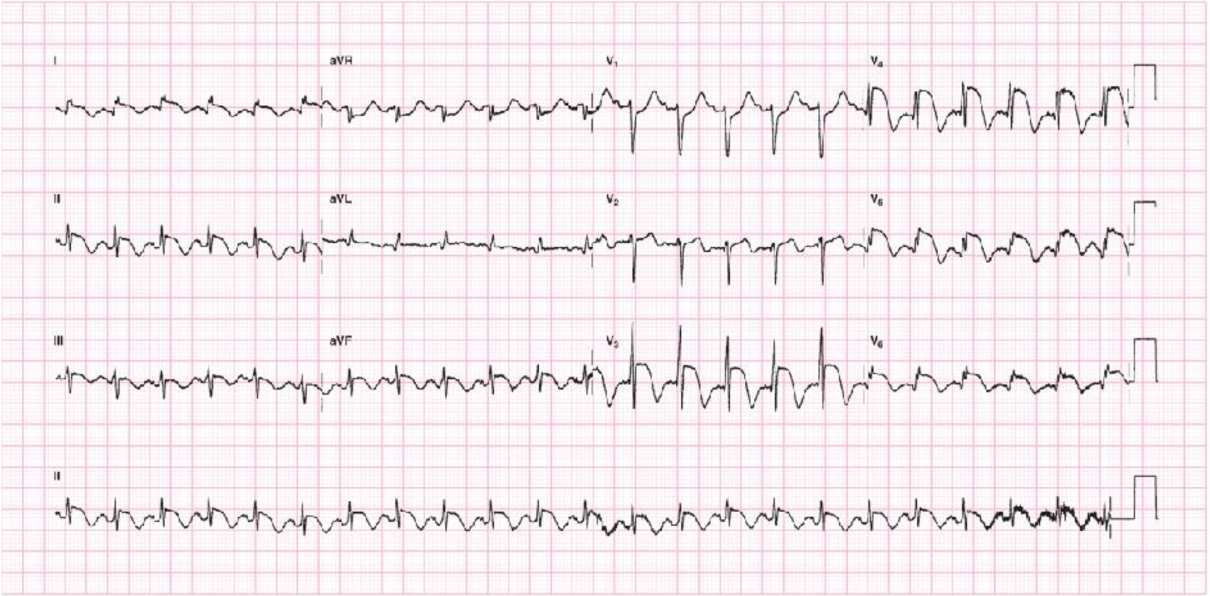

FIGURE 14-76 A 12-lead electrocardiogram showing an acute apical myocardial infarction.

Reproduced from *Introduction to 12-Lead ECG: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Description

To rule out some of the more serious differential diagnoses when acute apical MI is suspected, a complete history and clinical evaluations are needed; in addition, radiographic testing, echocardiograms, and more sophisticated tests such as cardiac catheterizations may be necessary. Problematically, no single exam or test is completely reliable for diagnosing acute apical MI.

Acute Right Ventricular Myocardial Infarction

This section predominantly deals with the criteria for identifying RVMI. Further study of RVMI is suggested to obtain a better understanding of its pathophysiology, clinical diagnosis, and management.

RVMI is strongly associated with IWMIs in 30% to 50% of cases **FIGURE 14-77** because both of these areas are most often perfused by the RCA and its branches. An occlusion of the RCA would likely affect both regions of the heart at the same time. In a small percentage of cases, the left circumflex artery can supply regions of the inferior wall and right ventricle; in these cases, an occlusion in the left circumflex artery could, therefore, cause the same pattern of infarction. RVMIs accompany an additional 10% of anterior wall MIs. Because of the high coexistence of RVMI with IWMI, it is important for CCTPs to maintain a high index of suspicion and check for other criteria.

Description

When RVMI is present, the ST segment is greater in lead III than in lead II **FIGURE 14-78**. Because of the RVMI, the electrical impulse flows unopposed from the interventricular septum and is directed anteriorly, inferiorly, and to the right. Because this impulse flow causes the vector to move toward the lead III electrode, it is recorded with greater amplitude there than in lead II.

FIGURE 14-78 Electrocardiographic changes seen with a right ventricular infarction. Note the ST-segment elevation in lead V_1. Depending on how much of the RV is affected, this ST-segment elevation can extend up to V_6. In addition, the amount of ST-segment depression has to be less than half of the ST-segment elevation in lead aVF to warrant the diagnosis of RVMI.

© Jones & Bartlett Learning.

Description

With ST-segment elevation in (septal) lead V_1 and (inferior) leads II, III, and aVF, RVMI should be suspected. Because the electrical impulses are not being transmitted through infarcted tissue, they continue to travel unopposed in all other directions. The alteration in the wave of depolarization generally causes ST-segment elevation in V_1 and ST-segment depression in V_2. Depending on the extent of the MI in the involved heart tissue, ST-segment elevation can sometimes extend through V_5 or V_6.

As mentioned, ST-segment elevation will occur in V_1, but it will usually be depressed in V_2. This difference arises because MI-related alterations in the electrical impulse will cause the vector to travel more directly toward V_1 and past V_2.

An ST-segment depression in V_2 that is less than half the height of the ST-segment elevation in aVF indicates the infarct is localized to the inferior right ventricular region. An ST-segment depression in V_2 that is more than half the height of the ST-segment elevation in aVF indicates that the infarct is larger and includes the inferior wall, right ventricle, and posterior wall.

The use of nonstandard or additional leads on the right side of the chest is important for localizing an infarction. An ST-segment elevation of 1 mm or more in the right-side chest leads, V_4R to V_6R, is the most specific indication for RVMI. Evidence of IWMI (eg, ST-segment elevation and T-wave inversion in leads II, II, and aVF) combined with 1 mm or more ST-segment elevation in V_4R is considered diagnostic of an inferior RVMI. If right-side chest leads are being obtained, a complete set, including V_4R through V_6R, should allow for a more complete view of the right ventricle. In the presence of IWMI, right ventricular leads should always be recorded as well.

The criteria for diagnosing RVMI are as follows:

- IWMI
- ST-segment elevation greater in lead III than in lead II
- ST-segment elevation in V_1 that could extend through V_5 or V_6

- ST-segment depression in V_2 (unless the ST-segment elevation extends through V_5 or V_6)
- ST-segment depression in V_2 that is not more than half of the ST-segment elevation in aVF
- 1 mm or more of ST-segment elevation in the right-side leads (V_4R to V_6R)

The ECG in **FIGURE 14-79** represents an RVMI. The first notable changes on the standard 12-lead ECG are the classic findings of an IWMI and ST-segment elevation in leads II, III, and aVF, with reciprocal findings of ST-segment depression in leads I and aVL. An RVMI is suspected because of the IWMI; lead III shows an ST-segment elevation greater than that noted in lead II. Additional criteria for RVMI are met with the ST-segment elevation in V_1 and the ST-segment depression in V_2 that is less than half of the ST-segment elevation in aVF.

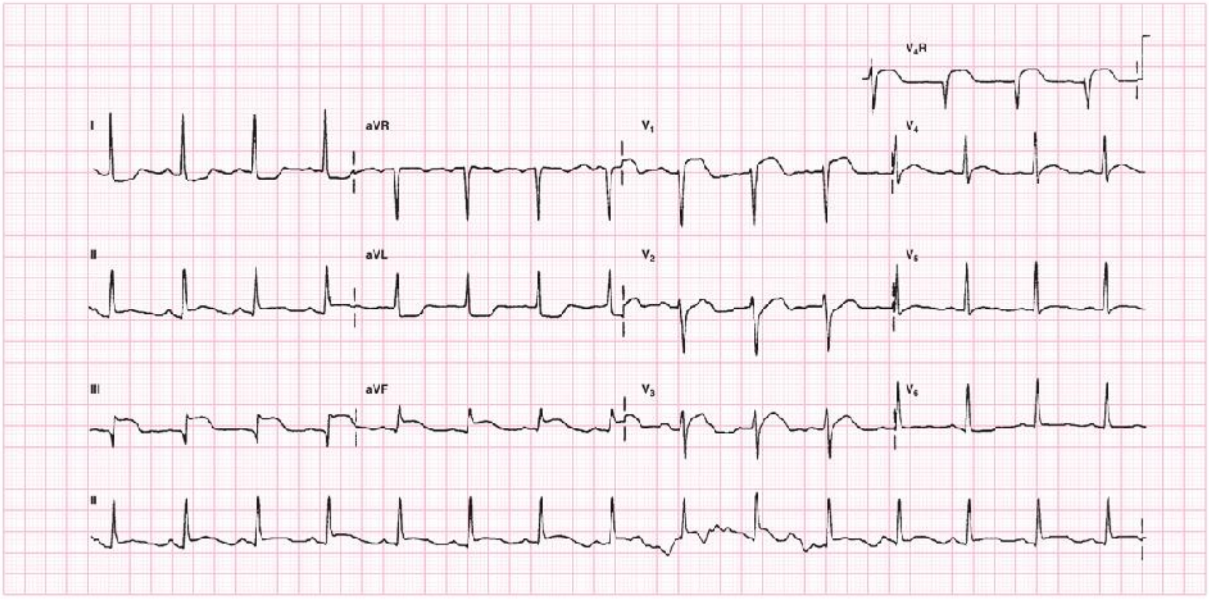

FIGURE 14-79 A 12-lead electrocardiogram showing a right ventricular infarction.

Description

With the criteria met for RVMI in the standard 12-lead ECG, the additional right-side chest leads V_4R to V_6R should be considered. The ST-segment elevation in lead V_4R completes the diagnostic criteria for RVMI. (Note: The example in Figure 14-79 shows only lead V_4R.)

Acute Posterior Wall Myocardial Infarction

A PWMI is caused by an occlusion of the RCA. The RCA bifurcates into the posterior descending artery and the right posterolateral artery in 80% to 85% of the population; the posterior descending artery comes off of the left circumflex artery in the remaining 15% to 20% of the population. The posterior descending artery, which is sometimes called the posterior interventricular artery, supplies the inferior wall, ventricular septum, and posteromedial papillary muscle. The right posterolateral artery divides into branches that supply the posterior surface of the left ventricle.

On a standard 12-lead ECG, there are no leads that specifically look at the posterior surface of the heart. Thus, when using standard 12-lead ECG technology, the diagnosis of PWMI is made by looking for reciprocal changes in leads V_1 and V_2. These changes include ST-segment depression, upright T waves, and tall R waves. Normally, the QRS complex in lead V_1 has a small R wave and a deep S wave. **FIGURE 14-80** shows the characteristic reciprocal changes of a PWMI as seen in leads V_1 and V_2. The addition of posterior leads can record a direct representation of electrical impulses through the posterior wall.

Description

An R wave with greater amplitude than the corresponding S wave is highly suggestive of a PWMI. In RVH, an R wave greater than the corresponding S wave is also present in lead V_1. The difference is that RVH also requires the presence of an RAD, which is not present in a PWMI.

Because the posterior descending artery branch of the right coronary artery also perfuses regions of the inferior wall, posterior and inferior wall MIs often occur together.

As discussed earlier, nonstandard or additional leads can be used to provide a direct view of the posterior wall of the heart. When there is reciprocal evidence of a PWMI, the CCTP should maintain a high index of suspicion and record the posterior leads (V_7, V_8, and V_9) for comparison. Record a standard 12-lead ECG first. Then add the additional posterior electrodes, attach the precordial leads as described, and record and “label” the posterior leads to avoid confusion. In the posterior leads, the electrical impulses must travel through the larger muscle mass of the back, which increases the electrical resistance. The complexes are typically positive but tend to have a lower amplitude.

Description

The ECG in **FIGURE 14-83** represents a PWMI with reciprocal changes seen on a standard 12-lead ECG. This ECG shows tall R waves in leads V_1 and V_2, as well as ST-segment depression with an upright T wave. These changes are all suggestive of a PWMI.

Description

As mentioned, in the majority of the population, the coronary blood supply to the posterior wall is also shared by the inferior wall and right ventricle. In consequence, patterns of infarction with changes associated with the inferoposterior and inferior-right ventricular-posterior areas are often seen.

Cardiomyopathy

Cardiomyopathy is a general term for diseases in which the myocardium becomes dilated, enlarged, or stiffened, ultimately progressing to HF, acute MI, or death. One variant, hypertrophic cardiomyopathy, is an autosomal-dominant hereditary disease. The main feature of hypertrophic cardiomyopathy is an excessive thickening of the heart muscle (*hypertrophy* means “to thicken or grow excessively”). In addition, microscopic examination of the heart muscle shows that it is abnormal. Patients may have shortness of breath, chest pain, palpitations, or syncope. Progression of cardiomyopathy is common, even with treatment, and sudden cardiac death can occur. A wide range of medications are used to arrest or delay progression of HF. Many patients require pacemaker and/or defibrillator implantation. Some will be referred for ventricular assist devices or heart transplant.

Heart Failure

Formerly known as congestive heart failure (CHF; also called chronic heart failure), the more contemporary term **heart failure (HF)** refers to a decline in the ability of the heart, for any reason, to pump powerfully enough or fast enough to empty its chambers. Although development of HF is not always a result of acute MI, the basic principles of diagnosis and treatment are similar, whatever the precipitating factors. It was previously believed that congestion and fluid overload were largely responsible for the dyspnea and edema of HF. Newer evidence has demonstrated that a significant number (perhaps as many as half) of patients presenting with acute decompensated HF are actually intravascularly volume depleted rather than fluid overloaded. This factor, coupled with the difficulty in differentiating HF from pulmonary causes of dyspnea and orthopnea, has significantly reduced the role of diuretics as first-line therapy in patients with dyspnea and adventitious lung sounds.

More than 6.2 million people in the United States have HF, and an additional 550,000 cases are diagnosed each year. One-fourth of the patients with HF classified as severe die within 1 year of diagnosis, half of patients die within 5 years of their HF diagnosis, and the remaining 25% die within 10 years. Severe cases are defined as patients with acute pulmonary edema and marked limitations of their physical activity; cases involving cardiogenic shock are life threatening. HF is often described in relationship to preserved or reduced ejection fraction (HFpEF or HFrEF).

HF can have a number of causes, including the following:

- Wall abnormalities (dilated and hypertrophic)
- Valve failure (mitral, tricuspid, aortic, and pulmonic)
- Damage as the result of infarctions
- Conduction abnormalities

In most cases, HF begins with a major infarction involving one or more of the left ventricle walls (septum, anterior, or lateral). Major infarctions can often involve the right side and inferior walls. In any case, the combination of subsequent inadequate coronary artery oxygenation and cardiac damage often leads to conduction path disturbances, particularly AV nodal blocks requiring pacemaker implantation.

Another problem occurs around the areas of a major infarction. The new nerve fibers develop with an increased density that results in hyperinnervation. In turn, this condition can lead to VT and ventricular fibrillation, requiring ICD implantation.

In cases of infarctions involving the septum, synchronization between the ventricles is lost and the ejection fraction is reduced. Patients often require biventricular pacing to restore synchrony.

Left-Side Heart Failure

The left ventricle is most commonly damaged during an acute MI. Likewise, in chronic hypertension, the left ventricle tends to reflect the long-term effects of having to pump against an increased afterload (constricted peripheral arteries). In both cases, the right side of the heart continues to pump relatively normally and to deliver normal volumes of blood to the pulmonary circulation. By comparison, the left side of the heart may no longer be able to adequately pump the blood being delivered from the pulmonary vessels. As a result, blood backs up behind the left ventricle, and the pressure in the left atrium and pulmonary veins increases. As the pulmonary veins become engorged with blood, serum is forced out of the pulmonary capillaries and into the alveoli. This serum mixes with air in the alveoli to produce foam (in pulmonary edema).

When fluid fills the alveoli, oxygenation is impaired. The patient experiences that impairment as shortness of breath (dyspnea), particularly when in a recumbent position. Such orthopnea may occur in conjunction with **paroxysmal nocturnal dyspnea**—that is, severe shortness of breath occurring at night after several hours of recumbency, during which fluid builds up in the lungs; the person is forced to sit up to breathe. Paroxysmal nocturnal dyspnea is caused by left-side HF or the decompensation of COPD. If left ventricular failure is the result of chronic overload (as opposed to acute MI), the patient is likely to give a history of a week or two of paroxysmal nocturnal dyspnea. To compensate for the impairment in oxygenation, the patient's respiratory rate increases (tachypnea); even so, if the patient's condition is advanced enough, hypoxia may become evident. In some patients with pulmonary edema, especially elderly patients, Cheyne-Stokes respirations may be present.

Fluid from the pulmonary vessels also leaks into the interstitial spaces in the lungs, and increasing interstitial pressure causes narrowing of the bronchioles. Air passing through the narrowed bronchioles creates wheezing, whereas air bubbling through the fluid-filled alveoli produces crackles. Furthermore, the patient may cough up edematous fluid in the form of foamy, blood-tinged sputum. As the airways narrow and the lungs grow moist from the accumulation of fluid, the work of breathing increases, which puts an even greater strain on the already floundering heart. Dyspnea and hypoxemia produce a state of panic, which induces the release of epinephrine from the adrenal glands. The heart is pushed to work even harder, and its oxygen demand is increased precisely when fluid in the alveoli is reducing the amount of oxygen available.

To make matters worse, the sympathetic nervous system response produces peripheral vasoconstriction: Peripheral resistance (afterload) increases, and the weakened, hypoxic heart finds itself trying to push blood out into smaller and smaller pipes. Clinically, peripheral vasoconstriction is apparent as pallor and elevated blood pressure. The massive sympathetic discharge also produces sweating of the pale, cold skin.

It is not unusual for a patient with left-side HF to become frantic from air hunger. The patient may pace or thrash about or may even be combative and struggle with health care providers. Furthermore, hypoxemia results in inadequate oxygen supply to the brain, often manifested as confusion or disorientation. If hypoxemia is severe, brady-asystolic cardiac arrest may follow.

Signs and Symptoms of Left-Side Heart Failure

The signs and symptoms of left-side HF include extreme restlessness and agitation, confusion, severe dyspnea and tachypnea, tachycardia, elevated blood pressure, crackles and possibly wheezes, and frothy, pink sputum. Sometimes, it may be difficult to distinguish the wheezing of asthma from that of left-side HF. Capnography waveform analysis is often helpful in differentiating bronchoconstriction from respiratory distress secondary to pulmonary edema.

Management of Left-Side Heart Failure

If a CCT team is transporting a patient with left-side HF, the patient has probably experienced or is having an acute MI.

Pulmonary edema occurs as the result of the reduced ejection fraction and CO of the left ventricle. Because the CO from the right ventricle is normal, pulmonary hydrostatic pressure is increased. This greater pressure causes fluids to cross the alveolar-capillary membranes, filling the alveoli.

The priorities when managing left-side HF are as follows:

1. Decrease pulmonary congestion.
2. Reduce afterload.
3. Normalize myocardial oxygenation.
4. Decrease myocardial oxygen demands.

From a critical care point of view, if the patient is conscious and is able to maintain their airway, application of noninvasive ventilation (such as continuous positive airway pressure [CPAP] or bilevel positive airway pressure [BPAP]) addresses all of these objectives. Noninvasive ventilation provides a positive end-expiratory pressure (PEEP) that opens the terminal bronchi, expands the alveoli, and creates enough pressure to overcome the increased pulmonary hydrostatic pressure, theoretically forcing fluids back into the capillaries and reducing afterload.

If the patient's level of consciousness is such that they cannot maintain the airway, endotracheal intubation is indicated. Once successful intubation has been achieved, apply PEEP using a transport ventilator and manage secretions with endotracheal suctioning. Waveform capnography must be used to monitor ventilation.

Once the airway and ventilation are controlled, the blood pressure must be managed. If the patient has significant fluid overload, consider administering a diuretic to promote increased urine output.

Hypertension should be managed with IV antihypertensive medications. IV nitroglycerin is used to manage cardiac chest pain. This medication is usually started at a rate of 10 mcg/min, with the dose then being increased in 10-mcg increments until the patient obtains pain relief. The ceiling is considered to be a rate of 200 mcg/min, although many patients will experience intolerable headaches at lower doses of nitroglycerin.

Hypotension should be managed with pressors and cautiously with volume repletion. Use of a pressor that also provides inotropic support is likely to be more helpful than administration of a pure pressor agent alone. Although the best choice is currently unclear, dopamine, epinephrine, and norepinephrine are often chosen initially. Hypotensive patients with LV failure are quite likely to be in cardiogenic shock. An ideal IV agent for patients with such HF is dobutamine, as it provides both inotropic support and afterload reduction by vasodilation. Dobutamine is contraindicated in patients with hypotension.

When fluid overload is suspected, IV diuretics can be considered. Furosemide is often the first-line choice. Dosing is variable, but this medication is usually given as 0.5 to 1 mg/kg, not to exceed 80 mg. Continuous infusions of diuretics are also effective for patients with significant volume overload.

With all patients with HF or pulmonary edema, the CCTP should obtain a 12-lead ECG and monitor the patient for arrhythmias.

If there is evidence of an evolving or acute MI, the therapies discussed previously for ACS will also be needed during transport.

Signs and Symptoms

Left-Side Heart Failure

- Extreme restlessness and agitation
- Confusion
- Severe dyspnea and tachypnea
- Tachycardia
- Elevated blood pressure
- Crackles and possibly wheezes
- Frothy, pink sputum

Right-Side Heart Failure

Right-side HF most commonly occurs as a result of left-side HF. As blood backs up from the left side of the heart into the lungs, the right side has to work increasingly harder to pump blood into the engorged pulmonary vessels. Eventually, the right side of the heart cannot keep up with the increased workload, and it, too, fails. Right-side HF may also occur as a result of pulmonary embolism or long-standing COPD, especially chronic bronchitis.

When right-side HF occurs, blood backs up from the right ventricle, increasing pressure in the systemic veins and causing them to become engorged. Distention can be seen in surface veins, such as the external jugular veins. Over time, as the pressure within the systemic veins increases, serum is forced out of the veins and into the surrounding tissues, producing edema. This edema is most evident in dependent parts of the body, such as the legs and feet in an ambulatory patient (pedal edema) or the lower back in a bedridden patient (sacral edema). Edema is also present in parts of the body that are *not* visible; a painful liver that is easily palpable in the right upper quadrant, for example, signals engorgement and swelling (hepatomegaly).

The development of right-side HF can actually improve left-side HF because the failing right side of the heart can no longer pump as much blood into the lungs. The decrease in right-side output amounts to a decrease in preload for the left side of the heart and may lessen pulmonary congestion.

Transport Management

Left-Side Heart Failure

- If the patient is conscious and is able to maintain a patent airway, apply noninvasive ventilation (CPAP or BPAP).
- Intubate the patient if they cannot maintain the airway.
- Use the transport ventilator to apply PEEP to manage pulmonary edema.
- Suction the endotracheal tube, if in place, to manage secretions.
- Use continuous waveform capnography to monitor the patient's response to ventilation.
- Manage the patient's blood pressure (with vasodilators or pressors).
- Consider inotropic therapy for patients with significant HF symptoms.
- Obtain a 12-lead ECG.
- Monitor for arrhythmias.
- Provide analgesia and, if indicated, anxiolytics.
- If acute MI is identified, consider STEMI/ACS interventions (eg, antiplatelet agents, heparin, ADP inhibitors).

Right-side HF, by itself, is seldom a life-threatening emergency. Usually it develops gradually over days to weeks; likewise, it requires days to weeks to reverse the process, with therapy focusing on slowly ridding the body of excess salt and water. Field treatment of right-side HF, therefore, is simply to make the patient comfortable, which is generally accomplished by placing the patient in the semi-Fowler position. Monitoring is always indicated in any patient with significant cardiac disease. If signs of associated left-side HF are present, treat them as outlined in the previous section.

Signs and Symptoms

Right-Side Heart Failure

- Edema

Transport Management

Right-Side Heart Failure

- Provide supportive care.
- Place the patient in a comfortable position, preferably a semi-Fowler position.
- Treat any signs of associated left-side HF.

Pulmonary Edema

Noninvasive ventilation, which includes CPAP, BPAP, and, in the opinion of some experts, high-flow nasal cannula (HFNC), is the mainstay of treatment for acute pulmonary edema in patients who are able to maintain their airways. Depending on the modality employed, noninvasive ventilation may improve alveolar ventilation and gas exchange, decrease the work of breathing, decrease preload and afterload, and increase lung compliance and functional residual capacity. (Ventilator support is discussed in Chapter 6, *Respiratory Emergencies and Airway Management*, and Chapter 7, *Ventilation*.)

Intubation of patients with acute respiratory distress resulting from asthma, COPD, or pulmonary edema should be seen as a last resort. Noninvasive ventilation leads to fewer complications and greater patient comfort. Transport ventilators should be capable of providing both CPAP and BPAP. Although currently available HFNC units are not designed for transport, if a sufficient gas supply is available, these devices may be utilized in CCT. HFNC units designed for transport are in development.

Transport Management

Pulmonary Edema

- Use noninvasive ventilation if the patient is able to maintain their own airway.
- Continue any afterload-reducing agents, inotropic agents, or diuretic infusions started prior to transport.
- Place the patient in a position of comfort.

Special Populations

Cardiovascular complications can be exacerbated by pregnancy. It is not uncommon for CCTPs to transport a pregnant patient to a tertiary center for aortic or mitral valve issues, coronary artery disease, thromboembolic events (including pulmonary embolism), or (although rare) aortic dissection.

Cardiac Electrophysiology

Although electrocardiography is routinely used to monitor cardiac rhythms, disturbances may require more sophisticated monitoring and, in some cases, evaluation in an **electrophysiology** lab. Using equipment and facilities similar to those found in a cardiac catheterization lab, an electrophysiologist is able to evaluate and map the focus of many cardiac rhythm disturbances. The specialty of electrophysiology involves evaluation and management of cardiac rhythm disturbances including VTs, SVTs (including AF), bradycardias, AV blocks, and syncope suspected to be of cardiac origin.

In a hospital setting, an electrophysiologist may conduct an electrophysiology study to assess the electrical activity of the heart by stimulating and recording activity from multiple catheters at several sites in the heart. Such a study records and maps electrical signals from the heart to determine the location of a heart block (AV node versus bundle of His), the origin of tachycardia (supraventricular versus ventricular), and other important considerations, such as the response to specific medications or devices used in treatment of arrhythmias. These clinical data assist in the following:

- Determining whether the patient’s symptoms are related to a tachyarrhythmia
- Assessing the risk for lethal tachyarrhythmias
- Developing and testing appropriate therapies based on the induced tachyarrhythmia and its mechanism

An electrophysiologist may also perform catheter ablation of areas where irritable foci originate. This type of ablation uses radiofrequency, cryothermy, microwave, laser, or surgical catheters or procedures to isolate or eliminate sources of rhythm disturbances.

The CCTP’s role during transport of a patient who requires electrophysiology studies or procedures is to anticipate the rhythm disturbances that initiated the referral and to address them as necessary during transport.

Patients presenting with symptoms suggestive of cardiac arrhythmias may be fitted with a Holter monitor, a battery-operated wearable device that continuously records ECG data. Holter monitoring is usually done for a minimum of 24 hours and can be continued for several weeks, depending on the indication and frequency of symptoms. In patients with difficult-to-determine rhythms or when long-term monitoring is required, an implantable loop recorder (ILR), also called an implantable loop monitor, may be used **FIGURE 14-84**. Made by pacemaker manufacturers, ILRs are USB-size, bipolar (single)-lead ECG monitoring devices that are implanted subcutaneously, usually in the patient's left parasternal area. The ILR's loop memory is capable of recording and storing 48 to 49 minutes of ECG data. Data recording is either activated by the patient (or a bystander) or automatically triggered by the occurrence of preprogrammed bradyarrhythmia or tachyarrhythmia **FIGURE 14-85**. These data can then be downloaded in a physician's office or transmitted telephonically. Loop recorders have a typical battery life of 3 years.

Description

Therapeutic Options for Patients With Arrhythmias

Pharmacologic, electrical, and surgical therapies for patients with arrhythmias have evolved tremendously over the years, and they continue to advance rapidly. The primary in-hospital arrhythmia therapies are catheter ablation, pharmacologic treatment, and implantable devices, such as pacemakers and ICDs.

Catheter Ablation

Ablation (destruction or isolation) of discrete areas in the heart may reduce or eliminate susceptibility to arrhythmias. Radiofrequency catheter ablation, microwave catheter ablation, cryothermy ablation, laser catheter ablation, and surgical ablation procedures can be highly effective for WPW syndrome and other SVTs, including atrial flutter, atrial tachycardia, AV node reentrant tachycardia **FIGURE 14-86**, and some VTs. Improvements in mapping techniques have made a wider variety of arrhythmias eligible for ablation.

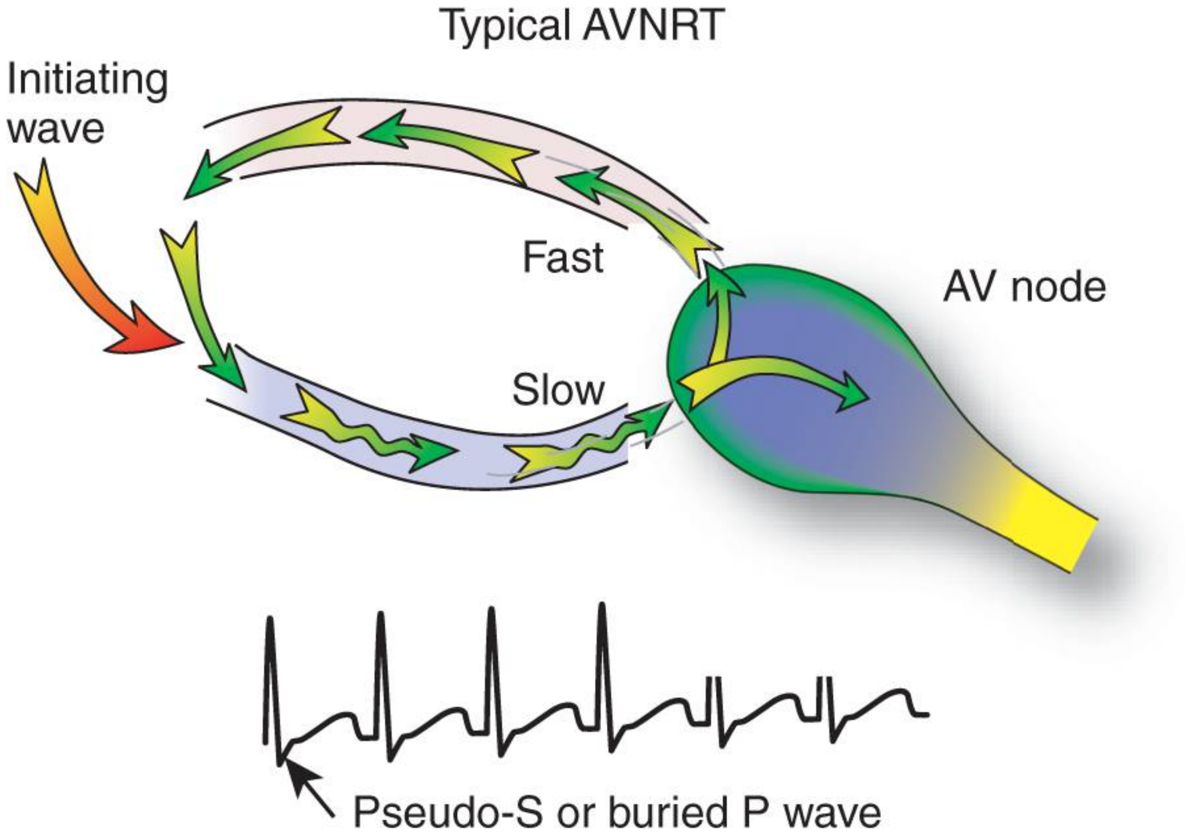

FIGURE 14-86 Atrioventricular (AV) node reentrant tachycardia (AVNRT).

© Jones & Bartlett Learning.

Description

Catheter ablation has completely changed the approach to the long-term care of patients with recurrent SVTs. Electrophysiologists often are able to perform ablation as an outpatient procedure. Ablative therapy is effective 90% to 98% of the time, frequently offers a long-term cure, and has a very low incidence of complications. For many patients with SVT, ablation eliminates the need for long-term medical therapy, which can result in drug-induced adverse events and reduced quality of life. Patients who are poorly compliant with prescribed medications or are reluctant to undergo long-term drug therapy may be candidates for catheter ablation.

Medications may also be used to interfere with electrical conduction or impulse formation at the AV node, accessory pathway, or origin of a focal tachycardia. Examples include digoxin, calcium antagonists, beta blockers, class IA agents (procainamide, disopyramide, quinidine gluconate, quinidine sulfate), class IC agents (propafenone, flecainide), and class III agents (amiodarone, sotalol). Long-term digoxin therapy is contraindicated in patients with WPW syndrome and patients with the capability of rapid **antegrade conduction** over the accessory pathway.

Atrial Ligation

While not a treatment for AF itself, left atrial appendage (LAA) ligation, occlusion, or excision is increasingly being employed as a preventive measure against thromboembolic events such as stroke, especially in patients with contraindications to long-term anticoagulation. In patients with AF, the left atrium is believed to be the primary source of thromboemboli. The LAA can be occluded or excised during cardiac bypass or valve surgery. Percutaneously inserted devices, such as the Watchman **FIGURE 14-87**, may also deployed into the LAA using a transseptal approach (ie, across the atrial septal wall).

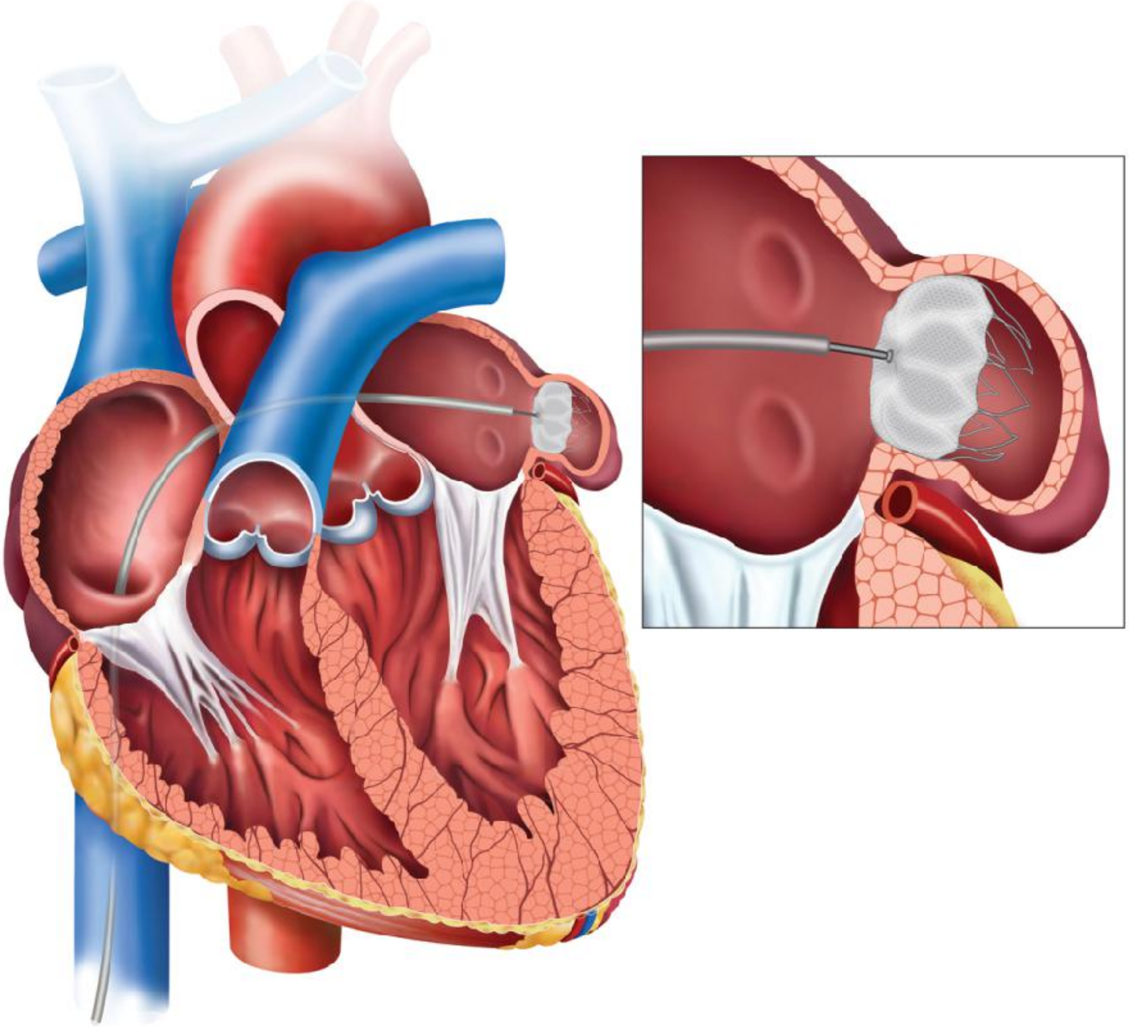

FIGURE 14-87 The Watchman device is percutaneously inserted into the left atrial appendage to permanently close off this portion of the heart.

Implanted Pacemakers

An implanted pacemaker provides impulse generation in a diseased heart whose own impulses may be characterized as follows:

- Intermittent
- Irregular

- Occurring at an inappropriate rate for the patient's metabolic demand
- Absent

A block can occur at any point within the SA node, AV node, bundle of His, or distal conduction system.

Contemporary pacemakers support heart function in multiple ways. They provide effective and consistent cardiac depolarization, prevent unnecessary pacing by sensing cardiac activity, synchronize right and left heart depolarization, increase the heart rate to match metabolic or physical demands, and store information about events and physiologic changes.

Implantable Cardioverter-Defibrillators

The **implantable cardioverter-defibrillator (ICD)** has been shown to prevent sudden death in patients with HF and in patients with a history of being resuscitated from sudden cardiac death. Evidence has confirmed that patients receive a greater benefit from ICD therapy than from antiarrhythmic drugs for the treatment of life-threatening ventricular tachyarrhythmias. Studies have also shown that ICDs are as much as 99% effective in terminating life-threatening ventricular tachyarrhythmias. All ICDs currently on the market also have pacing capability.

Wearable Cardioverter-Defibrillators

Patients at risk of sudden arrhythmogenic cardiac death may be prescribed a wearable cardioverter-defibrillator (WCD). These devices are discussed in greater detail later in this chapter.

Pacemakers

The first implantable pacemakers, developed in 1960, were asynchronous; they paced without regard to the heart's intrinsic action. The North American Society of Pacing and Electrophysiology (NASPE)/British Pacing and Electrophysiology Group (BPEG) Generic (NBG) codes appear later in this chapter in Table 14-10, which explains abbreviations related to pacemaker (also called pacer) function.

Single-chamber demand pacemakers appeared in the late 1960s. In 1979, the first **dual-chamber pacemaker** was introduced. Subsequently, the first single-chamber, rate-responsive pacemaker came into use in 1985. Today, dual-chamber pacemakers are available with a wide variety of programmable functions that allow rate-responsive pacing that mimics the heart's innate ability to respond to exercise and changes in metabolic needs. These devices are also equipped with antitachycardia pacing modes that aim to take rate control away from irritable foci in the atria or ventricles and restore normal rate and rhythm without cardioversion or defibrillation.

In a normally functioning heart, the SA node stimulates depolarization of the ventricles. When the SA node becomes impaired or otherwise dysfunctional, artificial pacing may be needed. The primary indications for pacing are as follows:

- Sinus node dysfunction (SND) with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms
- Symptomatic chronotropic incompetence (inability to sufficiently increase or lower the heart rate)
- Symptomatic sinus bradycardia resulting from necessary drug therapy
- Reflex syncope
- Third-degree and advanced second-degree AV blocks associated with symptomatic bradycardia, pauses, AF, or after catheter ablation of the AV node
- Cardiac resynchronization in certain patients with HF
- Hypersensitive carotid sinus syndrome
- Overdrive or antitachycardia pacing for atrial or ventricular tachycardias

Pacing Fundamentals

The Pacing Impulse

Electricity is the flow of electrons along a conductive medium. A **pacing impulse** has current, voltage, and impedance.

- **Current** is the movement of electrons through an electrical circuit over time, measured in amperes.
- **Voltage** is the force that causes current to flow, measured in volts. Voltage in a pacing system, referred to as amplitude, reflects the strength or intensity of a pacing pulse.
- Resistance to current, called **impedance**, is the sum of all factors that resist the flow of current along the conduction pathway, measured in ohms. One ampere is produced by 1 volt, acting through a resistance of 1 ohm.

The main sources of resistance in a pacing circuit are the lead conductor, the electrode, and the concentration of electrically charged ions at the electrode–tissue interface (polarization). Electrode resistance improves pacing efficiency; lead conductor resistance and polarization do not. Reviewing the following definitions and formulas will help CCTPs understand the basic concept of electricity as it pertains to pacing.

Ohm's law is an expression of the relationship between current (I), voltage (V), and resistance (R). Ohm's law states the following:

$$I = \frac{V}{R}$$

Consequently,

$$V = I \times R$$

$$R = \frac{V}{I}$$

With these equations, volts, current, and resistance may be calculated if the other parameters are known. If the voltage drops by half, the current flow does as well. Doubling impedance will also cut the current flow in half. Voltage and impedance are important determinants of battery longevity.

A **joule** is a measurement of energy:

$$\text{Energy} = \text{Volts} \times \text{Current} \times \text{Time}$$

Energy is expressed in joules or microjoules, as appropriate for the device.

The Pacing Circuit

A pacing system forms an electrical circuit in the patient's body in combination with body tissue and fluid. A **pacing circuit** consists of a power source, lead, cathode, anode, and body tissue, which form a conduction pathway along which electricity flows.

The pacemaker battery is the power source that generates electrical impulses. The lead conductor wire carries the impulses to the tissue. The **cathode** is an electrode with a negative charge that delivers the impulse to the myocardium. The impulses return through the **anode**, an electrode with a positive charge, after stimulating the heart. Body tissue and fluids between the anode and the cathode are also part of the conduction pathway. Passage of the pacemaker's electrical impulse between the cathode and the anode, through cardiac tissue and body fluids, is the event in the pacing circuit that stimulates cardiac depolarization. In a **bipolar system**, body tissue is part of the circuit only in the sense that it affects impedance at the electrode–tissue interface. In a **unipolar system**, contact with body tissue is essential to ground the **implantable pulse generator (IPG)**.

During pacing, an electrical impulse begins in the pacemaker battery, travels along the lead to the cathode, stimulates the heart, and then returns through body tissues to the anode to complete the pacing circuit **FIGURE 14-88**.

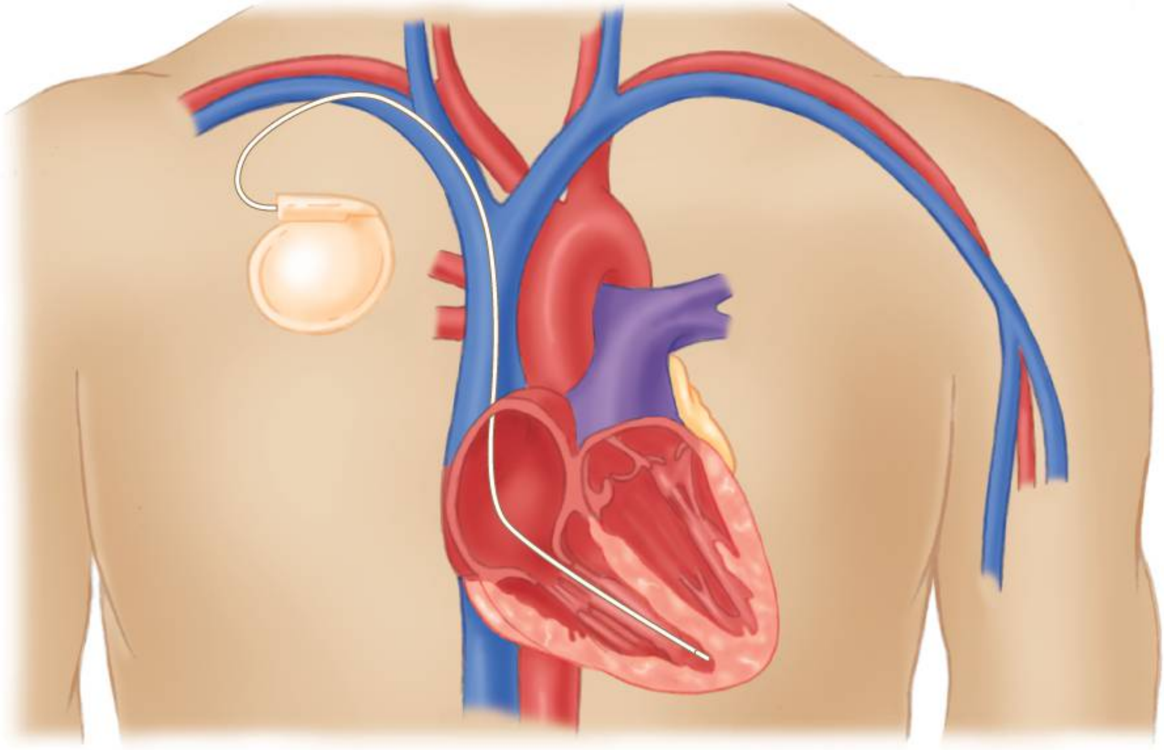

FIGURE 14-88 The pacing circuit. The electrical impulse travels along the lead, stimulates the heart, and returns through body tissues.

© Jones & Bartlett Learning.

Pacemaker Components and Functions

Pacemakers stimulate cardiac depolarization, sense intrinsic cardiac activity, respond to metabolic needs, and store diagnostic information. All pacemakers can provide fixed-rate pacing, in which the heart is paced at a predetermined rate. Most also provide rate-adaptive (rate-responsive) pacing, increasing and decreasing the pacing rate in response to input from rate sensors. This feature prevents the pacemaker from competing with normal cardiac function. In addition, modern pacemakers collect and store information about the patient's heart and the implanted pacemaker. This information allows clinicians to monitor pacing therapy, optimize programmed settings, and check battery and lead status. A basic pacing system consists of the following components:

- An IPG that contains a power source (ie, the battery that generates the impulse) and sensing, timing, and output circuitry that controls pacemaker operation
- Leads—one or two insulated wires that deliver electrical impulses from the pulse generator to the heart and return electrical signals from the heart to the pulse generator
- Electrodes—conductors at the ends of the leads that deliver impulses to the heart

Most IPGs include a telemetry coil for sending and receiving programming instructions and receiving diagnostic data. Many have sensors that measure indicators of exertion and use the results to change heart rate.

Leads. Lead insulation prevents contact between the conductor wire and body tissue, ensuring that stimulation occurs only at the tip of the electrode. About 95% of pacing leads are **endocardial (transvenous) leads**, which are threaded through veins—usually subclavian or cephalic—to the right atrium or ventricle. Their placement involves an introducer (hollow tube) and a stylet (stiff wire). The clinician uses imaging, usually fluoroscopy, to guide insertion and final placement. **Epicardial leads**, which attach to the external surface of the heart with sutures or another fixation device, account for the other 5% of pacing leads. Because epicardial placement requires a thoracotomy (chest incision), epicardial leads are considered desirable only when endocardial placement is not an option or fails to achieve capture when placed.

A pacing lead may be unipolar or bipolar. A **unipolar lead** has one conductor wire connecting to a single electrode. The cathode is in contact with the heart, and the IPG housing is the anode. A pacing pulse travels from the IPG to the tip of the electrode (cathode) to stimulate the heart and returns to the IPG housing through chest tissues to complete the pacing circuit. The current flows through a substantial part of the chest and forms a large current loop; the resulting pacing spike is readily visible on an ECG.

A **bipolar lead** has two conductor wires; both the anode and the cathode are in contact with the heart. The anode—that is, the ring electrode located 0.8 inch to 1.2 inches (2 to 3 cm) above the cathode—has a separate lead connecting it to the IPG. The pacing pulse travels from the IPG to the cathode and then through tissue to the ring electrode. It returns to the IPG by way of the second conductor wire. Because the current loop is small, passing through only a limited area of cardiac tissue, the pacing spike on the ECG is also small.

Electrodes. As mentioned, a cathode is the electrode that is in contact with heart tissue. It is negatively charged when electrical current is flowing. The anode is the electrode that receives the electrical impulse after depolarization of cardiac tissue. It is positively charged when electrical current is flowing.

Small electrodes with a porous surface increase electrode resistance and reduce the effects of polarization. The porosity significantly increases the electrode surface area without increasing the radius and, therefore, reduces the wasteful effects of polarization. The porous surface also promotes tissue ingrowth and improves sensing by providing a larger electrode–tissue contact area.

Steroid Elution. There are two types of transvenous pacemaker leads: passive fixation and active fixation. The active fixation leads require higher stimulation than the passive fixation leads do. Nevertheless, they are preferred for the following reasons:

- Passive fixation leads involve atrial appendage placement, which is difficult in patients who have undergone prior cardiac surgery.
- Active fixation leads allow for more placement areas.
- Active fixation leads reduce the incidence of dislodgement.

To make the active fixation more beneficial, a steroid-eluting lead was developed. In the past, the steroid reservoir in the tip of the lead contained dexamethasone sodium phosphate. The inclusion of the steroid-eluting reservoir in the active fixation lead improved stimulation thresholds and was found to extend the pulse generator's longevity.

Steroid elution reduces inflammation and the growth of fibrous tissue at the electrode site. Both inflammation and fibrosis decrease the electrical excitability of cardiac tissue, requiring increased output to achieve capture. By inhibiting their development, the steroid helps maintain a better electrode–tissue interface.

Steroid-eluting electrodes have a silicone plug that contains a small dose (less than 1 mg) of steroid. Body fluids seep into the electrode and gradually dissolve the steroid, which then flows in the body fluids to the electrode–tissue interface. Initially, the rate of steroid elution is high, but it decreases over time. The steroid typically lasts for several years.

Single-Chamber Versus Dual-Chamber Systems. A single-chamber pacing system uses one lead that may be placed in either the right atrium or the right ventricle **FIGURE 14-89**. A dual-chamber pacing system uses two leads, with one lead placed in each of these chambers **FIGURE 14-90**. The dual-chamber approach compensates for two potential limitations of single-lead systems: the inability to coordinate AV timing (AV synchrony) and the lack of ventricular backup pacing in the absence of AV conduction.

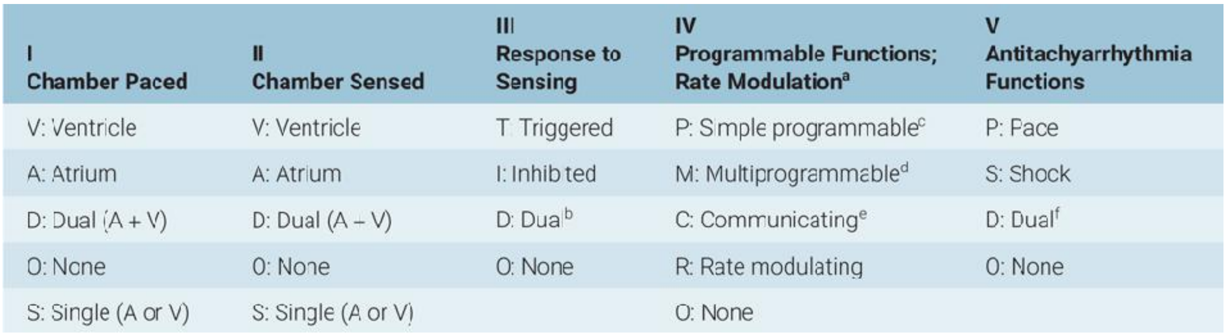
NBG Codes

Developed by a joint effort of North American and British electrophysiology groups, **NBG codes** (NASPE/BPEG Generic codes) provide a succinct way to describe pacemaker functions and capabilities. These terms may be encountered in patient documentation; a general familiarity with them is very helpful in determining appropriate pacemaker function. **TABLE 14-10** lists the codes and their meanings.

TABLE 14-10 **NBG Codes**



I Chamber Paced	II Chamber Sensed	III Response to Sensing	IV Programmable Functions; Rate Modulation[a]	V Antitachyarrhythmia Functions
V: Ventricle	V: Ventricle	T: Triggered	P: Simple programmable[c]	P: Pace
A: Atrium	A: Atrium	I: Inhibited	M: Multiprogrammable[d]	S: Shock
D: Dual (A + V)	D: Dual (A + V)	D: Dual[b]	C: Communicating[e]	D: Dual[f]
0: None	0: None	0: None	R: Rate modulating	0: None
S: Single (A or V)	S: Single (A or V)		0: None	

[a] This sequence is hierarchical; it is assumed that if a pacemaker has rate modulation capabilities (R), it can also communicate (C).

[b] Inhibited and triggered. In single-chamber mode, *triggered* means initiating a pacing pulse immediately after sensing an intrinsic event. In dual-chamber mode, this term means that a sensed atrial event will initiate an atrioventricular (AV) delay.

[c] Rate and/or output.

[d] Rate, output, sensitivity, and so forth.

[e] Can send information to and receive information from the programmer.

[f] Pace and shock available.

© Jones & Bartlett Learning.

Description

The first letter in the NBG code identifies the chamber where the pacing occurs: either the atrium, the ventricle, both, none, or single (which can signify the atrium or ventricle). The second letter in the NBG code identifies the chamber where the pacing is sensed. The options in this category are the same as those in the first category.

The third letter indicates how the pacemaker responds to sensing. Options in this category include triggered, inhibited, dual, and none. The I (inhibited response) setting indicates that the pacemaker is set to fire only under certain conditions. For example, the pacemaker may fire only when the patient’s heart rate falls below a certain rate. In other words, when the pacemaker senses an impulse from the patient, it inhibits or does not fire its own impulse. The T (triggered response) setting indicates that the pacemaker, after sensing an impulse from the patient, triggers a pacemaker impulse. The D (dual) setting indicates that the pacemaker can perform in either an inhibited manner or a triggered manner, as needed. The O (no response) setting may be used when a technician wants to ignore sensed beats from the patient and fire the pacemaker regardless of any underlying patient rhythm.

The fourth letter identifies the pacemaker's programmability and rate-modulation capability, which is simply a representation of how much programming can be done externally. Pacemakers may have many external programming options (M) or just a few (P). C (communicating) indicates that the pacemaker can transmit data, such as with telemetry. R (rate modulation) means that the pacemaker can adjust its rate depending on the body's needs.

The fifth letter represents antitachyarrhythmia functions. P (pacing) indicates that a tachyarrhythmia is converted by pacing. S (shock) indicates that a tachyarrhythmia is converted by defibrillation administered by the pacemaker. D (dual) indicates that the pacemaker can pace and administer a shock to address a tachyarrhythmia.

An example of an NBG code is VVI. In a VVI pacemaker, pacing occurs in the ventricle, sensing occurs in the ventricle, and the response setting is inhibited. In day-to-day practice, only the first three letters of the NBG code are typically used.

Types of Pacemakers

Five major categories of cardiac pacemakers are available:

- Transcutaneous
- Implantable
- Transthoracic and epicardial
- Transvenous
- Leadless

Transcutaneous Pacemakers

The most basic pacer is the transcutaneous pacemaker (TCP), which is most commonly used as an initial emergency pacer. With this device, multifunction TCP pads (electrodes) are attached to the patient's chest wall in the anterior-posterior positions. The electrical pacing impulse is transferred to the heart through the skin and thoracic cavity. Although this is the quickest and most convenient method of pacing, it requires the greatest amount of energy and is the least reliable option owing to the relatively poor quality of the skin-to-pad contact and the thoracic impedance that must be overcome. A TCP is also extremely uncomfortable for most patients and often requires administration of analgesics and/or sedatives to alleviate the muscle discomfort resulting from transthoracic electrical stimulation. Such a device is generally used as a temporary measure until a transvenous pacing wire can be placed. The TCP is useful as an emergency tool both to initiate pacing and in case other pacing modalities fail.

Implantable Pacemakers

Implantable pacemakers consist of a battery-operated pulse generator attached to pacing/sensing leads. An interventional cardiologist or thoracic surgeon implants the lead or leads in the myocardial wall, usually by accessing the subclavian vein and traversing the myocardium until the desired location is reached, which differs depending on the pacer indication. The pulse generator is then surgically implanted in the patient’s body, usually in a sac created between the pectoral muscle and the cutaneous layer of the skin. In some cases, when leads cannot be placed conventionally or capture cannot be achieved with traditional leads, the pacemaker electrode(s) are screwed onto the myocardial wall.

Implanted pacers can have a variety of lead configurations. They may be programmed to deliver single-chamber, dual-chamber, atrial, ventricular, biventricular, biatrial, atrial–ventricular, overdrive, antitachycardia, and synchronizing pacing, among other less common modes.

Pacemakers can operate on demand; alternatively, the patient’s heart can be fully paced. A demand pacer intervenes when the patient’s normal rhythm fails. In this case, the ECG will show the patient’s normal rhythm with periodic pacer intervention. In contrast, an ECG for a patient with a fully paced heart will show only the paced rhythm.

Most pacers today are atrial and ventricular, and many include a built-in ICD. Virtually all newer pacemakers are compatible with magnetic resonance imaging (MRI). Biventricular pacers are used in patients with ventricular asynchrony (often seen in cardiomyopathies) to restore right and left ventricular synchrony and improve ejection fraction. Pacer circuitry is less complicated than defibrillator circuitry and requires less power. Statistically, pacer circuits show a lower incidence of failure compared to ICDs. The most common sources of failure are the following:

- Battery failure
- Lead wire failure or detachment

Less common sources of failure are as follows:

- Failure of the pulse-generator circuitry
- Dislodgment from the myocardial wall

Transthoracic and Epicardial Pacemakers

A third class of pacers comprises the transthoracic and epicardial pacers. This type of pacing is done only by interventional cardiologists or cardiac surgeons and involves placing pacing electrodes directly into the heart through the thoracic cavity. Such pacing is limited to the inpatient setting and would be encountered in the CCT environment only if the CCTP were called to transport a patient postoperatively. Epicardial wires are attached to the atria and/or ventricles and brought out through the chest wall. A connector cable is used to attach epicardial wires to the same type of temporary pulse generator used for transvenous pacing.

Transvenous Pacemakers

Transvenous pacemakers are employed as a temporary method of pacing until the problem requiring pacing is resolved or until a permanent pacemaker can be implanted. A transvenous pacing wire is considered more reliable compared to transcutaneous pacing. Because it has direct myocardial contact, the wire is located in the heart itself, and it requires considerably less energy to achieve capture. Additionally, because an external pulse generator is attached directly to the pacing wire, tighter control and more sophisticated settings can be used than with transcutaneous pacing. An interventional cardiologist or other credentialed practitioner places the transvenous lead wires and connects the battery-operated pulse generator externally to the pacing leads **FIGURE 14-91**.

The external pulse generator provides the following controls:

- Pacing rate
- Output
- Sensitivity

The lead wires are externally connected to the pulse generator.

It is recommended that CCTPs become familiar with the types of transvenous wire(s) and temporary pacemakers used by local hospitals and receive a tutorial on troubleshooting these devices. The difficulty most likely to be encountered during transport is migration of the pacing wire in the heart with subsequent loss of capture or disconnection of lead wires. The CCTP can take specific steps to prevent these and other potential issues that might arise during transport.

Four important pieces of information are needed when transporting a patient with a temporary pacemaker:

1. When and why was the temporary pacemaker wire inserted?
2. What is the underlying rhythm?
3. Is the patient hemodynamically dependent on the pacer?
4. What are the present settings?
    - Milliamperes (mA) (output)
    - Rate
    - Sensitivity
    - Mode

Knowing why a temporary pacemaker was inserted, what the underlying rhythm is, and whether the patient's hemodynamic stability depends on the pacemaker will prepare the CCTP to react aggressively should a loss of capture occur or the pacemaker fail. The duration for which the pacer has been in use may provide a window into any problems that have occurred during that time, but also suggests whether the pacemaker output might need to be increased. Over time, owing to local inflammation and scarring at the site, many temporary pacing wires require a gradual increase in output (mA) to achieve capture. The CCTP should also have some familiarity with the amount of leeway in the present settings for the pacemaker, should adjustments become necessary during transport. For example, a patient who requires 20 mA output to achieve ventricular capture is close to the maximum output available from most temporary pacers. In such a case, there is little margin for increases should a higher output be needed.

After gathering the necessary information about the indications, underlying rhythm, and settings of the pacer, take the following steps during patient packaging:

1. Confirm that the settings provided are the actual settings on the temporary pacemaker. Pay particular attention to the mode, especially with ventricular pacing. It is not uncommon during surgical procedures or insertion of a pacing wire to set an asynchronous or fixed (VOO) mode. For patient safety (to avoid an “R-on-T” event, in which an electrical stimulus is delivered to the ventricle during the repolarization period), the mode should be switched to demand pacing (VVI) as soon as practical.
2. Confirm electrical and mechanical capture. A pulse oximeter waveform is a helpful visual aid that can be compared to the ECG.
3. Place transcutaneous pacing pads on the patient during packaging. Gaining access to the patient to place pads in an emergency situation during transport is fraught with difficulty. Patient safety concerns require the CCTP to be prepared for emergencies.
4. Ensure that transvenous or epicardial pacing wires are looped at their exit sites and securely taped to the patient’s body to avoid inadvertent dislodgement should they become ensnared during movement.
5. Tape all connecting wires, cables, and adapters to prevent inadvertent disconnection.
6. Place the temporary pacemaker in a readily accessible location, such as hanging on an IV pole, secured between the patient’s legs, or at the head of the stretcher. The CCTP must be able to readily reach the pacer should adjustments be needed.
7. Ensure that there is a fresh battery in the temporary pacemaker and that a spare battery is available for the transport.
8. Ensure that there is a quality ECG tracing on the transport monitor and that the monitoring lead chosen offers the best view of pacing spikes.

In addition to the typical problems that may be encountered with any pacemaker (eg, loss of capture, disconnection, undersensing), one problem frequently encountered in the transport environment is oversensing. Many forms of energy, including vibration, electromagnetic interference, cellular or radio signal interference, on-board inverters, generators, and engine artifact have been known to interfere with pacemakers in demand mode. Decreasing the pacemaker's sensitivity is an appropriate action to resolve interference that may be inhibiting necessary pacing.

Pacing Spikes

Transport monitors are often configured to eliminate artifactual noise experienced while moving patients and, as a consequence, may not display pacing spikes in patients who are being paced. A quick remedy to this potential loss of information is to print a rhythm strip; most monitors will not only display pacing spikes on the printed strips, but also mark the spikes on the bottom of the ECG.

Leadless Pacemakers

Leadless pacemakers are self-contained pacemakers with pacing/sensing leads implanted as a unit directly into the right ventricle **FIGURE 14-92**. While it is considered in the category of implanted pacemakers, the leadless pacemaker is 90% smaller and is implanted using a transcatheter approach via a femoral vein. There are no chest incisions and no pacemaker pocket in the skin. Leadless pacemakers provide single-chamber ventricular pacing, are MRI compatible, and have a battery life of 5 to 15 years, after which they can be turned off and a new pacemaker implanted. Leadless pacemakers are theoretically retrievable, but, like conventional pacemaker leads, they are likely to become encapsulated in cardiac tissue.

Pacemaker Troubleshooting

Pulse-generator failure is a rare occurrence; its incidence is 0.46%, or 1.3 malfunctions per 1,000 persons annually. By comparison, pacemaker system malfunction occurs occasionally. The primary areas of failure are the following:

- Battery failure
- Problems at the lead electrode–tissue interface
- Coiling or damage to the lead–generator interface
- Insulation failure of the lead wires
- Dislodgement of the lead at the implantation site (very rare)
- Pacemaker programming
- Pacemaker pocket stimulation (muscle tissue in the vicinity of the implanted pacemaker is stimulated by the pacer itself; more

common with unipolar pacers than with other types)
- Diaphragmatic stimulation
- Electromagnetic interference (cell phones and other personal electronic devices)

Electromagnetic interference is the collective effect of radiofrequencies and other signals from environmental sources that may be picked up by the pacemaker. This interference may enter a pacemaker by conduction if the patient is in direct contact with the source or by way of radiation if the patient is in an electromagnetic field with the pacemaker lead acting as an antenna. Exposure to electromagnetic interference can affect pacers in various ways, all of which can prevent it from functioning appropriately.

TABLE 14-11 details the four general types of in-hospital solutions available to correct abnormal pacing behavior. These kinds of remedies cannot be applied during transport except with temporary external pulse generators.

TABLE 14-11 Options for Correcting Pacer Malfunction

Solution	Use or Indication
Reprogramming	Correct oversensing, undersensing, and loss of capture As a temporary solution in some cases of an insulation break Adjust the atrioventricular intervals and rate response to optimize pacing therapy
Repositioning the lead	A lead slips out of position and pacing and/or sensing is compromised Muscle, diaphragmatic, or phrenic nerve stimulation occurs Pacing the left side of the heart unintentionally (a lead may traverse the septal wall or innominate vein) Leads are reversed in the implantable pulse generator header block at implant

Solution	Use or Indication
Replacing the lead or the pacemaker	Lead failure is confirmed The battery is depleted The patient is symptomatic (hemodynamically compromised) as a result of single-chamber pacing The passive fixation lead does not remain in place after attempts to reposition it True circuit malfunction
Observation	Transient problems with the following: • Lead maturation • Changes in drug therapy

© Jones & Bartlett Learning.

During transport, CCTPs must be aware of the signs of pacemaker failure. The cardiac monitor will show failure to capture, and a 12-lead ECG is helpful, but even more important is patient assessment. First, the CCTP should confirm that the patient's pulse corresponds to the pacer presentation on the ECG. Next, the CCTP should determine whether the patient shows signs of decompensation, such as the following:

- Syncope
- Dizziness
- Palpitations
- Bradycardia
- Heart blocks
- Hypotension
- Tachycardia
- Extracardiac stimulation (sometimes shown by hiccups)

If these conditions exist, alternative treatment should be initiated.

To troubleshoot the device quickly, look for obvious sources of malfunctions, such as cell phones or other personal electronic devices. If the patient is using such a device, it should be shut off and the patient should be reevaluated. If a device in the ambulance has just been turned on and the pacemaker malfunctions, the device should be shut off and the patient should be reevaluated. If these quick fixes do not improve pacemaker performance, begin immediate treatment of the patient. If bradycardia, heart blocks, or syncope exists, apply transcutaneous pacer (multifunction) pads and initiate transcutaneous pacing. Tachycardia as the result of pacemaker runaway (pacemaker-mediated tachycardia) has been largely eliminated; if tachycardia is observed on the ECG, however, confirm it by checking the patient's pulse before considering treatment. Tachycardias that allow for adequate perfusion should be left alone, but tachycardias that result in inadequate perfusion should be treated following advanced cardiac life support (ACLS) protocols.

Identifying the exact cause of pacemaker failure is difficult for CCTPs who do not have training in the use of an external diagnostic device. The easiest cause to diagnose is extracardiac stimulation, which is evidenced by frequent hiccups. The hiccups are caused by pacing electrodes being placed too far into the apex of the ventricle, causing stimulation of the diaphragm.

Unfortunately, CCTPs cannot do much to correct implanted pacemaker malfunction because the device is not accessible to them. Even if the device were accessible, a CCTP would need specific training in the repair of the particular device to initiate reprogramming. Some manufacturers provide a doughnut-type, bar, rectangle, or horseshoe magnet that may be helpful in correcting pacemaker malfunctions **FIGURE 14-93**. Various responses are seen to magnet application, depending on the pacemaker's programming. All pacemakers switch to an asynchronous mode when a magnet is placed near them. DDD pacers switch to DOO; VVI to VOO; and AAI to AOO. The pacer rate depends on its programming and the battery status.

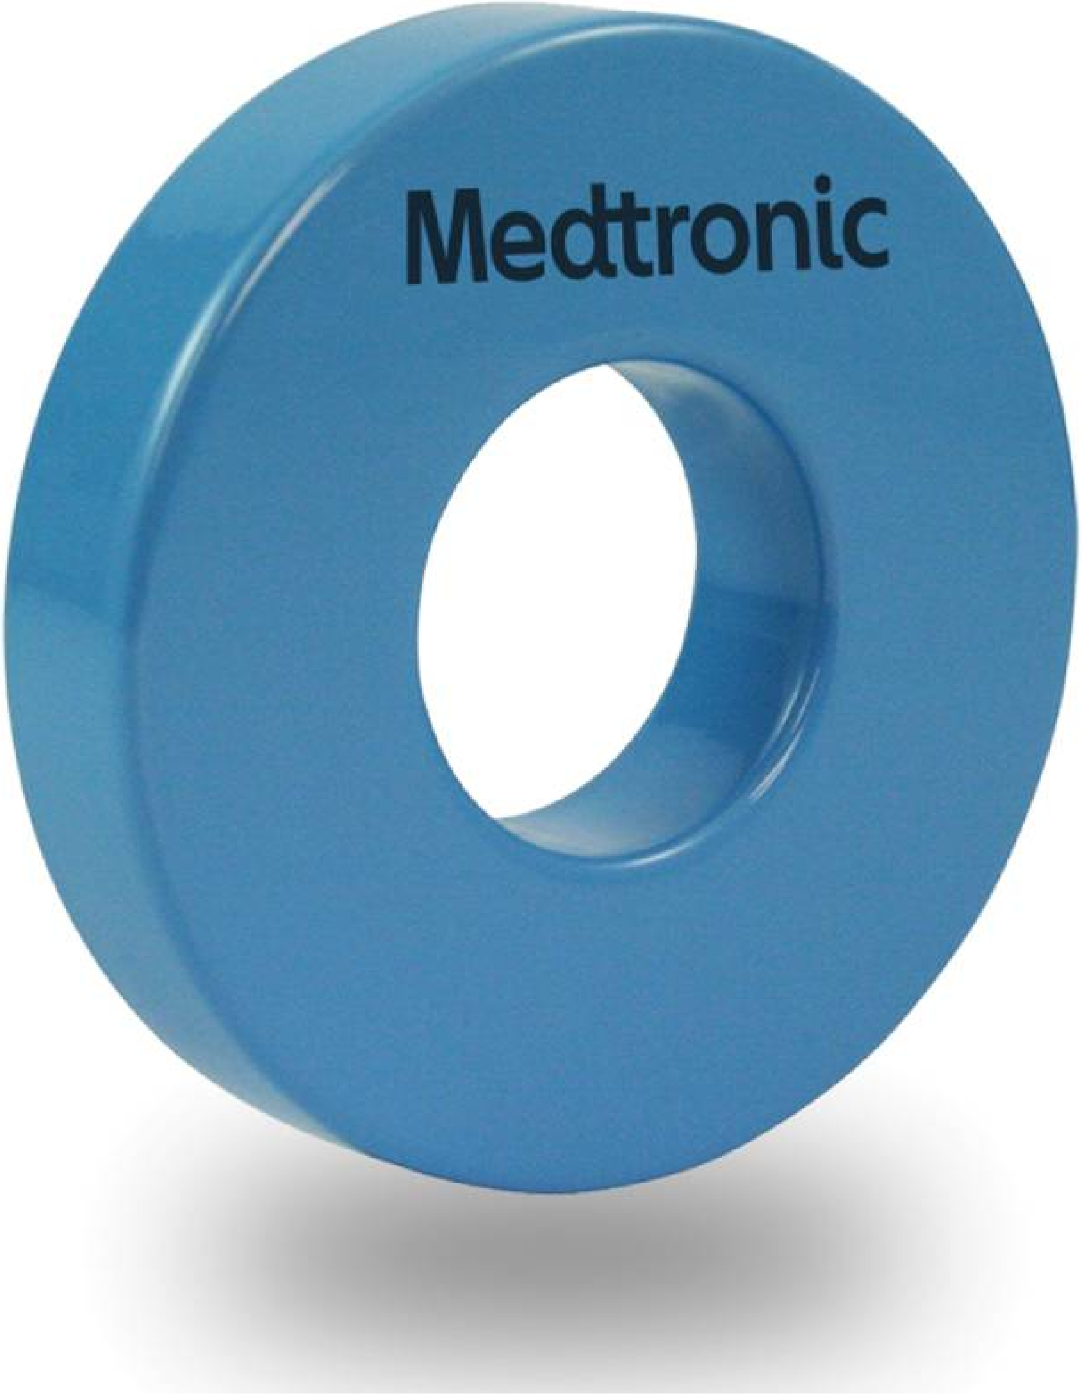

FIGURE 14-93 A pacemaker magnet may help correct malfunction of implanted pacemakers.

Reproduced with permission of Medtronic.

Transport Management

Pacemaker Failure

- Shut off the patient’s cell phone or other personal electronic device.
- If the pacemaker malfunction occurred after a device in the ambulance was turned on, shut off that device and reevaluate the patient.
- If the malfunction persists and the patient has bradycardia, heart blocks, or syncope, initiate transcutaneous pacing.
- Confirm tachycardia with a pulse reading; treat tachycardias that result in inadequate perfusion per ACLS protocols.

Pacemakers and the ECG

Single-Chamber Systems

The sole electrode in a single-chamber pacemaker system is implanted on the atrium or ventricle. Single-chamber systems require implantation of only one lead, but they do not provide AV synchrony or ventricular backup in the absence of AV conduction.

Pacing in the ventricular pacer (VVI/R) mode and loss of AV synchrony can lead to **pacemaker syndrome**, a variety of symptoms that result from hemodynamic deterioration and cause nonphysiologic timing of atrial and ventricular contractions. This asynchrony can result in a rate that does not respond to physiologic needs. Atrial pacemakers are appropriate only for patients who have proven AV conduction and have regular access to follow-up testing.

Atrial and Ventricular Tracings

FIGURE 14-94 shows an example of atrial pacing. The strip begins with an atrial pacemaker firing at a rate of 60 beats/min. A pacemaker spike precedes the P wave in these complexes. The ventricular rate is 60 beats/min. The paced P waves are conducted through the ventricles via a normal conduction pathway. Starting with the fourth complex, the intrinsic pacemaker begins depolarizing at a rate of 94 to 100 beats/min. There are no pacemaker spikes with these complexes. The pacemaker continues to sense the intrinsic atrial depolarizations. Implications for the CCTP depend on the patient’s history (ie, what caused the intrinsic pacemaker to fail in the first place) and hemodynamic status.

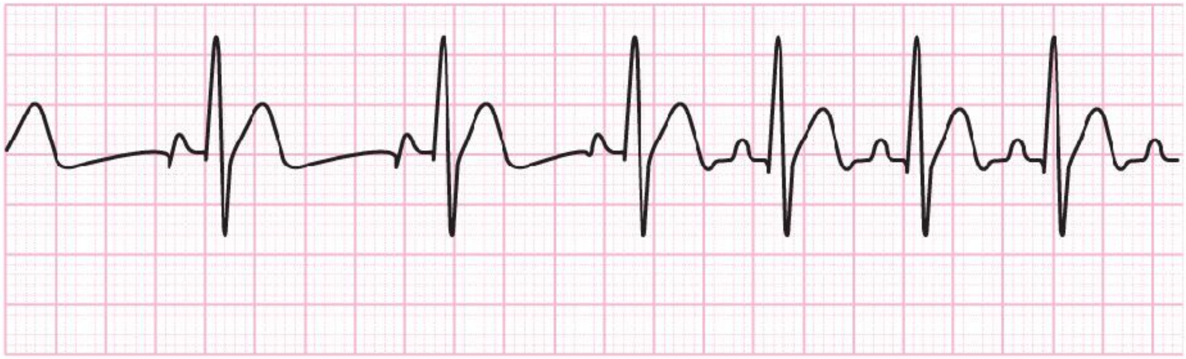

FIGURE 14-94 An electrocardiogram from a patient with an atrial pacer (AAI). Mode: AAI; rate setting: 60.

© Jones & Bartlett Learning.

Description

FIGURE 14-95 shows an ECG from a patient with a ventricular pacer (VVI). Following the second paced ventricular beat, a capture beat appears and is conducted normally. The pacemaker does not fire during this capture beat because it is sensed as normal depolarization. When another capture beat fails to appear, the ventricular pacemaker senses this and fires, depolarizing the ventricles. It paces two beats, and then another capture beat appears and is conducted. The pacemaker senses when this does not produce a sustained rhythm, and begins firing again at a rate of 60 beats/min. The implication for the CCTP is that this patient’s heart is probably failing, but still has the ability to generate electrical impulses periodically. Monitor the patient’s hemodynamic status and treat accordingly.

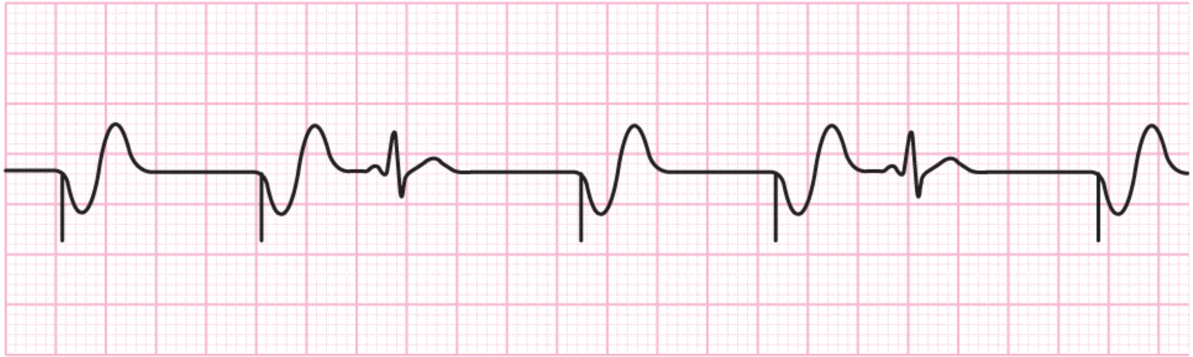

FIGURE 14-95 An electrocardiogram from a patient with a ventricular pacer (VVI). Mode: VVI; rate setting: 60.

© Jones & Bartlett Learning.

Description

Many implanted pacemakers do not show prominent spikes on the ECG, necessitating that the CCTP check several leads to identify spikes. Many transport monitors require reconfiguration to identify pacemaker spikes. It is a good idea to ask the sending nurse which type of pacer the patient has and what the paced beats looked like on the hospital's ECG monitors.

Dual-Chamber Systems

Dual-chamber pacemaker systems feature two leads, one each in the atrium and the ventricle. This ensures AV synchrony and provides for ventricular depolarization even without AV conduction. This mode of pacing is known as atrial synchronous pacing, atrial tracking, or AV sequential pacing.

As outlined in Table 14-10, DDD and DVI are pacemaker acronyms that refer to dual-chamber pacemaker systems. DDD stands for dual sensed, dual paced, and dual mode (fixed or demand), and DVI stands for dual sensed, ventricular paced, and inhibited (demand) mode. DDD is the most common type of pacemaker in use today. Figures 14-96 through Figure 14-99 show samples of ECG rhythms from dual-demand pacemakers.

FIGURE 14-96 shows a dual-chamber intrinsic atrial pacemaker depolarizing at a rate of approximately 60 beats/min. The pacemaker senses atrial electrical activity and does not need to provide atrial pacing. The atria depolarize but conduction is blocked and does not reach the ventricles. The ventricular mode of the DDD senses no conduction and fires to depolarize the ventricles at a rate of 60 beats/min. Pacemaker spikes precede each ventricular complex. This patient has a severe conduction problem, as impulses are not reaching the ventricles. For the CCTP, the implications would be to monitor the patient’s hemodynamic status and treat accordingly.

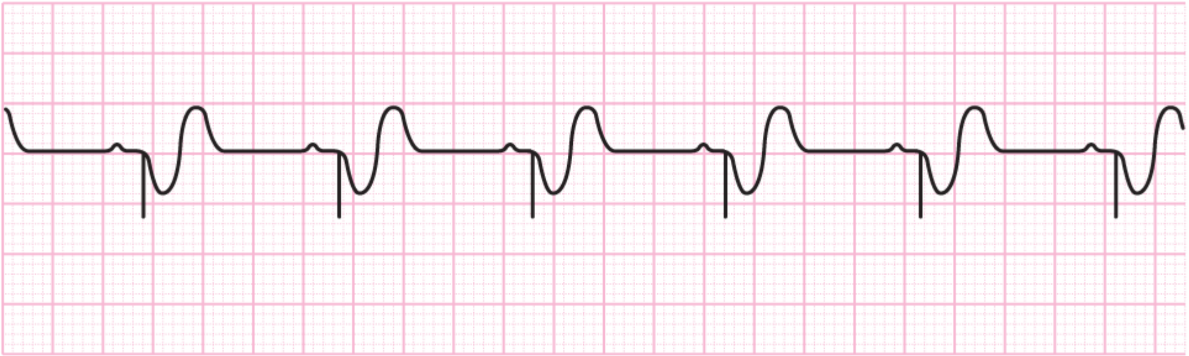

FIGURE 14-96 Mode DDD; lower rate setting, 60; upper rate setting, 120. Atrial sensing and ventricular pacing.

© Jones & Bartlett Learning.

Description

FIGURE 14-97 shows a demand dual-mode pacer sensing intrinsic pacemaker depolarizing at a rate of approximately 80 beats/min. The electrical activity is transmitted from the atria to the ventricles without interruption. The underlying rhythm is a regular sinus rhythm at a rate of approximately 78 beats/min. The implication for the CCTP is to always compare ECG findings with the patient’s clinical presentation.

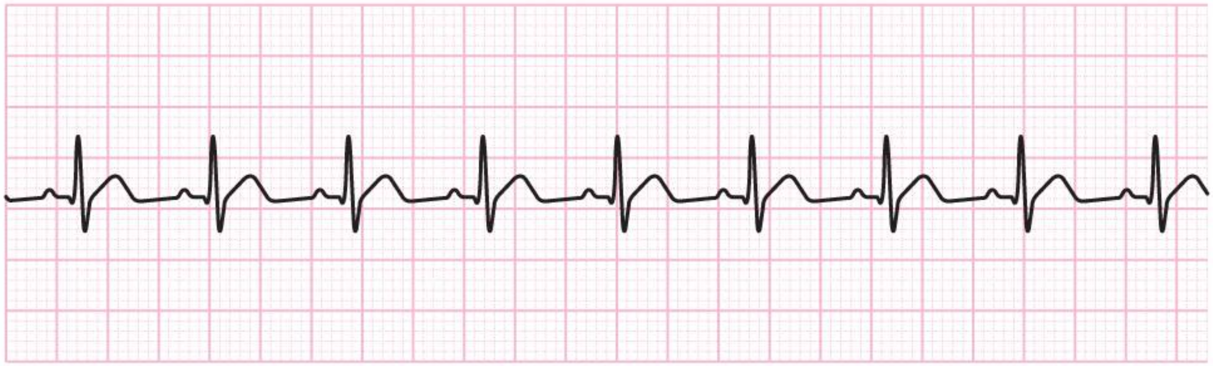

FIGURE 14-97 Mode DDD; lower rate setting, 60; upper rate setting, 120. Atrial and ventricular sensing.

© Jones & Bartlett Learning.

Description

FIGURE 14-98 shows a dual-demand mode pacemaker rhythm. On this strip, the demand DDD pacemaker does not sense any intrinsic electrical activity and depolarizes the atria, as indicated by a spike preceding each P wave at a rate of 60 beats/min. With no ventricular activity and the atrial pacing not being transmitted through to the ventricles, the ventricular mode of the DDD fires, depolarizing the ventricles at a rate of 60 beats/min. The implication for the CCTP is that the patient's cardiac electrical activity depends solely on the pacemaker. As always, compare the ECG findings with the clinical findings and treat the patient accordingly.

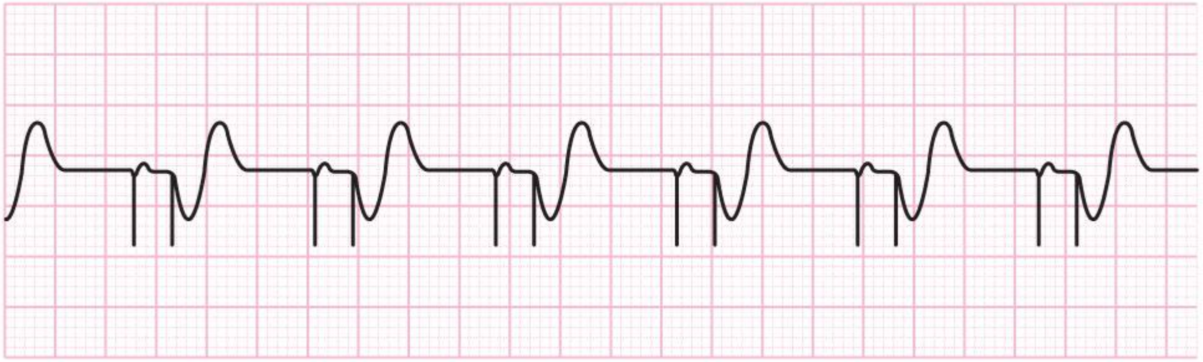

FIGURE 14-98 Mode DDD; lower rate setting, 60; upper rate setting, 120. Atrial and ventricular pacing.

© Jones & Bartlett Learning.

Description

FIGURE 14-99 shows another demand dual-mode pacemaker rhythm. The underlying rhythm appears to not be producing an atrial intrinsic pacemaker rhythm. The DDD pacer senses this and paces a rhythm at 60 beats/min. Note the pacemaker spike preceding each P wave. The electrical impulse generated by the pacemaker is transmitted through to the ventricles without interruption, allowing the ventricles to depolarize "normally" from above. This indicates that there is no AV block. The ventricular portion of the pacemaker continues to sense the ventricular conduction and does not need to fire. There should be no implications for the CCTP with this rhythm (unless it started after the transport began, which could indicate the patient's condition is deteriorating).

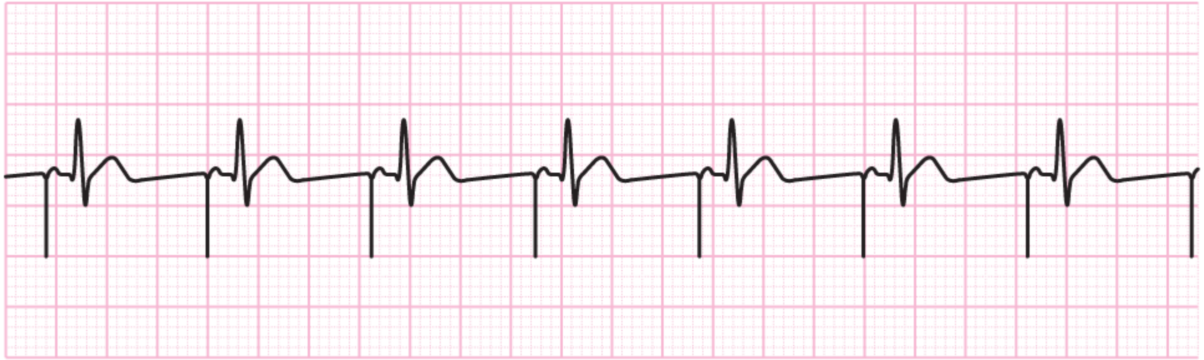

FIGURE 14-99 Mode DDD; lower rate setting, 60; upper rate setting, 120. Atrial pacing and ventricular sensing.

Description

Atriobiventricular Pacing (Cardiac Resynchronization Therapy)

A CCTP may transport a patient with HF to a facility for cardiac resynchronization therapy (CRT) pacemaker insertion. Mortality and morbidity rates are high for patients with HF, but one treatment shown to improve quality and length of life relies on a modified cardiac pacemaker or ICD to resynchronize the heart chambers (ie, CRT). As cardiomyopathy progresses, the right and left ventricles often begin to contract asynchronously, resulting in an unnatural back-and-forth movement of the ventricular septum that further impairs ventricular ejection. A biventricular pacemaker synchronizes ejection of the right and left ventricles of the heart, resulting in more effective ejection. To accomplish this coordination, pacing leads are placed in both ventricles and then their synchronization is optimized.

In a typical biventricular implant, one lead is placed in an atrium and one lead is placed in each ventricle (right and left) **FIGURE 14-100**. A biventricular pacing waveform would be indistinguishable from that of a dual-chamber pacer on a typical monitor lead, because the ventricles are paced simultaneously **FIGURE 14-101**. Analysis by 12-lead ECG and history would lead to a more definitive answer regarding the type of device implanted.

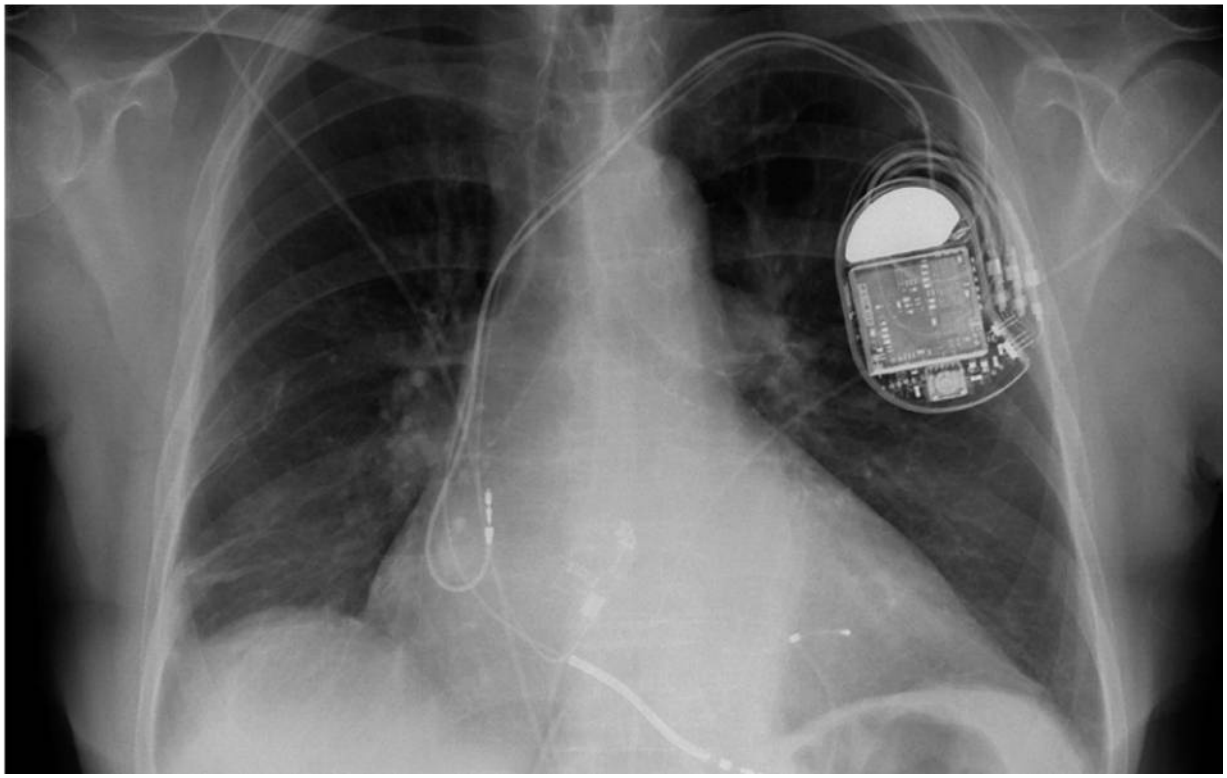

FIGURE 14-100 An implanted atriobiventricular pacing system.

Description

Implantable Cardioverter-Defibrillators

ICDs automatically attempt to convert a fibrillating heart to sinus rhythm using a shock from voltage **FIGURE 14-102**. Since their introduction in 1985, the estimated number of ICD implants has increased steadily to more than 200,000 each year. As their numbers rise, so does the frequency of ICD-related issues.

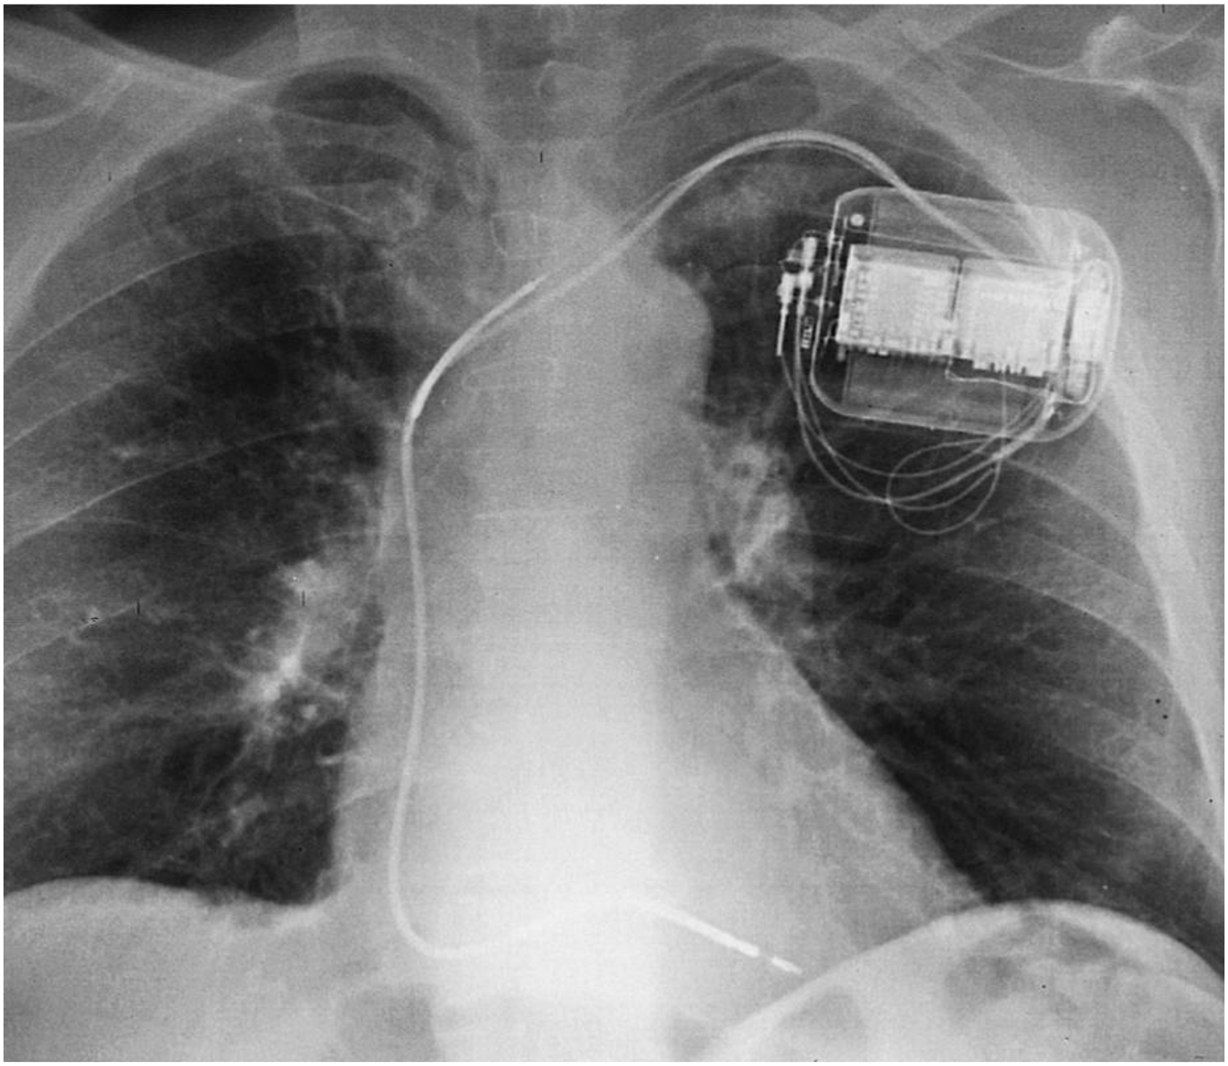

FIGURE 14-102 An implantable cardioverter-defibrillator is attached directly to the heart and continuously monitors heart rhythm, delivering shocks as needed. The electricity from the device is so low that it has no effect on rescuers.

© American Academy of Orthopaedic Surgeons.

Basic Function

Components

Each patient with an ICD has a custom ICD system consisting of a housing (can) and a variable number of pacing and high-voltage leads. The leads can be placed in the abdominal or pectoral region **FIGURE 14-103A**; the lead is itself often one of the electrodes in the system. Most ICDs have one or two transvenous leads that are used for pacing and shocking. The leads enter the venous system through the subclavian or cephalic vein, for placement into the right ventricle or the superior vena cava. Early ICD implants required the pacing leads and high-voltage patches to be placed directly on the epicardial surface **FIGURE 14-103B**. Patients with mechanical heart valves are also limited to epicardial placement.

Sensing and Therapies

An ICD delivers therapy when it determines that the heart is in a tachyarrhythmia, based on the ventricular rate. The ICD counts the number of R-R intervals that are faster than a programmed threshold. When the count reaches the threshold, the device delivers electrical therapy. Because an ICD bases its decision on the ventricular rate alone, atrial arrhythmias and electromagnetic interference can lead to inappropriate shocks.

For ICD purposes, fast heart rhythms are loosely classified into two groups: VT and ventricular fibrillation. An ICD may deliver antitachycardia pacing or cardioversion shocks for episodes of VT. Antitachycardia pacing consists of a series of 6 to 15 pacing pulses with cycle lengths of 70% to 95% of the arrhythmia **FIGURE 14-104A**. In Figure 14-104A, when VT is sensed, antitachycardia pacing begins as indicated by pacemaker spikes (arrow at right). In cardioversion, high-voltage shocks are synchronized to an intrinsic R wave **FIGURE 14-104B**. The device delivers unsynchronized defibrillation shocks for episodes of ventricular fibrillation. In Figure 14-104B, when VT is sensed, a single cardioversion shock is administered, as indicated by the large spike. The rhythm is converted to a supraventricular rate of approximately 70 beats/min. There appears to be a first-degree AV block with a prolonged PR interval.

Description Description

ICDs will administer a preprogrammed number of shocks (usually four or five) for each episode of an arrhythmia. Hence, if a patient is in VT, an ICD will stop therapy after the preprogrammed number of shocks, if there is no change in the rhythm. If it detects a different rhythm for which shocks are indicated, it will again deliver its predetermined number of shocks.

Implantable Cardioverter-Defibrillator Troubleshooting

Because an ICD is an implantable device within the patient, it is not accessible to CCTPs. The device must be explanted (in the hospital) to correct the malfunction.

The most common sources of failure are the following:

- Wire (lead) detachment or insulation failure
- Battery failure or abnormalities
- Pulse-generator failure
- Movement of the wire tip in the ventricle

In addition, dual-chamber ICDs are subject to all of the problems described in the pacemaker section earlier in this chapter. When a magnet is applied over an ICD, most of these devices suspend antitachycardia therapy (ie, rapid pacing and defibrillation) but continue to operate in pacemaker mode.

Information Gathering

If an ICD fires during the care of a patient, everything possible should be done to gather information that will help specialists confirm later whether the therapy was appropriate. After such an event, the patient’s electrophysiologist will want to review the transport documentation and data from the ICD. Programming equipment that is unique to the ICD model makes it possible to retrieve detailed information from the device.

Many patients who have been shocked before recognize the symptoms of ventricular arrhythmias and can correctly identify appropriate and inappropriate therapies. A number of historical factors can have a role in ICD malfunction or offer clues about the nature of the problem. Among the most useful are the following:

- *Number of times shocked.* In patients with VT “storms,” the device may give more than 100 shocks in a 24-hour period. When a patient has an atrial arrhythmia that conducts rapidly to the ventricle, it is common to deliver repeated unsuccessful therapies. Application of a pacemaker magnet over the ICD will temporarily suspend shocks.

- *Recent medical procedures.* Surgical and medical procedures can damage an ICD system, especially when performed on areas of the body in proximity to the ICD. Diathermy, lithotripsy, MRI, and radiation treatments are among the most common offenders.
- *Recent changes in medical condition or in patient adherence to the medication regimen.* It is not uncommon for patients to stop taking antiarrhythmic drugs if they have been arrhythmia free for several months or years. Likewise, patients withdrawing from benzodiazepines, alcohol, or other substances may experience increased arrhythmias.
- *Activity at the time of shock.* During intense exercise, an ICD may inappropriately shock a sinus tachycardia. Likewise, a patient with an ICD who experiences new-onset AF may receive unwarranted shocks.
- *Proximity to water or an electrical source*. Poorly grounded water pipes can produce trickle electrical currents that the ICD may pick up as a rapid heart rate. Likewise, a nearby source of electromagnetic interference can cause the ICD to discharge inappropriately.

Identifying the Problem

Occasionally, a patient with an ICD will experience multiple inappropriate defibrillator discharges as the result of defibrillator malfunction. This phenomenon is uncomfortable and agitating to the patient, to say the least, and may cause damage to the myocardium if allowed to continue. A magnet can be used to temporarily disable the ICD to prevent further discharges. Manufacturers of ICDs often provide special magnets (usually doughnut shaped) that are placed directly over the pulse generator. The magnet creates a magnetic field that trips a reed switch in the ICD. When the magnet is applied, detection of tachycardia and therapy are discontinued. For most applications, a single magnet is all that is required; however, for patients with obesity or edema, two magnets may be necessary. Before using the magnet, multifunction pads must be placed on the patient and hooked to the monitor; then the ICD can be deactivated.

Some ICD manufacturers make an external interrogation device that will help identify the source of the problem and, in some cases, allow reprogramming of the ICD. CCTPs should receive special training before using such a device.

In a patient with cardiac arrest, external defibrillation can be delivered, but the paddles or pads should not be placed directly over the ICD. CPR can also be performed on a patient with an ICD, with no danger to providers, the patient, or the implanted device. When delivering defibrillation, it is important to use anterior-posterior placement and position the pads away from the ICD.

FIGURE 14-105 and **FIGURE 14-106** illustrate some of the common problems with ICDs. The ICD stores the data for the episode in each case; this information can be retrieved later with the appropriate programming equipment.

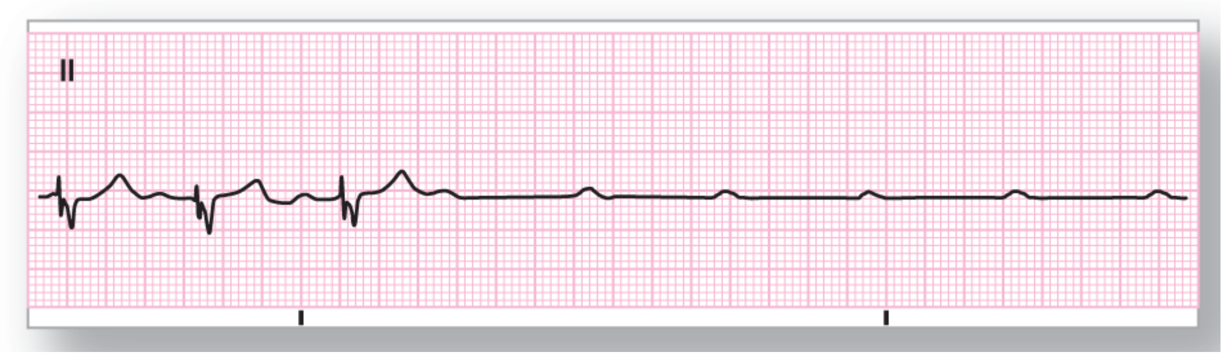

FIGURE 14-105 An electrocardiogram in which the implantable cardioverter-defibrillator is oversensing the P wave.

© Jones & Bartlett Learning.

Description

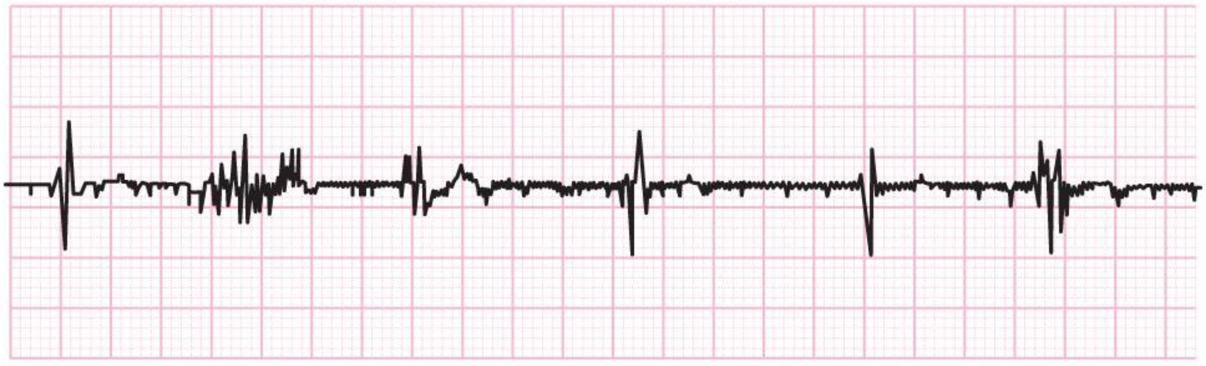

FIGURE 14-106 An example of pacemaker lead malfunction.

© Jones & Bartlett Learning.

In Figure 14-105, the ICD is oversensing the electrical activity that is present. The initial three pacer spikes function as expected, and each generates a QRS complex. However, after that the pacemaker inappropriately oversenses the P wave and is suppressed by it. This suppression of the pacemaker leads to the complete heart block seen in the remainder of the rhythm strip, with only P waves present initially. In this case, the CCTP should first check the patient's clinical status. If the patient is unconscious and unresponsive (which would likely be imminent with this ECG), the CCTP should check the patient's pulse and initiate ACLS protocols.

Figure 14-106 shows an example of lead malfunction. Intervals in the range of 120 to 150 ms are usually not physiologic, but more likely indicate electromagnetic interference or a problem with the sensing lead. In this case, there appears to be an irregular rhythm conducting at a rate of 60 to 80 beats/min. The ECG indicates the ventricular pacemaker is sensing at an irregular rate as well (malfunction). There are no clear pacemaker spikes indicating that it is firing appropriately. In this case, the CCTP should monitor the patient for hemodynamic stability and initiate CPR and external pacing as indicated.

Atrial Tachycardia Implantable Cardioverter-Defibrillators

Atrial fibrillation is one of the most common arrhythmias. Significant risks associated with AF include thromboembolism and a resulting increased incidence of stroke. Conventional methods to convert AF have centered on antiarrhythmic medications and external cardioversion. For recurrent arrhythmias, internal cardioversion or antitachycardia pacing with an atrial ICD is the preferred mode of treatment. Advances in lead design and the use of biphasic energy waveforms have made this therapy possible. With a biphasic waveform, lower energy levels may be used to effectively convert AF to a normal sinus rhythm.

Three modes for activating the atrial tachycardia ICD are currently in use. In the patient-activated mode, the patient uses a small, handheld remote device to initiate therapy after the device notifies the patient that AF is present. Alternatively, a physician may activate the device to provide appropriate therapy. A third option is even more commonly used today: The pacemaker or ICD is programmed to automatically deliver therapy after detecting the arrhythmia. All ICDs can act as pacemakers, and their atrial and ventricular leads may be dual purpose.

Wearable Cardioverter-Defibrillators

Short-term use of WCDs has been a treatment option since 2001. Candidates for use of these devices include patients at high risk for sudden cardiac death, such as those with a recent MI, low ejection fraction, new-onset arrhythmias, or survival of a recent or suspected sudden cardiac death episode. A WCD may also be appropriate for patients who require explant of an infected ICD while awaiting resolution of an infectious process. Use of WCDs is increasing, and CCTPs are likely to encounter these devices in their patients.

In the United States, this technology is available in the form of the ZOLL LifeVest WCD. LifeVest consists of a lightweight monitor that is worn around the waist or from a shoulder strap and an electrode belt with a garment worn around the patient’s chest **FIGURE 14-107**. The electrodes are dry and nonadhesive. Gel in the therapy pads is released just prior to the device delivering a treatment shock. The device is programmable. The essential performance of the LifeVest WCD is that it detects ventricular fibrillation or ventricular tachycardia, then delivers a defibrillating shock. When it detects a treatable arrhythmia, it begins an alarm sequence that provides a conscious patient with enough time to stop the shock by holding two response buttons. If the patient fails to respond or releases the response buttons, the treatment sequence continues, including continued alarms and voice warnings to bystanders that a shock will be delivered. If the initial shock is ineffective, up to five additional defibrillations may be given. The entire sequence from detection to first shock typically occurs in about 1 minute. Shock energies are biphasic, programmable from 75 to 150 joules, with a default setting of 150 joules.

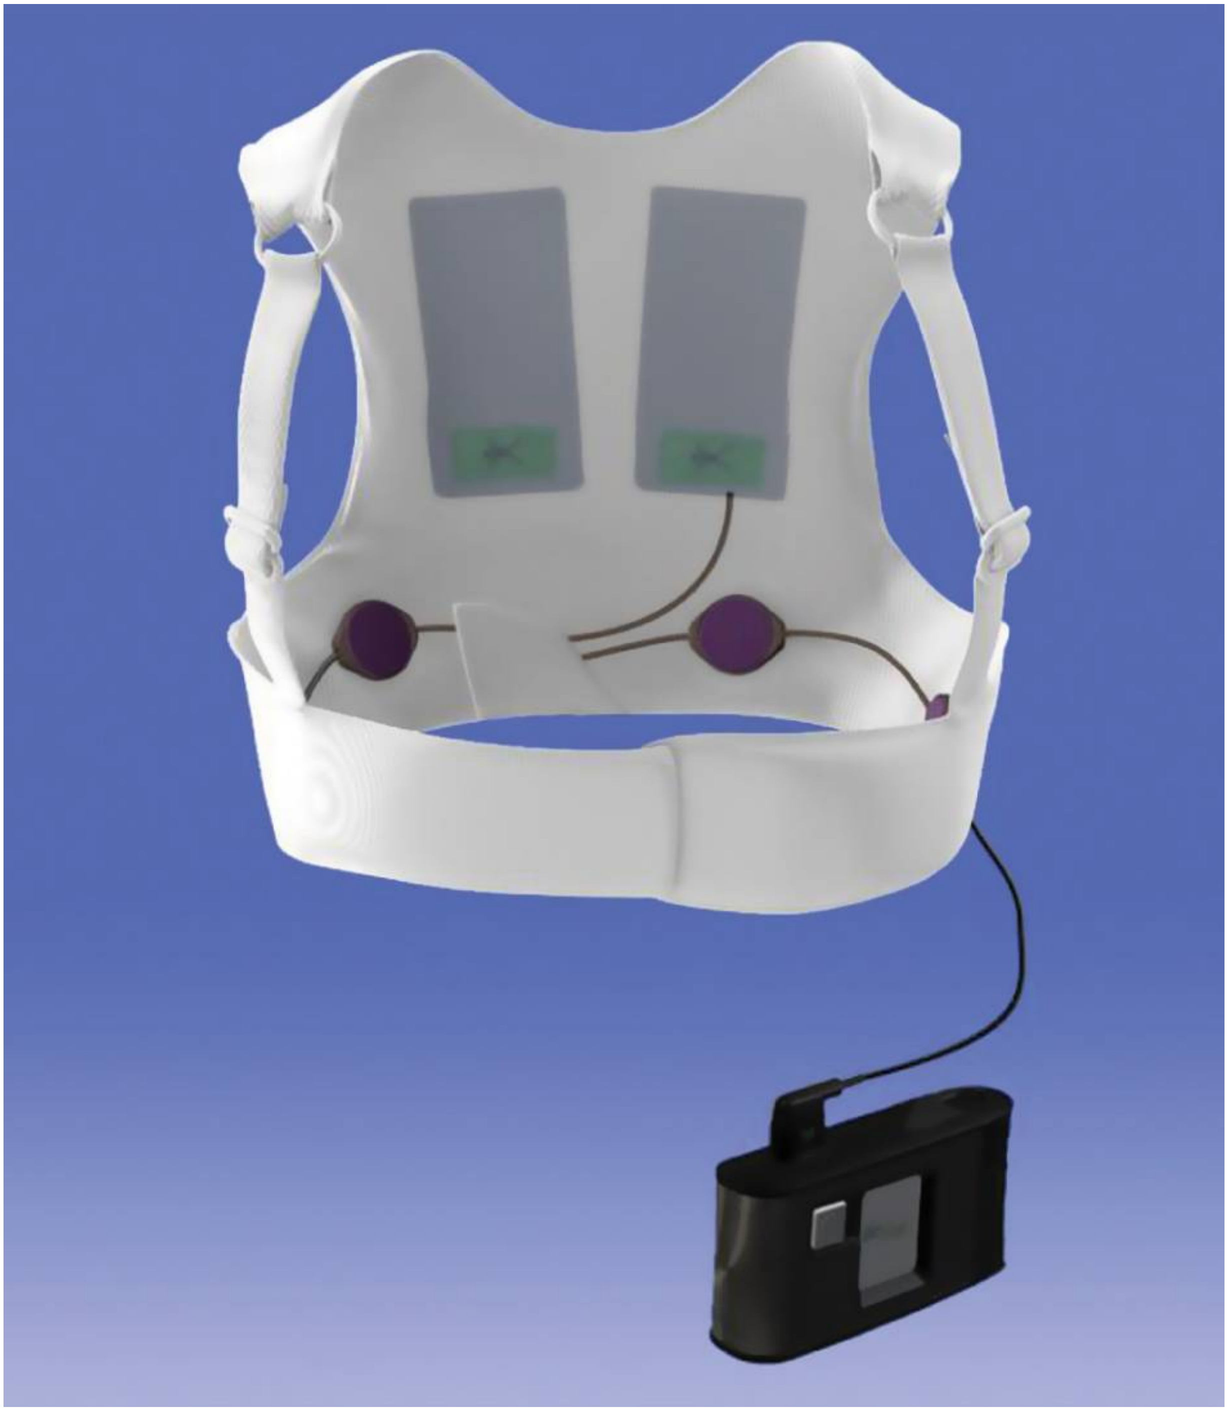

FIGURE 14-107 A wearable cardioverter-defibrillator.

Patients download the data collected by the WCD via a hotspot in the device charging station to the ZOLL Patient Management Network, thereby allowing health care providers to see ECG recordings, uses, and device-related information. A warning label on the WCD garment advises rescuers to remove the WCD if the patient requires conventional defibrillation, because the WCD may interfere with defibrillation or may be damaged by automated external defibrillators (AEDs) or manual defibrillators. Audible and vibratory alarms include messages on the monitor screen, a gong alarm that tells the patient when to adjust the belt or electrode pads, and a siren alarm that sounds when an arrhythmia has been detected.

Patients prescribed WCDs should wear them continuously except when bathing or showering. The greatest risk to patients is while the WCD is not being worn.

Subcutaneous Implantable Cardioverter-Defibrillators

In 2015, a subcutaneous implantable cardioverter-defibrillator (S-ICD) was approved for use in the United States **FIGURE 14-108**. The S-ICD uses a low-profile ICD called a "can" that is surgically placed in the subcutaneous tissue near the fifth and sixth ribs at the midaxillary line. An electrode/defibrillator lead is then tunneled from the can to the xiphoid process and up along the left sternal border, terminating near the manubrium. The S-ICD does not require any venous leads or wires, so it is associated with less risk of infection compared to a traditional ICD. It has pacing capability in case the patient requires ventricular pacing following a shock, but it is not recommended for patients who have symptomatic bradycardia or arrhythmias that respond to antitachycardia pacing.

Transport Considerations

When caring for and transporting cardiac patients, CCTPs must recognize that familiarity with temporary and implanted pacemakers and defibrillators is invaluable. Thus, ensuring transport safety and troubleshooting problems that may arise with these cardiac devices are key skills for CCTPs.

Preparation

The management of patients with a pacemaker or ICD begins well in advance of any transport request. CCTPs should receive advance training on any pacemaker or cardioverter-defibrillator device that they might encounter in the field. Pacemakers and defibrillators from a variety of manufacturers may be implanted at different sending facilities, requiring CCTPs to exercise additional scrutiny when picking up or dropping off patients at these facilities. Services transporting critically ill cardiac patients should have a magnet capable of temporarily reprogramming an implanted pacemaker or ICD readily available. It may be necessary to review the instructions for a particular device while en route to a patient transport if the CCTP has not used the relevant equipment recently.

Transport-Related Issues

Any patient with a pacemaker or defibrillator device must have electrical and mechanical pacemaker capture assessed and confirmed. A CCTP may make a potentially lethal error by mistakenly assuming that the electrical capture present on an ECG tracing represents the true mechanical capture. Mechanical capture is demonstrated by palpable pulses (or evidence of myocardial contraction exhibited on a pulse oximeter waveform or ultrasound) with each pacemaker complex on the ECG. Sometimes electrical capture may appear on the ECG without any actual contraction and pumping of the heart, disguising an underlying arrhythmia or cardiac arrest. If it goes unrecognized, lack of mechanical capture may have lethal consequences.

It is not always possible to continue using the same transcutaneous pacemaker or transvenous or transthoracic pulse generator for transport that is being used at the sending facility. Switching from the device used in a sending facility to the device used by the transport team is often a source of anxiety for CCTPs and other providers. Transvenous and transthoracic pacemaker leads are typically compatible with pulse-generator devices from many, if not all, manufacturers. Care must be taken to ensure equipment compatibility and to correctly match rate, output, mode, and sensitivity settings as the devices are switched. CCTPs must carefully check the patient for electrical and mechanical capture, in addition to other clinical indicators, when a change from one pacemaker to another is implemented. If the CCT team does not have a compatible device available, it may be worth considering using the device from the sending facility for the transport and returning it promptly after the transport has been completed, although this may not be possible in many situations. Many transcutaneous pacemakers have adapters that allow for the use of pads from multiple manufacturers. If such adapters are not available, it may be necessary to completely change the transcutaneous pacing pads for the duration of the transport.

CCTPs should also inquire about whether the patient has an ICD. The presence of an ICD may require use of an alternative site (not over the device) for transcutaneous pacing or defibrillation if needed during transport. An improperly functioning ICD has the potential to inappropriately discharge, causing patient discomfort, myocardial damage, and changes on the ECG. Inappropriate shocks are the most common ICD complication. CCTPs may use a pacemaker-type magnet to temporarily suspend cardioversion or defibrillation when an ICD administers continued inappropriate shocks.

A properly functioning ICD may terminate certain potentially lethal arrhythmias without the need for a CCTP to perform any external cardioversion or defibrillation during transport. Even so, it is still essential to have an external cardioverter-defibrillator immediately available. CCTPs may experience a mild sensation if they are in contact with a patient as an ICD discharges, but no serious injuries to bystanders or health care providers have been reported.

Factors in the transport environment may require special consideration for patients with pacemakers or ICDs. Electromagnetic interference is the major cause of pacemaker dysfunction, particularly in older pacemakers that lack adequate internal shielding. Modern chip-based pacemakers are less susceptible to this type of interference. Neither small single-engine airplanes nor larger commercial aircraft pose an increased risk for electromagnetic interference affecting implanted pacemakers or ICDs.

CCTPs should be aware that devices such as headphones and microphones with internal magnets may cause interference in older pacemakers when placed within 1 to 2 inches (2.5 to 5 cm) of the device. The American Heart Association recommends that any type of headphone remain more than 1 inch (3 cm) from the pacemaker to avoid the risk of electromagnetic interference. If patients are provided with headsets or intercom systems during air transport, CCTPs should take care to keep these items safely away from the pacemaker device, which is usually visible as a mass under the patient's skin.

Flight Considerations

Pacemaker malfunction does not usually occur as a result of the flight environment. Some isolated reports have described helicopter vibration affecting pacemaker function; occasionally, rate-responsive pacemakers increase their firing rate as a result of vibration during helicopter transport. Nevertheless, in a study involving helicopter transport of dozens of patients with pacemakers, no pacemaker malfunctions occurred. This sort of issue rarely arises in the fixed-wing environment, although it could occur if the aircraft encounters significant turbulence. CCTPs working on medical helicopters should be aware of this potential and be prepared to intervene if necessary.

Finally, always remember that as altitude increases, monitoring oxygen saturations to determine if supplemental oxygen is needed is important.

Summary

Providers' ability to diagnose and treat patients with cardiac arrhythmias has been greatly enhanced by advances in technology, and keeping up-to-date with the latest developments on this front is imperative for all CCTPs. This chapter reviewed how to interpret 12-lead ECGs in the context of the CCT setting. One of the most valuable skills that can be learned is the ability to better identify an early MI, relay this information to the receiving facility or treating physician, and decrease the time to treatment. In addition to identifying an MI, acquiring a diagnostic-quality 12-lead ECG in the field, even if the findings are normal, will provide the treating staff with a baseline against which to compare serial ECGs done as part of the follow-up evaluation of the patient.

Over the years, pacemakers and ICDs have evolved through a variety of designs with varying functions and capabilities. Although detailed information about a patient's implanted device is often not readily available to CCTPs, general familiarity with basic concepts will always be helpful in determining whether these devices are functioning properly.

Pacers and ICDs share numerous basic components and functions. Modern devices all sense heart rate and use programmed circuitry to decide whether or how to respond. The exact types of sensing they perform and the therapies they deliver are where the types of devices differ the most.

Knowing the NBG codes is perhaps the single most valuable tool in a CCTP's approach to a patient with a pacemaker. Studying ECGs of real patients with pacers and ICDs will help CCTPs prepare for identifying and managing problems in the transport environment. In any case of suspected or certain malfunction, it will be important to the electrophysiologist that the CCTP obtain ECG recordings, ensure availability of data from the device, and provide detailed written documentation of the incident.

CASE STUDY

Just as you are finishing your lunch, dispatch advises you of an emergency transfer of a critical cardiac patient from Community Hospital to St. Patrick's Hospital. Your crew, which consists of an emergency medical technician (EMT) driver, you, and a fellow paramedic, responds in 12 minutes to the Community Hospital emergency department (ED).

On arrival, you obtain a report from the transferring physician, Dr. Jans, who states that your patient is a 67-year-old, 245.5-lb (111.36-kg) Native American man who arrived in the ED approximately 45 minutes ago complaining of severe substernal chest pain. The patient also had hypertension. The patient's 12-lead ECG revealed no acute ST-segment changes, but bloodwork showed an elevated troponin level, suggesting ACS. His medications in the ED included 324 mg of aspirin; 0.4 mg of nitroglycerin, 2 doses; 3 mg of morphine IV; 300 mg of clopidogrel; and 20 mg of eptifibatide. Currently, the patient is receiving a continuous infusion of nitroglycerin at 20 mcg/min and an eptifibatide infusion at 222 mcg/min. The patient is being transferred to Dr. Webb at St. Patrick's catheterization laboratory for emergency cardiac catheterization.

When you assess the patient, you obtain the following readings: heart rate, 94 beats/min, sinus rhythm; respiratory rate, 18 breaths/min, with clear and equal breath sounds bilaterally; blood pressure, 145/88 mm Hg; temperature, 99.1°F (37.3°C); pulse oximetry reading, 95% on room air; carbon dioxide, 42 mm Hg; heart tones, normal with no rubs, gallops, or murmurs; and peripheral edema, 1+ in the lower extremities.

Further interview of the patient reveals a past medical history of hypertension and hepatitis. At present, he takes no medications and has no allergies. The patient states that the pain started approximately 90 minutes ago and began radiating to his left arm. Initially, he rated the pain as 10 on a 10-point scale; after morphine was given, the score decreased to 2 on a 10-point scale. As your partner secures the patient onto the stretcher, you transfer the infusions to your transport IV pump.

As you review the patient's lab studies, you note the following values of interest:

- Glucose: 98 mg/dL (normal range, 70 to 110 mg/dL)
- Chloride: 110 mmol/L (normal range, 96 to 106 mmol/L)
- Potassium: 4.1 mmol/L (normal range, 3.5 to 5.0 mmol/L)
- Calcium: 8.6 mg/dL (normal range, 8.2 to 10.2 mg/dL)
- Magnesium: 1.7 mEq/L (normal range, 1.3 to 2.1 mEq/L)
- Blood urea nitrogen (BUN): 13 mg/dL (normal range, 8 to 23 mg/dL)
- Creatinine: 1.3 mg/dL (normal range, 0.6 to 1.2 mg/dL)
- BUN/creatinine ratio: 10.0 calculated (normal range, 12.0 to 20.0 calculated)
- Prothrombin time: 14.1 s (normal range, 10 to 13 s)
- Activated partial thromboplastin time: 53.0 s (normal range, 25.0 to 40.0 s)
- Troponin T: 1.6 ng/mL (normal range, 0.0 to 0.1 ng/mL)
- Brain-type natriuretic peptide: 140 pg/mL (normal range, <167 pg/mL)
- Alanine aminotransferase: 392 U/L (normal range, 10 to 40 U/L)
- Aspartate aminotransferase: 110 U/L (normal range, 10 to 30 U/L)

You load the patient into the ambulance and proceed on an emergency basis to St. Patrick's Hospital, which is located approximately 110 miles away. The patient appears to be in a moderate amount of distress; however, he rates his pain as 2 on a 10-point scale. As you reassess the patient, your partner increases the nitroglycerin to 25 mcg/min in an attempt to make the patient more comfortable. The patient acknowledges the improvement: "Thanks, that helps me relax and not hurt quite as bad."

Your partner repeats a 12-lead ECG to compare with the ECG that was done in the ED, and it is unchanged. The remainder of the transport is unremarkable, and you deliver the patient to Dr. Webb and the waiting catheterization laboratory team.

1. If this patient did not have any ECG changes, how were you able to determine that he was experiencing an MI?
2. Why was this patient receiving nitroglycerin? Eptifibatide?
3. What are the side effects of these medications?
4. What are the possible complications that may be experienced en route with this patient?

Analysis

Because of your critical care training, you are able to recognize that this patient was experiencing an NSTEMI based on the given lab values. You know that troponin will increase 3 to 6 hours after infarction and is the most specific cardiac marker.

Nitroglycerin is indicated in MI situations owing to its vasodilatory properties on systemic and large coronary vessels. Systemic venodilation reduces preload, lowering ventricular volume. To a much lesser degree, arterial vasodilation also occurs, reducing afterload. The subsequent decrease in cardiac workload results in increased oxygen and blood supply to ischemic cardiac tissue. The possible side effects of using nitroglycerin for this patient are hypotension, reflex tachycardia, and cardiac arrhythmias.

Eptifibatide is indicated in patients with unstable angina or NSTEMI to reduce the risk of acute ischemic events. This antiplatelet medication selectively blocks the platelet glycoprotein IIb/IIIa receptor. Possible side effects of eptifibatide are uncontrollable bleeding, anemia, and thrombocytopenia.

Owing to the nature of this patient's situation and the different medications that have been administered, careful monitoring en route is essential. Some of the potential problems that might occur en route include hypotension from inadvertent nitrate overdose, cardiogenic shock caused by pump failure, respiratory arrest due to narcotic potentiation, and, ultimately, cardiopulmonary arrest.

That evening, as you are delivering another patient to the ED at St. Patrick's, you see Dr. Webb and ask about the status of the patient whom you brought in earlier. According to the physician, the patient underwent cardiac catheterization that revealed significant narrowing of the left anterior descending artery. Owing to the severity of the narrowing, placing a stent was contraindicated, so the patient underwent an emergency coronary artery bypass graft in which a section of the left internal mammary artery was removed and grafted to the left anterior descending artery. The patient is expected to make a complete recovery and be released in 3 to 5 days.

PREP KIT

Ready for Review

- Oxygenated blood reaches the heart through the coronary arteries, which are vulnerable to blockage and narrowing by plaque formation, a condition called atherosclerosis.
- The major heart sounds are the two normal sounds, S_1 and S_2, and the two abnormal sounds, S_3 and S_4.
  - S_1 (the "lub" sound) occurs near the beginning of ventricular contraction (systole), when the tricuspid and mitral valves close. Any delay in the closing of these two valves, heard as a split sound, is considered abnormal.
  - S_2 (the "dub" sound) occurs near the end of ventricular contraction (systole), when the pulmonary and aortic valves close. The two valves can close simultaneously or with a slight delay between them under normal physiologic circumstances.
  - S_3 ("dub-lub-dub") signals the end of the rapid filling period of the ventricle during the beginning of diastole. In older adults, it often signifies heart failure.
  - S_4 ("lub-dub-dub") coincides with atrial contraction at the end of ventricular diastole. If heard at any other time, the patient may have resistance to ventricular filling.
- The cardiac cycle comprises one complete phase of atrial and ventricular relaxation (diastole), followed by one atrial and ventricular contraction (systole).
- During diastole (normally 520 ms), the left atrium fills passively with blood under the influence of venous pressure, and approximately 80% of ventricular filling occurs.
- In systole (normally 280 ms), ventricular filling is completed, the atrioventricular (AV) valves snap shut, the two ventricles contract (ventricular systole), and the semilunar valves are forced open.

Blood squeezed out of the right ventricle moves into the pulmonary arteries; blood from the left ventricle is pushed into the aorta.

- If the right side of the heart fails, blood backs up behind the right atrium, evidenced by distention of the external jugular veins, and fluid leaks into the surrounding tissues, causing edema in the subcutaneous and internal tissues.
- If the left side of the heart fails, blood backs up behind the left atrium, and fluid is squeezed into the alveoli, producing pulmonary edema, evidenced by dyspnea, bubbling crackles, and frothy sputum.
- In addition to the output of the heart and the volume of blood present in the system, the relative constriction or dilation of arteries, which is controlled by the autonomic nervous system, influences blood pressure.
- Key parameters associated with the heart’s functioning include CO (the amount of blood pumped out by either ventricle), stroke volume (the amount of blood pumped out by either ventricle in a single contraction), and heart rate (the number of cardiac contractions per minute).
- Changes in the heart’s contractility (the degree of contraction of its muscle without changing the stretch on the muscle) may be induced by medications that have a positive or negative inotropic effect.
- The heart can generate its own electrical impulses without stimulation from nerves (automaticity) and has specialized conduction tissue that can rapidly propagate electrical impulses to the muscular tissue of the heart.
- The dominant pacemaker in the heart is the sinoatrial (SA) node; if the right coronary artery is occluded, as in a myocardial infarction (MI), the SA node may become ischemic.
- Depolarization of the heart, the process by which muscle fibers are stimulated to contract, occurs because of an influx of sodium and calcium ions into the myocardial cells. It results in a “wave of

depolarization" as the electrical charges pass in all directions from one cell to another.

- Repolarization occurs when the sodium and calcium channels close and potassium channels open; during this process, sodium ions move out of the cell and potassium ions flood back in.
- In the absolute refractory period, the heart muscle has been drained of energy; it will not contract during this period. In the relative refractory period, the heart is partially charged, albeit not strongly enough to create a full contraction.
- The electrical conduction events in the heart can be recorded on an electrocardiogram (ECG) as a series of waves and complexes. Depolarization of the atria produces the P wave; as the electrical impulse slows through the AV node or AV junction, it can be seen on the ECG as the PR interval; depolarization of the ventricles produces the QRS complex; repolarization of the atria and ventricles produces T waves.
- A U wave may be present after the T wave, although there is no definitive agreement as to what it represents.
- The 12-lead ECG graphically represents electrical activity in cardiac tissue.
- Today's cardiac monitor-defibrillators typically combine continuous 3-lead ECG monitoring, 12-lead electrocardiography, semiautomatic and manual defibrillation, external pacing, capnography, pulse oximetry, blood pressure monitoring, end-tidal carbon dioxide measurements, invasive pressure monitoring, and other capabilities.
- Assessment of the patient's cardiac status, which takes place before monitoring, should include analysis of the cardiac rhythm and 12-lead ECG to determine any underlying electrical disturbances caused by changes in the heart's structure or function as the result of disease, ischemia, injury, or infarction.
- Cardiac monitoring, the continuous observation of the patient's condition in relation to the cardiac rhythm, typically uses lead

configurations that allow for viewing the rhythm simultaneously from one to three leads.

- The gold standard for 12-lead ECG interpretation is the ability to perform serial evaluations for comparison; however, it is important to use consistent lead placements to ensure that all providers compare “apples to apples.”
- The electrode is the sensing device that connects directly to the skin; the lead is the designated position of the electrode (ie, limb and precordial leads). The cable is the physical wire that connects the electrode to the ECG monitor.
- The six limb leads (I, II, III, aVR, aVL, and aVF) provide a view of the heart in a coronal or vertical plane (the frontal plane); the six precordial leads (V_1 to V_6), or chest leads, show a transverse or horizontal plane. The combination of limb leads and precordial leads provides a three-dimensional view of the heart.
- If the flow of electrical activity proceeds unimpeded toward a positive lead, it appears as a positive deflection on the ECG. If the flow of electrical activity moves away from a positive lead, it is deflected negatively. An electrical impulse that crosses perpendicular to a positive lead is called isoelectric.
- If the heart’s electrical impulse is deflected by a change in structure or function, it will be less positive, aberrantly conducted, or deflected away from the selected electrode.
- Placement of additional or nonstandard right-side heart leads V_4R, V_5R, and V_6R and posterior heart leads V_7, V_8, and V_9 is indicated in suspected right ventricular and posterior MIs and when a patient has clinical findings suggestive of acute coronary ischemia, but the standard 12-lead ECG is normal or nondiagnostic.
- Before running the ECG with right-side leads, the critical care transport professional (CCTP) should complete the standard 12-lead ECG. Then, using the precordial (chest) leads, the additional leads are attached as follows: V_4R, V_5R, V_6R, V_7, V_8, and V_9.
- The CCTP should confirm placement of leads before transport and several times during transport.

- A “new” 12-lead ECG should be recorded and evaluated before transport and repeated at regular intervals, when any changes in the ECG are noted, and on arrival at the receiving facility.
- The transport of a patient with STEMI to definitive care should not be delayed for the sake of obtaining additional ECGs.
- Placing the patient in a supine position is recommended when obtaining ECGs; however, an adequate ECG can be obtained with the patient in a semisitting (semi-Fowler) position.
- Before obtaining a 12-lead ECG, the device should be standardized or calibrated at 1 mV = 10 mm high and 200 ms wide.
- In the limb leads, the P wave is typically upright in leads I, II, aVL, and aVF. It is frequently biphasic in lead III, and is purely negatively deflected in lead aVR. A change in the P-wave morphology suggests an ectopic atrial focus.
- In the precordial leads, the P wave is typically upright in leads V_5 and V_6. Lead V_1 is biphasic, and leads V_2 and V_4 are variable.
- The PR interval spans the time from the start of atrial depolarization to the start of ventricular depolarization; it also includes the delay in conduction that occurs at the AV junction. It usually lasts from 120 to 200 ms.
- The QRS complex is a representation of ventricular depolarization. Septal depolarization is not always seen on the ECG; when it is, a small Q wave may be visible in leads I, aVL, V_5, and V_6.
- The keys to being able to quickly read an ECG are experience and consistency. Interpretation of 12-lead ECGs is a skill that must be practiced repeatedly using a standard method of analysis.
- Interpretation of rhythms and arrhythmias is a fundamental building block for ECG analysis.
- The 12-lead ECG shows groupings of complexes that are recorded simultaneously by each lead. The rhythm strip, which

typically appears at the bottom of the ECG, records for the entire time the 12-lead ECG is being obtained.

- Each cell in the heart can produce its own electrical impulse (vector), which varies in intensity and direction. The axis is the direction of the wave of depolarization as it passes through the heart.
- The sum of all the electrical impulses is called the mean electrical axis. It should progress in a downward and leftward direction; a change in the axis indicates that a change has occurred in the structure or function of the heart.
- To calculate the direction and intensity of the electrical axis, the hexaxial system, which relies on a circular diagram oriented in the frontal (coronal) plane, can be used.
- Before transporting a critically ill patient, a baseline ECG should be acquired and analyzed on the cardiac monitor and abnormalities should be noted, including in the mean electrical axis. An axis that deviates outside the normal range or is different from the patient’s preexisting axis usually has clinical implications. In such a case, the CCTP should check the ECG for corresponding changes suggestive of the underlying cause of the deviation.
- Cardiac causes of axis deviation include ischemia, infarction, left or right ventricular hypertrophy, ectopic beats and rhythms, dextrocardia, and conduction defect of the left posterior-inferior fascicle of the left bundle branch.
- Other conditions that are not cardiac in origin can contribute to a shift in axis; examples include anatomy (such as tall, thin stature), young age, chronic obstructive pulmonary disease, obesity, and pregnancy.
- A disruption of the electrical impulse in the right and left atria will result in a change in the shape of the P wave.
- An injury to the tricuspid and mitral valves or disruption of the electrical impulse in the AV node can result in lengthening or shortening of the PR interval.

- Injuries in the bundle of His, the left and right bundle branches, the fascicles, and the Purkinje fibers can result in a bundle or fascicular block.
- With a right bundle branch block (BBB), the representative complex displayed on the ECG includes a prolonged QRS interval of 120 ms or more; a slurred S wave in leads I and V_6; and the RSR′ pattern in lead V_1, with the R′ wave being taller than the R wave.
- No specific treatment is required for an isolated right BBB, but the patient should be seen for periodic follow-up evaluations.
- With a left BBB, the representative complex displayed on the ECG includes a prolonged QRS interval of 120 ms or more; V_6 should have a notched R wave with no Q wave; and wide, deep S waves should be seen in lead V_1 (this lead may also have a small r wave with a large S wave).
- A left BBB usually indicates the presence of a serious cardiac problem within the conduction system or ischemia from coronary artery disease. Patients with this condition require complete cardiac evaluation.
- A hemiblock is a block in the electrical conduction of one of the two fascicle branches of the left bundle branch. It causes little to no widening of the QRS complexes.
- The criteria for diagnosing left anterior hemiblock are left axis deviation within –30° to –90°; a qR complex or large R wave in lead I; and an rS complex in lead III (likely to also appear in leads II and aVF).
- A bifascicular block (ie, two conduction pathways blocked at the same time) is diagnosed by concurrent findings of a right BBB with a left anterior hemiblock or left posterior hemiblock. A new onset of bifascicular block with ischemia is not stable and often deteriorates into a complete heart block, especially in the presence of an acute MI.
- When transporting a critically ill cardiac patient with an existing bifascicular block consisting of a right BBB and left anterior

hemiblock, if signs of ischemia or infarction develop, the patient will likely need acute pacemaker placement, especially in the presence of second- or third-degree AV block. The CCTP should contact medical control, prepare the patient for external cardiac pacing, and notify the receiving facility to be urgently prepared for pacemaker placement.

- A trifascicular block is the combination of a bifascicular block (a right BBB with a block in the left anterior or left posterior fascicle) that occurs with a first-degree heart block (prolonged PR interval); its presence after an MI implies extensive cardiac damage. True trifascicular blocks require immediate temporary pacing followed by the placement of a permanent pacemaker.
- Hyperacute T waves that appear as a result of ischemia and infarction appear only in the leads that view the area of ischemia and infarction.
- In addition to being present after an MI, ST-segment elevation is observed with a left BBB, ventricular rhythms, left ventricular hypertrophy, pericarditis, and early repolarization. A persistent ST-segment elevation may indicate the formation of a ventricular aneurysm.
- The combination of hypertrophy and dilation means that the heart has a larger muscle mass in the affected area and the chamber is enlarged. The larger the muscle mass, the higher the concentration of electrical impulses or vectors is.
- Left atrial enlargement produces a P wave with a notched, double-humped appearance.
- The characteristic findings in right atrial enlargement are tall, peaked P waves in the inferior leads II, III, and aVF that have an amplitude of 2.5 mm or more. The tall, peaked P waves are known as P pulmonale.
- Patients with left ventricular hypertrophy (LVH) have a higher risk for coronary artery disease, making them more susceptible to the sequelae of that disease, and exhibit increased mortality relative to patients who experience an MI without LVH. Increased R-wave

amplitude in the leads that look at the left ventricle informs the ECG diagnosis of LVH.

- Patients with right ventricular hypertrophy exhibit a right shift in axis in leads I and aVF, and precordial leads V_1 and V_2 show increased R-wave deflection.
- When hypertrophy is uncomplicated by ischemia, the changes in QRS complexes are used to make the diagnosis. When subendocardial ischemia is present as well, changes to the ST segment and T wave appear as a strain pattern.
- It is important to distinguish between the strain pattern and the ST-segment and T-wave changes seen in ischemia and infarction, because the ST-segment and T-wave changes can be immediately life threatening.
- In people with Wolff-Parkinson-White syndrome (WPW), the bundle of Kent (accessory pathway) does not have the same ability to slowly conduct electrical impulses as does the pathway through the AV node. This condition puts the person at risk for extremely fast heart rates that may cause hemodynamic instability. On the ECG, WPW is signaled by the presence of a slurred upstroke known as a delta wave.
- The two tachyarrhythmias that occur most often in WPW are paroxysmal supraventricular tachycardia (SVT) and atrial fibrillation. CCTPs should be aware of the potential for a wide complex tachycardia developing that is difficult to distinguish from ventricular tachycardia (VT).
- Treatment of unstable WPW tachyarrhythmias may require electrical cardioversion; management with drug therapy produces unpredictable results.
- Pericarditis (inflammation of the pericardium) may cause ST-segment elevation, T-wave flattening or inversion, and the appearance of low voltage in all leads.
- Long QT syndrome (LQTS) is characterized by a prolonged QT interval on ECG and has a tendency to deteriorate into ventricular tachyarrhythmias, including torsades de pointes, which can lead to

syncope and sudden cardiac death. In this condition, the rhythm is too fast to maintain effective CO, so the patient loses consciousness, often without warning.

- The deterioration of LQTS poses a management challenge for CCTPs. Carefully evaluating the ECG, reviewing the patient's medications, and obtaining a medical history will help provide clues to the diagnosis and alert the CCTP to the possibility of a tachyarrhythmia developing during transport.
- Treatment for torsades de pointes includes correcting the underlying cause, overdrive pacing, and administering magnesium sulfate. Other therapies for patients in unstable condition may include electrical cardioversion and defibrillation.
- Wide complex tachycardia is any cardiac rhythm of more than 100 beats/min with a QRS duration of 120 ms or more. This arrhythmia can be of ventricular or supraventricular origin; identifying its origin can lead to the correct diagnosis and proper therapeutic interventions.
- The most useful ECG criterion in establishing the diagnosis of VT is the presence of AV dissociation with more ventricular events than atrial events.
- In a patient with a right BBB with a QRS duration of greater than 140 ms, VT is the likely diagnosis. In a patient with a left BBB, a QRS duration of greater than 160 ms suggests VT.
- If the electrical axis is in the range of 180° to –90°, the wide complex tachycardia is not likely to be SVT. Electrical concordance across the precordium (all QRS complexes pointing in the same direction in leads V_1 through V_6) is more likely to be VT and is rarely consistent with SVT.
- Patients with wide complex tachycardia who have low blood pressure, pulmonary edema, severe chest pain, or other evidence of poor perfusion should be promptly treated using synchronized cardioversion.
- When a patient with wide complex tachycardia remains in hemodynamically stable condition, more time can be spent

reviewing the history, physical examination, and ECG findings, so as to make the correct diagnosis.

- When a patient has wide complex tachycardia of an uncertain cause, yet remains in hemodynamically stable condition, procainamide is the drug of choice because it can terminate SVT and VT. This agent is also useful in patients with a poor ejection fraction.
- Procainamide can be used with caution in a patient with wide complex tachycardia who remains in hemodynamically stable condition. This drug can cause a sudden drop in blood pressure with rapid IV administration and is contraindicated in patients with complete heart block.
- Lidocaine is useful for VT of ischemic origin but does not terminate SVT.
- If SVT is suspected, adenosine is a useful and diagnostic medication. When irregular wide complex tachycardia is the result of atrial fibrillation and pre-excitation over an accessory pathway, however, adenosine may lead to ventricular fibrillation.
- Following termination of wide complex tachycardia, preventive treatment for maintaining a stable rhythm should be initiated, usually in the form of an antiarrhythmic drug (eg, continuation of the drug that terminated the wide complex tachycardia).
- In patients presenting with a wide complex tachycardia rhythm, BLS is the first step in patient management, closely followed by ACLS practices. If the patient is in hemodynamically unstable condition, wide complex tachycardia should be managed as if it were VT until proven otherwise, with synchronized cardioversion being the initial therapy of choice.
- Polymorphic or pulseless VT should be treated as ventricular fibrillation: Give immediate defibrillation, secure the airway, provide CPR, perform endotracheal intubation, support ventilations, and administer an antiarrhythmic medication.
- When changes in electrolytes, especially potassium and calcium, occur, their effects are often seen on the ECG.

- Hyperkalemia, the most dangerous of all electrolyte abnormalities, can cause death and prevent some drugs used in resuscitation efforts from being effective. On the ECG, hyperkalemia can cause changes in the appearance of all waveforms, and it can cause virtually any arrhythmia. Rapid recognition and correction of this electrolyte disturbance is essential.
- Hypokalemia does not cause the dramatic changes on the ECG, but rather is associated with mild, nonspecific changes such as ST-segment depression, a slightly decreased amplitude of the T waves, minimal prolongation of the QRS interval, and the presence of a prominent U wave.
- ECG changes associated with hypercalcemia include a shortened ST segment, a shortened QT interval, a prolonged PR interval, and flattened or inverted T waves. A variable degree of heart block may also develop.
- Hypocalcemia that occurs acutely can be the result of medications or surgical effects. It causes the opposite effects of hypercalcemia.
- There is a higher incidence of adverse effects with use of calcium channel blockers and beta blockers, but the mortality rate is higher in patients who experience digoxin toxicity. The margin between toxic and therapeutic doses of digoxin is small.
- At toxic levels of digoxin, the excessive increase of intracellular calcium associated with this medication elevates the resting potential and predisposes the heart to arrhythmias. The most common ECG changes seen in patients with digoxin toxicity include AV, junctional, or ventricular ectopic beats; first-degree AV block; slow ventricular response in atrial fibrillation; and an accelerated AV or junctional rhythm. More severe arrhythmias may include severe bradycardia, high-degree heart blocks, and malignant ventricular rhythms.
- Early recognition and aggressive treatment of digoxin toxicity are lifesaving.

- If one of the coronary arteries becomes blocked, the muscle it supplies will be deprived of oxygen (ischemia). If this oxygen supply is not quickly restored, the ischemic area of heart muscle will eventually die (undergo infarction).
- In atherosclerosis, plaque infiltrates the arterial wall and decreases its elasticity; it also narrows the arterial lumen and interferes with blood flow through the vessel. The narrowed, roughened area of the arterial intima provides a locus for the formation of a fixed blood clot (thrombus) that may obstruct the artery, and calcium may begin to precipitate from the bloodstream into the arterial walls, causing arteriosclerosis.
- Atherosclerosis is rarely the primary cause of medical emergencies but is a major contributor to other conditions that may become medical emergencies.
- Arterial bruits (turbulence or “swishing” sounds heard with a stethoscope placed over the carotid arteries) signal the presence of atherosclerosis and contraindicate the use of carotid sinus massage.
- Other peripheral vascular disorders associated with atherosclerosis include claudication and phlebitis. An example of claudication is a severe pain in the calf muscle caused by narrowing of the arteries in this muscle and leading to a painful limp. Phlebitis is inflammation, swelling, and pain along the veins that can lead to the formation of blood clots and thrombophlebitis, which is venous inflammation associated with a thrombus.
- The most dangerous complication of peripheral vascular disorders is pulmonary embolism, in which a thromboembolus travels to the heart and through its right side, lodging in the pulmonary arterial tree.
- Signs of peripheral vascular occlusion may include pain, flushing, swelling, warmth, and tenderness in the extremity; claudication; and arterial bruits.
- If a blockage or potential embolus is suspected, the CCTP should administer IV heparin or other anticoagulant, monitor the affected

limb via ultrasonography or Doppler imaging (if available), and maximize blood flow to the extremity by using warm compresses.

- A patient being transported over a long distance with a blood clot that has the potential to become a pulmonary embolus should have a baseline ECG performed before transport begins and must undergo frequent 12-lead ECG monitoring. ST-segment depression in the limb and precordial leads accompanied by an increase in right axis deviation may indicate a pulmonary embolism. As a diagnostic tool, the ECG is neither specific nor sensitive for pulmonary embolism.
- Acute coronary syndrome (ACS) comprises any group of clinical symptoms consistent with acute myocardial ischemia. Acute myocardial ischemia typically presents as chest pain as the result of insufficient blood supply to the heart muscle because of coronary artery disease.
- ACS includes conditions that cause episodes of ischemic discomfort (chest pain) as the result of disruption of plaque within a coronary artery. These substances promote a chain reaction of platelet activation, adhesion, aggregation, thrombin formation, and, ultimately, thrombus formation, with the end result being complete occlusion of the coronary artery or one of its branches.
- The 12-lead ECG is used to categorize two groups of patients who have experienced ACS: patients with ST-segment elevation MI (STEMI) and patients without STEMI (NSTEMI).
- A 12-lead ECG should be performed within 10 minutes of contacting a patient with chest discomfort or other signs and symptoms suggestive of STEMI. If the findings are not conclusive, but the patient remains symptomatic and a high degree of suspicion is present, serial 12-lead ECGs should be performed while maintaining continuous ST-segment monitoring.
- All patients with ACS should receive antithrombin and antiplatelet therapy, regardless of the presence or absence of ST-segment elevation. Patients with STEMI are candidates for prompt reperfusion therapy, either pharmacologic or catheter based, to

restore blood flow in the occluded artery; patients with NSTEMI should receive anti-ischemic therapy and be considered for catheter-based therapy.

- Marked ST-segment depression in leads V_1 through V_4, with tall R waves in the right precordial leads and upright T waves, is suggestive of a true posterior wall MI. Placement of additional electrodes in the posterior position to form leads V_7, V_8, and V_9 is recommended to confirm the diagnosis because primary percutaneous coronary intervention may be appropriate in patients with true posterior MI.
- Lethal ventricular arrhythmias may develop in patients with STEMI, so continuous ECG monitoring is required.
- Many patients whose ECG displays ST-segment elevation will ultimately have a STEMI.
- In case of ACS, the role of the CCT team is to transport the patient from a basic-care hospital to a cardiac-specialty hospital with the least possible decline in the patient’s condition and to prevent further loss of heart muscle. If transport times will be long or the degree of blockage is severe to the point of being life threatening, administration of tissue plasminogen activators may be required.
- Angina occurs when the supply of oxygen to the myocardium is insufficient to meet the demand. When obtaining a history from a patient with chest pain, it is important to distinguish between stable angina (follows a recurrent pattern) and unstable angina (follows no pattern).
- In the CCT environment, nitroglycerin should be given intravenously to patients with stable angina, especially for long transports.
- Unstable angina is characterized by noticeable changes in the frequency, severity, and duration of pain and often occurs without predictable stress. It is often a warning sign of an impending MI.
- An MI occurs when the cardiac muscle is deprived of coronary blood flow long enough for death of myocardial tissue to occur.

Causes include narrowed vessels, coronary artery occlusion, spasm of a coronary artery, and reduction of overall blood flow.

- Acute MI is the leading cause of death in the United States. The majority of infarctions involve the left ventricle.
- The infarcted tissue is invariably surrounded by a ring of ischemic tissue, an area that is relatively deprived of oxygen but still viable. This ischemic tissue is often the source of cardiac arrhythmias.
- The three initial components for the diagnosis of an MI are history and physical examination, testing for cardiac enzymes, and interpretation of ECG changes associated with an MI.
- Biomarkers for MI include troponin I and troponin T, both of which increase after an MI. When troponin assays are available, creatine kinase and myoglobin are no longer considered useful for diagnosis of ACS.
- Increased oxygen demand caused by an increased workload or a decrease in supply caused by coronary artery disease or a blocked artery can lead to ischemia, injury, and, ultimately, infarction. Ischemia and injury may be reversible, and rapid intervention when they occur can often prevent infarction.
- On the ECG, findings associated with ischemia include ST-segment depression and an inverted T wave. With MI, the T wave inverts symmetrically; when other causes (such as ventricular hypertrophy with strain and a BBB and cerebral hemorrhage) are to blame, the T-wave inversion is often asymmetric or “slurred.”
- If ischemia continues uninterrupted, the injured area does not repolarize completely, leading to an elevated ST segment.
- If ischemia and injury continue uninterrupted, infarction can occur. Because the infarcted tissue no longer generates or transmits electrical impulses, no direct wave is recorded on the ECG. Electrical impulses, which are deflected away from the area of infarct, are represented by Q waves.
- For Q waves to be significant (ie, indicating pathology), they must be more than one-third the total height of the QRS complex with which they appear and wider than 40 ms in duration.

- The prognosis and therapeutic implications for a patient who has had an MI are determined largely by which area of the heart has died.
- Q waves from old infarctions can be present with findings of a new MI and can complicate the process of making the correct diagnosis from the ECG. For this reason, CCTPs should review an “old” ECG from the patient’s chart, acquire a new 12-lead ECG before transport, and make serial evaluations along the way.
- In an anterior wall MI, the normal pattern of R-wave progression may not occur, a phenomenon called poor R-wave progression.
- An anteroseptal MI is common with an occlusion of the left anterior descending artery and is often associated with hemodynamic compromise and cardiogenic shock. To identify this pattern of MI, the CCTP should analyze the septal leads V_1 and V_2 and the anterior leads V_3 and V_4.
- In an acute anteroseptal MI with lateral extension, changes can be seen in all precordial leads (specifically, V_5 and V_6 for the lateral extension) and in leads I and aVL; significant Q-wave formation is not always present, but reciprocal changes can be found in leads II, III, and aVF.
- Hyperacute T-wave changes occur only during the first 15 to 30 minutes of an acute MI. If these changes are found during transport, the CCTP is in a unique position to initiate care, even if it is only early notification of the receiving facility to decrease the door-to-treatment time.
- In an acute lateral wall MI, ECG changes are often seen in lateral leads I, aVL, V_5, and V_6. Reciprocal changes may be seen in inferior leads II, III, and aVF.
- With an inferior wall MI, characteristic ECG changes can be seen in inferior leads II, III, and aVF. Reciprocal changes are seen as ST-segment depression in leads I and aVL unless the high lateral wall is included in the infarction.
- In a patient without signs of acute infarction, pathologic Q waves are considered to have an indeterminate age; that is, without a

good patient history, there is no way to tell how old the infarction is.

- In an acute inferolateral MI, ECG changes are seen in inferior leads II, III, and aVF and in lateral leads I, aVL, V_5, and V_6. ST-segment changes will be found in leads V_2 to V_4 if the infarct extends anteriorly, and classic ST-segment and T-wave changes will be evident in lateral precordial leads V_5 and V_6.
- In an acute apical MI, direct ECG changes can be found in inferior leads II, III, and aVF; lateral leads I and aVL; and precordial leads V_2 through V_6. Because of the diffuse ECG changes, this type of MI can be confused with pericarditis.
- Right ventricular infarction is strongly associated with an inferior wall MI, so when it is present, CCTPs should maintain a high index of suspicion and check for other criteria. Right ventricular infarction should be suspected with ST-segment elevation in (septal) lead V_1 and (inferior) leads II, III, and aVF.
- The diagnosis of a posterior wall MI is made by looking for reciprocal changes in leads V_1 and V_2—specifically, ST-segment depression, upright T waves, and tall R waves.
- When there is reciprocal evidence of a posterior wall MI, CCTPs should maintain a high index of suspicion, and record posterior leads (V_7, V_8, and V_9) for comparison.
- Patients with cardiomyopathy may have shortness of breath, chest pain, palpitations, or syncope; sudden cardiac death is also possible.
- Heart failure occurs when the heart cannot pump powerfully enough or fast enough to empty its chambers; as a result, blood backs up into the systemic circuit, the pulmonary circuit, or both.
- In left-side heart failure, the left side of the heart is no longer able to pump the blood being delivered from the pulmonary vessels. As a consequence, blood backs up behind the left ventricle, the pressure in the left atrium and pulmonary veins increases, and

serum is forced out of the pulmonary capillaries and into the alveoli.

- Pulmonary edema occurs as the result of a reduced ejection fraction and CO of the left ventricle, as serum mixes with air in the alveoli.
- The priorities when managing left-side heart failure are to remove the fluid from the lungs, reduce afterload, increase oxygen supply to the heart, and decrease myocardial oxygen demands.
- Right-side heart failure most commonly occurs as a result of left-side heart failure, but may also occur as a result of pulmonary embolism or long-standing chronic obstructive pulmonary disease, especially chronic bronchitis.
- The edema associated with right-side heart failure is most likely to be visible in dependent parts of the body (eg, the feet in a person who is sitting or standing or the lower back in a bedridden patient). It is also present in parts of the body that are not visible, such as the liver.
- Electrophysiology studies are not done during transport, but in the hospital setting they may be performed to assess electrical activity of the heart.
- The primary in-hospital arrhythmia therapies are catheter ablation; atrial ligation; pharmacologic treatment; implantable devices, such as pacemakers and implantable cardioverter-defibrillators (ICDs); and wearable cardioverter-defibrillators.
- The transcutaneous pacemaker is most commonly used as an initial emergency pacer (a temporary measure). It is the quickest and most convenient method of pacing, but also requires the most energy and is the least reliable owing to the quality of the skin-to-pad contact and the thoracic impedance that must be overcome.
- Many patients are transported between medical facilities with transvenous pacemakers accompanied by an external pulse generator. Generally, these transvenous pacers require little attention and are quite reliable; the primary sources of problems are battery failure and lead disconnection at the generator.

Voltage (the force that causes current to flow) and impedance (resistance to current) are important determinants of battery longevity in a pacemaker.

- The main sources of resistance in a pacing circuit are the lead conductor, the electrode, and the concentration of electrically charged ions at the electrode–tissue interface. Electrode resistance improves pacing efficiency; lead conductor resistance and polarization do not.
- Passage of the pacemaker's electrical impulse between the cathode and the anode—through cardiac tissue and body fluids—is the event in the pacing circuit that stimulates cardiac depolarization.
- Pacemakers stimulate cardiac depolarization, sense intrinsic cardiac activity, respond to metabolic needs, and store diagnostic information. All pacemakers can provide fixed-rate pacing; most also provide rate-adaptive (rate-responsive) pacing, increasing and decreasing the pacing rate in response to input from the rate sensors.
- Endocardial (transvenous) leads are threaded through veins, usually subclavian or cephalic, to the right atrium or ventricle. Epicardial leads are attached to the external surface of the heart with sutures or another fixation device.
- Steroid-eluting electrodes have a silicone plug that contains a small dose of steroid. Its release reduces inflammation and the growth of fibrous tissue at the electrode site.
- Pacemaker system malfunction may occur as a result of battery failure, problems at the lead electrode–tissue interface, coiling or damage to the lead–generator interface, insulation failure of the lead wires, dislodgement of the lead at the implantation site (very rare), pacemaker programming, pocket stimulation, diaphragmatic stimulation, or electromagnetic interference.
- If pacemaker failure occurs during transport, the cardiac monitor will show failure to capture a signal. To confirm the pacing failure,

the CCTP should compare a 12-lead ECG with the patient’s pulse and assess the patient for signs of decompensation.

- Pacing in the ventricular pacer mode and loss of AV synchrony in a single-chamber pacemaker can lead to pacemaker syndrome, which results from hemodynamic deterioration and causes nonphysiologic timing of atrial and ventricular contractions.
- Atriobiventricular pacemakers, which coordinate the actions of the right and left ventricles of the heart, may be used as a treatment for heart failure to resynchronize the heart’s chambers.
- ICDs automatically attempt to convert a fibrillating heart into a sinus rhythm using a shock from voltage. Each patient with an ICD has a custom ICD system consisting of a housing (can) and a variable number of pacing and high-voltage leads.
- Most ICDs are implanted with one or two transvenous leads used for pacing and shocking. The leads enter the venous system through the subclavian or cephalic vein for placement into the right ventricle or the superior vena cava.
- An ICD bases its decision to deliver a shock (to treat tachyarrhythmias) on the ventricular rate alone; thus, atrial arrhythmias and electromagnetic interference can lead to inappropriate shocks.
- If an ICD fires during care of a patient, the provider should gather the following information: the number of times shocked, recent medical procedures, recent changes in medical condition or changes in patient adherence to the medication regimen, presence of a coexisting pacemaker, patient’s activity at the time of shock, and proximity to water or an electrical source.
- If a patient with an ICD experiences multiple inappropriate defibrillator discharges as the result of defibrillator malfunction, the ICD can be temporarily disabled by use of a magnet, which will prevent further discharges.
- In case of cardiac arrest, a CCTP can deliver external defibrillation to a patient with an ICD, although the paddles or

pads should not be placed directly over this device. Providers can also perform CPR on a patient with an ICD.

- Significant risks associated with atrial fibrillation are thromboembolism and the resulting increased incidence of stroke. Methods to convert atrial fibrillation include antiarrhythmic medications, external cardioversion, and (the preferred method) internal cardioversion and/or antitachycardia pacing with an atrial ICD.
- Candidates for short-term use of wearable cardioverter-defibrillators include patients at high risk for sudden cardiac death and those who require explant of an infected ICD. These vest-like devices notify patients of treatable arrhythmias and perform defibrillation automatically if the patient does not respond.
- In 2015, a subcutaneous implantable cardioverter-defibrillator (S-ICD) was approved for use in the United States. This device does not require any venous leads or wires, so it is associated with less risk of infection compared to a traditional ICD.
- CCTPs should expect to transport patients who have or need a pacemaker or ICD, and should be prepared to manage any adverse situations related to either device. They should receive training on any transthoracic or epicardial, transcutaneous, or transvenous pacemaker device that their agencies use, and should be prepared to use a magnet to temporarily reprogram an implanted pacemaker or ICD if their agencies transport critically ill cardiac patients.
- When accepting a patient from a sending hospital for CCT, the CCTP must assess and confirm electrical and mechanical pacemaker capture for any patient with a transthoracic or epicardial, transvenous, transcutaneous, implanted, or leadless pacemaker device.
- Switching from the device used in the sending facility to the device used by the transport team is often a source of anxiety for CCTPs and other providers. If a compatible device is not available to the transport team, it may be worth considering using the device from

the sending facility for the transport and returning it promptly after the transport has been completed.

- The presence of an ICD may require use of an alternative site (not over the device) for transcutaneous pacing or defibrillation if either of those measures is needed during transport. It is essential to have an external cardioverter-defibrillator immediately available when transporting a patient with an ICD.
- Electromagnetic interference is the major cause of pacemaker dysfunction, particularly in older-style pacemakers lacking adequate internal shielding; they may be vulnerable to interference from headsets and intercom systems in air transport.
- Rate-adaptive pacemakers appear to be sensitive to helicopter vibrations. CCTPs working on medical helicopters should be aware of this potential and be prepared to intervene if necessary.

Vital Vocabulary

ablation Removal of a pathway or function by electrocautery or radiofrequency.

absolute refractory period The early phase of cardiac repolarization, wherein the heart muscle cannot be stimulated to depolarize.

acute coronary syndrome (ACS) Any group of clinical symptoms consistent with acute myocardial ischemia.

anode The electrode in a pacing circuit that is positively charged when current is flowing.

antegrade conduction Conduction in the normal direction between cardiac structures.

antiarrhythmic A medication used to treat and prevent cardiac rhythm disorders.

arterial bruits Turbulence or “swishing” sounds heard with a stethoscope placed over the carotid arteries that signal the presence of atherosclerosis.

bifascicular block The combination of a right bundle branch block and a block of one of the fascicles of the left bundle, the left anterior or left posterior fascicle.

biphasic A descriptor for a wave with negative and positive components; typically used in conjunction with P and T waves.

bipolar lead A conduction lead comprising two electrodes attached at specific body sites with different polarity, which is used to examine electrical activity by monitoring changes in the electrical potential between those sites.

bipolar system A closed system consisting of bipolar leads and a module to generate impulses and measure response.

bundle branch block (BBB) A disturbance in electric conduction through the right or left bundle branch from the bundle of His.

cable The physical wire that connects the electrode to the electrocardiography monitor.

cardiac monitoring The continuous observation of the patient’s condition in relation to the cardiac rhythm.

cardiomyopathy A general term for diseases in which the myocardium becomes thin, flabby, dilated, or enlarged, ultimately progressing to heart failure, acute myocardial infarction, or death.

cathode The electrode in a pacing circuit that is negatively charged when current is flowing.

chronotropic A medication that affects the rate of contraction of the heart.

claudication A severe pain in a muscle caused by narrowing of the arteries in that muscle and leading to ischemic pain with slight exertion such as that associated with walking.

current The movement of electrons through an electrical circuit over time, measured in amperes.

delta wave The slurring of the upstroke of the first part of the QRS complex that occurs in Wolff-Parkinson-White syndrome.

depolarization The process of discharging resting cardiac muscle fibers by an electrical impulse that causes them to contract.

dextrocardia A congenital cause of right axis deviation, in which the heart develops in a right-facing position, creating a mirror image of the normal left-facing heart.

digoxin A cardiac glycoside that produces positive inotropic and negative chronotropic activity in the heart and is primarily indicated in the treatment of chronic heart failure and to control the ventricular rate in atrial tachyarrhythmias.

discordant A descriptor for T waves that are in the opposite direction from the terminal portion of the QRS complex in bundle branch blocks.

dromotropic Affecting the velocity of conduction.

dual-chamber pacemaker An artificial pacemaker with two leads (one in the atrium and one in the ventricle) so electromechanical synchrony can be achieved.

ejection fraction The percentage of blood actually ejected from the ventricles.

electrical alternans An electrocardiogram pattern in which the QRS vector changes with each heartbeat. This pattern is pathognomonic of cardiac tamponade.

electrode In the context of a 12-lead electrocardiogram, an electrical sensor placed on the chest to record the bioelectrical activity of the heart. In the context of a pacemaker, a conductor in contact with cardiac tissue at the end of a pacing lead; it delivers impulses to that tissue.

electrophysiology The cardiac specialty that involves evaluation and management of rhythm disturbances.

endocardial (transvenous) leads Pacemaker leads guided by angiography and attached to the endocardium.

epicardial leads Pacemaker leads attached to the epicardium (outer surface of the myocardium); placement and troubleshooting of these leads are done in the hospital and require surgery and anesthesia.

heart failure (HF) A decline in the ability of the heart, for any reason, to pump powerfully enough or fast enough to empty its chambers; as a result, blood backs up into the systemic circuit, the pulmonary circuit, or both.

hemiblock Blocking of one of the fascicles of the left bundle branch, the left anterior or left posterior fascicle.

hexaxial system The system developed to describe the coronal plane that is created by the limb leads (I, II, III, aVR, aVL, and aVF).

hypercalcemia An increased level of calcium in the blood.

hyperkalemia An increased level of potassium in the blood.

hypertrophy An increase in the size of the cells as the result of synthesis of more subcellular components, leading to an increase in tissue and organ size.

hypocalcemia A low level of calcium in the blood.

hypokalemia A low level of potassium in the blood.

impedance Resistance to the flow of current along an electrical pathway, measured in ohms.

implantable cardioverter-defibrillator (ICD) A small, battery-powered electrical impulse generator that is implanted in patients at risk for sudden cardiac death as the result of ventricular fibrillation or pulseless ventricular tachycardia.

implantable pulse generator (IPG) The largest implanted element in a pacemaking system, containing the battery and control circuitry.

inotropic An effect on the contractility of muscle tissue, especially cardiac muscle.

intra-atrial conduction delay (IACD) Delayed conduction within one of the atria, often associated with left or right atrial enlargement.

intra-atrial pathways The anterior or Bachman bundle, middle bundle, and posterior internodal system, through which the electrical impulse passes after the sinoatrial node; represented by the P wave on the electrocardiogram. Also called intranodal pathways.

isoelectric When referring to a wave, the status of the wave as neither positive nor negative.

joule A unit of measurement for energy.

lead In the context of the 12-lead electrocardiogram, the designated position of the electrode, or the name of the electrode placement. In the context of a pacemaker, an insulated wire that carries signals in a pacemaking system between the implantable pulse generator and the heart tissue.

left anterior fascicle The portion of the electrical conduction system responsible for innervating the anterior and superior areas of the left ventricle. It is a single-stranded cord terminating in the Purkinje cells.

left posterior fascicle The portion of the electrical conduction system responsible for innervating the posterior and inferior areas of the left ventricle. It is a widely distributed, fanlike structure terminating in the Purkinje cells.

limb leads The electrocardiography lead electrodes attached to the limbs that form the hexaxial system, dividing the heart along a coronal plane into the anterior and posterior segments.

long QT syndrome (LQTS) A prolonged QT interval on the electrocardiogram that is primarily caused by a congenital disorder. Under certain conditions, it tends to deteriorate into ventricular tachyarrhythmias and can lead to syncope or sudden cardiac death; the patient loses consciousness, often without warning.

mean electrical axis The sum of all electrical impulses.

NBG codes North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group Generic codes; five-letter codes used to categorize pacemakers by their functions and capabilities, developed by a joint effort of North American and British electrophysiology groups.

Ohm's law The principle given by the equation $V = IR$, which states that applied voltage is equal to the current times the resistance of the circuit.

pacemaker syndrome The occurrence of symptoms relating to the loss of atrioventricular synchrony in ventricularly paced hearts or symptoms caused by inadequate timing and ventricular contractions in paced hearts.

pacing circuit The conduction pathway along which the pacing impulse flows; formed by a power source, one or two lead–electrode pairs, and body tissue.

pacing impulse The electrical impulse sent to the heart to stimulate the heart to beat.

paroxysmal nocturnal dyspnea Severe shortness of breath occurring at night after several hours of recumbency, during which fluid pools in the lungs; the person is forced to sit up to breathe. It is caused by left-side heart failure or decompensation of chronic obstructive pulmonary disease.

paroxysmal supraventricular tachycardia A supraventricular tachycardia that starts and ends abruptly.

pericarditis An inflammatory process involving the pericardium.

phlebitis Inflammation, swelling, and pain along the veins that can lead to the formation of blood clots and thrombophlebitis (venous inflammation associated with a thrombus).

P mitrale A double-humped, M-shaped P wave that is 120 ms wide or greater, with the tops of the humps 40 ms apart or greater. Found in limb leads I, II, and III, it represents left atrial enlargement.

poor R-wave progression An abnormal R-wave pattern; one of the factors that may signify anterior infarction.

P pulmonale A tall P wave that is 2.5 mm high or greater. Found in leads II and III, it indicates right atrial enlargement.

precordial leads The chest leads in an electrocardiogram.

PR interval The interval of time that occupies the space between the beginning of the P wave and the beginning of the QRS complex.

QRS complex Deflections in the electrocardiogram produced by ventricular depolarization.

reciprocal changes An electrocardiogram pattern in which a lead shows a pattern that is the opposite of the one shown in the lead located 180° from the other; for example, the electrode over the area of infarction records ST-segment elevation, whereas the electrode over the lead that is 180° away records ST-segment depression.

refractory period A short period immediately after depolarization in which the myocytes are not yet repolarized and are unable to fire or conduct an impulse.

relative refractory period The period in the cell-firing cycle during which it is possible but difficult to restimulate the cell to fire another impulse.

repolarization A state in which the cell becomes more negative, moving away from equilibrium with the extracellular fluid; it is an active process.

single-chamber demand pacemaker A pacemaker with the pacing lead placed in only one chamber of the heart, in which the generator stimulus is inhibited by a signal derived from the heart's depolarization, thus minimizing the risk of pacemaker-induced fibrillation.

strain pattern An electrocardiogram pattern that involves ST-segment changes and flipped, asymmetric T waves associated with right or left ventricular hypertrophy.

ST segment The section of the electrocardiogram complex from the end of the QRS complex to the beginning of the T wave, which represents the period of inactivity between ventricular depolarization and repolarization; mechanically, it represents the time that the myocardium is maintaining contraction.

ST-segment elevation myocardial infarction (STEMI) A myocardial infarction that shows ST-segment elevation on the electrocardiogram; patients with STEMI have a high probability of coronary thrombus occlusion.

thrombus A blood clot.

torsades de pointes An undulating sinusoidal rhythm in which the axis of the QRS complexes changes from positive to negative and back in a haphazard manner.

trifascicular block The combination of bifascicular block (a right bundle branch block with a block in the left anterior fascicle or left posterior fascicle) that occurs with a first-degree heart block (prolonged PR interval).

T wave The upright, flat, or inverted wave following the QRS complex of the electrocardiogram, representing ventricular repolarization.

unipolar lead A lead in which one of the electrodes is placed in the heart and the other lead is placed in an area of zero potential.

unipolar system A type of pacemaker system in which contact between the pacemaker itself and the body tissue forms the ground lead for the implantable pulse generator.

voltage The force that causes current to flow in a circuit, measured in volts; also called *amplitude* in a pacing system.

wide complex tachycardia A cardiac rhythm of greater than 100 beats/min with a QRS duration of 120 ms or greater; it can be of ventricular or supraventricular origin.

Wolff-Parkinson-White (WPW) syndrome A syndrome characterized by short PR intervals, delta waves, nonspecific ST-T wave changes, and paroxysmal episodes of tachycardia caused by the presence of an accessory pathway.

CHAPTER 15

Hemodynamic Monitoring

Mike McEvoy, PhD, NRP, RN, CCRN

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe cardiovascular anatomy and physiology, including the phases of the cardiac cycle (pp 784–787).
2. Discuss the principles of and indications for invasive hemodynamic monitoring (p 786).
3. Interpret hemodynamic values (p 788).
4. Discuss the indications, contraindications, and complications for arterial lines (pp 795–796).
5. Discuss indications, contraindications, and complications for central venous lines (pp 804–805).
6. Describe the significance of each pressure reading used in patient care (pp 801, 813).
7. Describe general transport considerations and troubleshooting procedures for common problems with invasive lines and hemodynamic monitoring devices during transport (p 812).
8. Discuss flight considerations related to invasive hemodynamic monitoring (p 828).

Introduction

The fundamental role of critical care, in terms of hemodynamic monitoring, is correction of perfusion deficits. The evolution of intensive care units (ICUs) began some 50 years ago to provide the specialized monitoring, personnel, and sophisticated treatments needed to monitor and correct perfusion deficits resulting from illness and injury. As the level of care across the spectrum of medicine advances, technologies that once required an ICU environment for their application have gradually become safer, more portable, less invasive, and more capable of being used for patient monitoring and treatment on medical–surgical wards, in transport vehicles, in long-term care facilities, and, in some cases, in patients' homes.

Accurate assessment of **perfusion**, or of the adequacy of the delivery of oxygen and nutrients to the tissues of the body, often eludes clinicians. Conventional physical assessment of vital signs, mentation, skin color, and urine output may provide clues about the presence of poor perfusion, but without the information obtained through more advanced technological monitoring, clinicians may be led to incorrectly believe that a patient has adequate perfusion.

Improved technology and better understanding of perfusion have shifted much of the focus of hemodynamic monitoring from central measurements to assessment of tissue-level circulation or **microcirculation**. The terminal end of vascular blood distribution consists of capillaries, arterioles, postcapillary venules, and subunits where oxygen is actually delivered to tissues. Measuring this microcirculation or its surrogates has become a primary focus of hemodynamic monitoring.

As monitoring technology evolves, lessons from the past 50 years have taught us that no single measurement on its own provides a complete hemodynamic picture of a critically ill patient. Additionally, critical care interventions must be personalized according to the individual's current needs. This type of responsive, personalized care necessitates use of multiple monitoring devices and dynamic variables sensitive to changes in the patient’s condition over time.

Cardiovascular Anatomy and Physiology

A solid understanding of the anatomy and physiology of the pulmonary and cardiovascular systems is important when using and interpreting hemodynamic monitoring equipment and cardiac-assist devices. By way of review, a normal human heart is the approximate size of an individual's clenched fist. It lies in the thoracic cavity beneath the sternum; approximately two-thirds of it is left of the midsternal line.

The **atrioventricular (AV) valves** (mitral and tricuspid) lie between the atria and the ventricles, and the **semilunar valves** (aortic and pulmonic) are the exits from the ventricles **FIGURE 15-1**. The AV valves have **chordae tendineae**, which attach the edge of the valve to the **papillary muscles**, which are themselves attached to the endocardium. The chordae tendineae hold the AV valves in place in the closed position and prevent them from prolapsing into the atria during systole, or ventricular contraction. In contrast, the semilunar valves do not have chordae tendineae but are attached to the respective vessels at the outer edges. The valve action depends on the valve leaflets (the thin, leaflike cusps or flaps that compose the valves) being pushed together by the force of the blood trying to flow back into the heart, which keeps them in a closed position, much like a parachute opening. The opening and closing of the semilunar valves is related to the pressure changes that occur in the heart, aorta, and pulmonary artery.

Description

The purpose of each of the cardiac valves is to prevent the backward flow of blood in the heart. If a valve is structurally defective, then a backward flow of blood through the valve is referred to as valvular regurgitation or insufficiency. A valve scarred so severely that its lumen is reduced while in the open position is referred to as stenotic.

The coronary arteries supply the heart muscle with oxygen. The ostia (openings) to the coronary arteries are located at the base of the aorta, just caudal to the attachment points of the aortic valve leaflets **FIGURE 15-2**. This anatomy is extremely important because the location means the ostia are obstructed when the aortic valve is in the open position. Therefore, although this is the time that the heart is ejecting blood, almost none of it can get into the coronary arteries. In addition, because the coronary arteries are embedded in the myocardium, resistance in these blood vessels increases greatly during systole. As a result of these two factors, almost all coronary perfusion occurs during diastole.

Description Description

Blood returns to the heart through the inferior and superior venae cavae, mixing in the right atrium (RA) before passing through the tricuspid valve into the right ventricle. The tricuspid valve is particularly susceptible to infection from foreign material or organisms introduced into the bloodstream (eg, from intravenous [IV] drug abuse or line sepsis). From the right ventricle, blood travels via an outflow tract through the pulmonic valve and pulmonary arteries into the lungs. Despite their name (ie, “arteries”), the pulmonary arteries actually carry the most deoxygenated blood found in the body **FIGURE 15-3**. Measurement of oxygen saturations in a pulmonary artery is valuable, when compared to arterial oxygen saturation, in assessing perfusion. Maximally oxygenated blood returns from the lungs to the left atrium (LA) and passes through the mitral valve en route to the left ventricle (LV). From the LV, blood exits an outflow tract leading to the aortic valve and then enters the central circulation.

Description

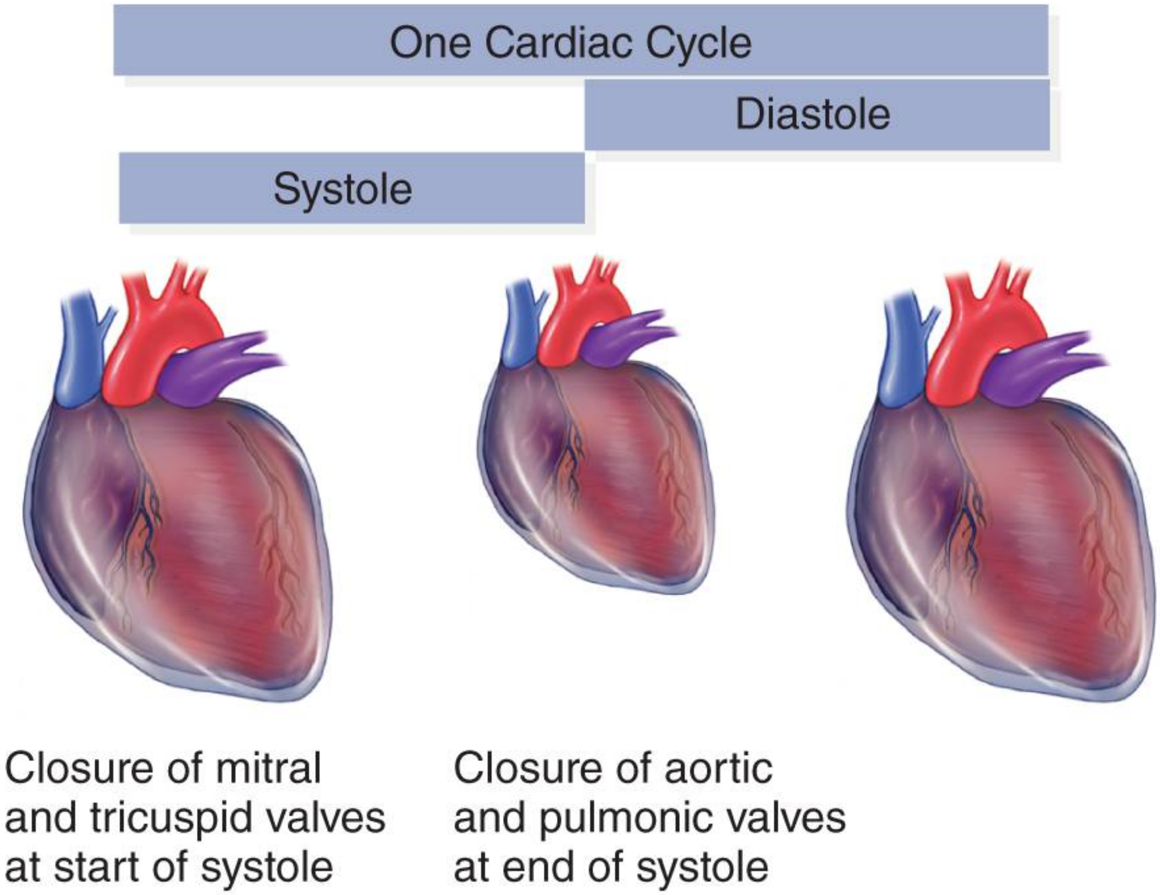
The anatomy of the myocardium is often incorrectly illustrated. Quite obviously, the heart is a biventricular system with much lower pressures on the right side than on the left side. Perfusing the brain and splanchnic organs necessitates the creation of higher pressures than are needed to deliver blood a few inches from the heart to the lungs. Hence, the LV is a more muscular chamber than the right ventricle, generating significantly higher pressures. Were those same pressures delivered to the lungs, significant congestion would develop, rapidly resulting in pulmonary edema.

Despite the differences in ventricular muscle mass and pressure between the right and left sides of the heart, there is ordinarily little difference in the cardiac output between the two sides. Indeed, any significant difference for a prolonged period would be incompatible with life, because the backup of blood on the side with the lower output would most certainly be fatal. **Invasive hemodynamic monitoring** often takes advantage of the lower pressures found in the right heart by placing catheters in this low-pressure system. Measurements of cardiac output on the right side of the heart are generally considered equivalent to those on the left side, whereas direct measurements on the left side of the heart are difficult to obtain because of the higher pressures and increased risks of bleeding.

Another significant consideration when using hemodynamic monitoring equipment is coronary perfusion. Most people have two coronary arteries: a right coronary artery (RCA) and a left main coronary artery (LMCA). The LMCA quickly divides into the left anterior descending artery and the circumflex, which together supply most of the LV. The RCA supplies much of the right ventricle and, in most people, also feeds the ventricular septum, including the cardiac conduction system. An assessment of blood pressure (BP) or flow through the coronaries would reveal that the heart receives its blood supply during diastole. Hence, an adequate diastolic BP (DBP) is critical to maintain coronary perfusion. The anatomic positioning of the myocardium in the thoracic cavity, where the right ventricle is the predominant anterior (forward-facing) feature, suggests that chest wall injuries should be monitored for arrhythmias when suspicion of myocardial contusion is present. The role of the RCA in supplying the conduction system also suggests that patients with significant arrhythmias should undergo cardiac catheterization to check the patency of their RCAs.

Cardiac Cycle

The cardiac cycle consists of two main stages: **systole**, the contraction phase of the heart cycle (ie, the period of work), and **diastole**, the relaxation phase of the heart cycle (ie, the period of rest). Systole and diastole can be further divided into five phases: atrial systole, isovolumetric contraction, ventricular ejection, isovolumetric relaxation, and ventricular filling **FIGURE 15-4**.



One Cardiac Cycle
Diastole
Systole
Closure of mitral and tricuspid valves at start of systole
Closure of aortic and pulmonic valves at end of systole

FIGURE 15-4 Systole and diastole.

Description

Atrial Systole

Atrial systole begins in response to an electrical impulse from the sinoatrial (SA) node, indicated as the P wave on an electrocardiogram (ECG). As the electrical impulse is conducted through the atrial myocardium and internodal pathways, the atrium depolarizes and contracts. The mitral and tricuspid valves are open before atrial systole, with blood already flowing passively from the atria into the ventricles. The contraction of the atria ejects additional blood into the ventricles and accounts for 20% to 30% of the ventricular filling volume (preload). This “atrial kick” raises the ventricular volume and pressure and is important to the effective contraction of the ventricle because of the relationship between the stretching of the myocardium and the force of contraction of the ventricles, known as the Frank–Starling curve or Frank–Starling law (discussed later in this chapter).

Isovolumetric Contraction

During **isovolumetric contraction**, the electrical impulse from the atria moves through the AV node to the ventricular conduction system, causing the ventricles to depolarize and contract. Immediately after ventricular contraction begins, ventricular pressure rises abruptly, closing the AV valves. The volume of blood in the ventricles just before these valves close is the ventricular **preload**. Ventricular preload is important to cardiac function because of the relationship between ventricular preload and contractility (Frank–Starling curve).

During isovolumetric contraction, the pressure in the aorta and pulmonary arteries is higher than the pressure in the ventricles and, therefore, the semilunar valves remain closed. The pressure in the ventricles continues to rise during ventricular contraction but, because all of the cardiac valves are closed, no change in ventricular blood volume occurs. (*Isovolumetric* means “same volume.”)

Ventricular Systole

Once the pressure in the pulmonary artery is equaled by the pressure in the right ventricle, the pulmonary valve opens and the right ventricle begins to eject blood into the pulmonary artery. The pulmonary valve opens slightly before the aortic valve because the pressure gradient is less for the pulmonary circulation. As the pressure in the LV exceeds the pressure in the aortic root (the section of the base of the aorta that is attached to the heart, including the leaflets of the aortic valve and the openings where the coronary arteries attach), the valve leaflets open and allow the LV to eject the blood into the aorta. During ventricular ejection, the aortic valve leaflets are forced against the wall of the aorta (the open position). No coronary perfusion occurs at this stage because when the aortic valve leaflets are open, they block the coronary arteries.

Isovolumetric Relaxation

Near the end of ventricular ejection, the ventricles begin to relax as the ventricular tissue starts to repolarize. The pressure in the ventricles then drops below the arterial pressure, and the semilunar (aortic and pulmonary) valves close as the blood attempts to flow backward into the heart. During this **isovolumetric relaxation** phase, the AV valves have not yet opened. Continued ventricular relaxation leads to the decrease in ventricular pressure that will soon allow the AV valves to open as atrial pressure increases.

Ventricular Filling

When the pressure in the ventricles drops below the pressure in the atria, the mitral and tricuspid valves open and ventricular filling begins. Blood flows passively from the atria through the AV valves into the ventricles. When the SA node produces an electrical impulse that initiates atrial systole, the cardiac cycle begins again.

The five phases of the cardiac cycle are summarized in **TABLE 15-1**.

TABLE 15-1 Summary of the Cardiac Cycle

Phase	Events
Atrial systole	The SA node gives impulse. Atrium depolarizes. Atria contract, forcing blood into ventricles. Ventricular volume and pressure are increasing.
Isovolumetric contraction	Impulse travels through the AV node. Ventricles depolarize. Mitral and tricuspid valves close. Ventricular pressure rises abruptly.
Ventricular ejection (systole)	Pressure in the pulmonary artery equals pressure in the right ventricle. Pulmonary valve opens; right ventricle ejects. Pressure in the LV exceeds pressure in the aortic root. Aortic valve opens; LV ejects blood.
Isovolumetric relaxation	Ventricles relax and repolarize. Pressure in ventricles drops to less than arterial pressure. Aortic and pulmonary valves close owing to blood attempting to flow backward.
Ventricular filling (diastole)	Ventricular pressure drops below pressure in the atria. Mitral and tricuspid valves open. Blood flows through the atria and into the ventricles. Cardiac cycle begins again.

Abbreviations: AV, atrioventricular; LV, left ventricle; SA, sinoatrial

Cardiac Output

Cardiac output (CO) is the amount of blood the heart ejects each minute, usually expressed in liters per minute. Normal CO in a healthy adult is in the range of 4 to 8 L/min. Healthy adults can readily increase their CO to more than 20 L/min when needed to meet intense physical demands. The CO is the product of **stroke volume (SV)** and heart rate (CO = SV × Heart rate). The SV, or amount of blood ejected with each ventricular contraction, is determined by the preload, afterload, and contractility of the heart. Normal SV in adults is 60 to 100 mL. Because SV results from three combined influences, heart rate has a far greater contribution and more immediate effect on CO than does any one component of SV. When confronted with a low CO, the critical care transport professional (CCTP) should investigate the patient's heart rate before evaluating the constituents of SV.

To account for differences in body size, some hemodynamic values are indexed. Indexing divides a hemodynamic parameter by the patient's total body surface area (TBSA), which is stated in terms of meters squared. The TBSA can be derived from a paper-and-pencil chart, but is most commonly calculated by hemodynamic monitoring software after the clinician enters the patient's height and weight values. For example, a **cardiac index (CI)** (average = 2.5 to 4.2 L/min/m^2) is the patient's CO divided by TBSA:

$$\text{Cardiac Index (CI)} = \frac{\text{CO}}{\text{TBSA}}$$

A CO of 4.5 L/min may be perfectly adequate for a 17-year-old, 100-pound (45-kg) female involved in a multivehicle collision, but not for a 21-year-old, 325-pound (147 kg) male athlete who crashed his motorcycle. The indexing of various hemodynamic parameters is often applied to ventricular work values, SVs, and calculations of oxygen consumption.

The formula most commonly used to calculate TBSA is the Dubois formula:

$$\text{TBSA (m}^2\text{)} = \text{height (cm)}^{0.725} \times \text{weight (kg)}^{0.425} \times 0.007184$$

Of particular concern to clinicians is the potential for error if the patient's height or weight is entered incorrectly into the software being used to perform hemodynamic calculations. Familiarity with typical TBSAs and normal CO ranges can aid in recognizing incorrectly entered values. Although the CI helps to interpret CO values for patients of various sizes, it should not be viewed in isolation; that is, CO should always be considered as well.

Heart Rate

The fastest means of increasing a patient’s CO is to increase the heart rate. Within seconds, raising the heart rate can double or even triple CO in a healthy patient’s system. Nevertheless, there are limits to improvements in CO driven by an increased heart rate. Rapid rates shorten ventricular filling time and, at certain thresholds that vary among patients, can significantly reduce CO.

Heart Rate Thresholds

Although formulas that utilize far-below-maximum heart rates are often used to determine exercise limits in healthy adults, the medicolegal ceiling for an acceptable heart rate in adult patients is 120 beats/min. The CCTP should endeavor to determine the cause of a sustained rate exceeding 120 beats/min in adult patients. Faster heart rates can also increase myocardial muscle oxygen consumption, adversely affecting CO. Additionally, the shortening of the diastolic period seen as the heart rate increases may decrease coronary perfusion, also leading to lower CO.

Conversely, lowered heart rates lead to increased ventricular filling time and prolonged diastolic intervals, which may then increase preload and improve coronary blood flow, with both of these effects resulting in increased CO. At heart rates of less than 50 beats/min, hemodynamic improvements are offset by decreased CO. Although some patients may tolerate heart rates in the high 40s, 50 beats/min is generally considered the lower threshold for heart rate in adults.

Heart Rate Regulation

Heart rate is regulated in three ways: by the autonomic nervous system, by receptors, and through metabolic demands.

The autonomic nervous system is divided into the sympathetic and parasympathetic branches. The sympathetic nervous system increases heart rate and contractility primarily through the release of norepinephrine, whereas the parasympathetic nervous system lowers heart rate and decreases contractility by releasing acetylcholine.

Many receptors in the body influence heart rate, the strongest of which are the baroreceptors located in the carotid bodies and the aortic arch. Baroreceptors sense pressure and, in response to decreases in BP, will stimulate an increased heart rate. In contrast, the detection of increased BP causes the baroreceptors to decrease heart rate. Historically, the baroreceptors in the carotid sinuses were used to slow supraventricular tachyarrhythmias through carotid sinus massage. This practice was abandoned in adults because it sometimes dislodged plaque deposits, which led to strokes.

Chemoreceptors play less of a role than baroreceptors but nonetheless influence heart rate in response to changes in pH and oxygen saturation. In the presence of lower pH or lowered oxygen saturations, chemoreceptors increase heart rate. When pH or oxygen saturation increases, receptors respond by lowering heart rate. Understanding this interaction can be helpful in many clinical situations. Supplemental oxygen administration, for example, may help to lower rapid heart rates while more definitive treatments are prepared.

Certain metabolic changes may also lead to increased heart rates, including fever, pain, hyperthyroidism, and exercise. Conversely, lower heart rates often result from hypothermia, analgesia or sedation, hypothyroidism, and athletic conditioning. Treatment of tachycardias and bradycardias must take these potential underlying causes into consideration; otherwise, it is likely to be ineffective.

Measurement of Heart Rate

Heart rate is a key sign of hemodynamic instability in emergency and critical care patients. Assessment of the pulse can be performed by arterial palpation; however, in the high-noise environment of an ICU or a critical care transport (CCT) vehicle, the heart rate obtained from a pulse oximeter is more reliable than manual assessment. Correlation with an ECG display or pulse oximetry plethysmographic (pleth) waveform provides additional reassurance.

Preload

Preload is the degree of myocardial fiber stretch induced by the volume in the ventricle at the end of diastole. Preload is synonymous with end-diastolic volume (EDV) and end-diastolic pressure (EDP).

Factors Affecting Preload

The three determinants of preload are total blood volume, blood volume distribution, and atrioventricular synchrony.

The relationship between preload and total blood volume is straightforward. Preload declines in patients experiencing hemorrhage and profound fluid loss from dehydration, vomiting, gastric suction, diaphoresis, diarrhea, or massive fluid shifts leading to third-space losses. Preload increases in patients in hypervolemic states such as fluid overload, renal failure, and significantly increased venous return.

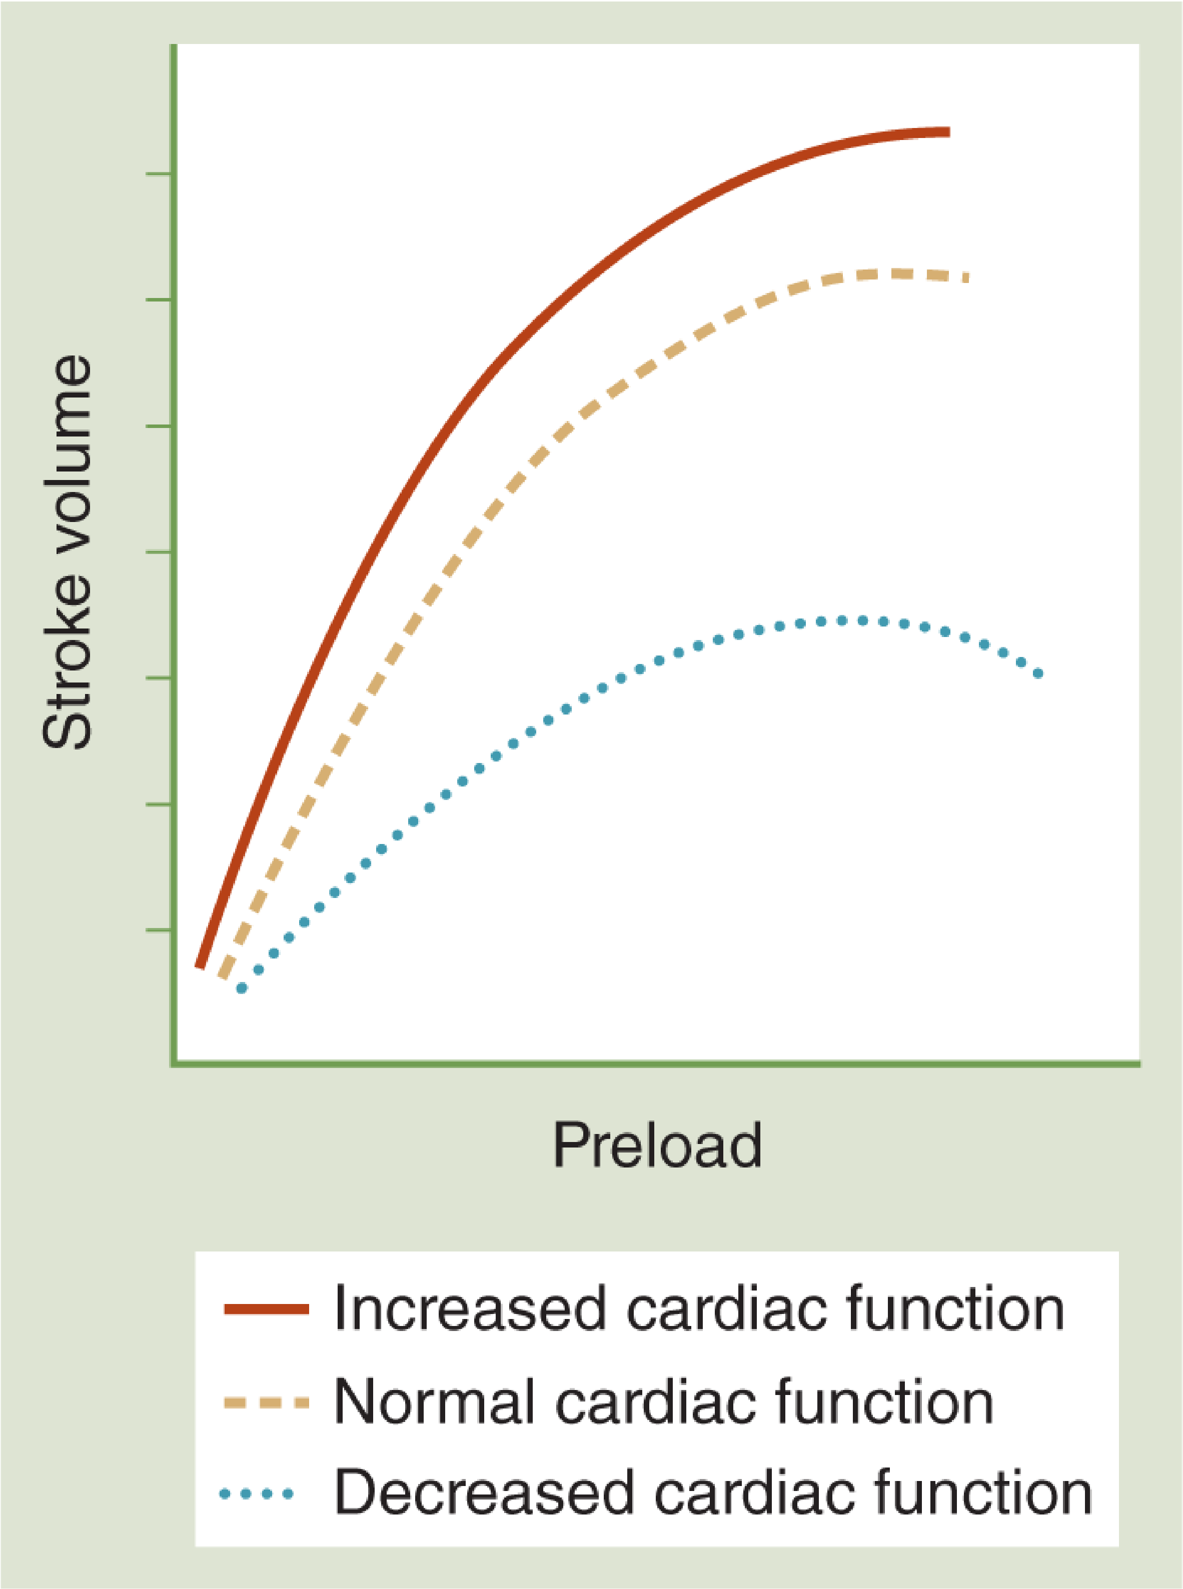
Blood volume distribution is more challenging to understand and to measure. Changes in venous tone (dilation and constriction) can result from physiologic attempts to compensate for changes in total blood volume, from administration of vasoactive medications (vasodilators or vasopressors), and from environmental or metabolic influences (eg, hypothermia, fever, or exercise). These changes affect preload by altering the size of the body's "tank." When the tank's capacity is greater or less than the total volume of blood in the system, preload will increase or decline.

One significant factor affecting blood volume distribution is changes in intrathoracic pressure. The two most significant influences on venous return to the right side of the heart are respirations and skeletal muscle activity. Continued skeletal muscle movements from physical activity and breathing serve to generate some forward flow of blood through the venous system toward the right heart. Changes in intrathoracic pressure from respirations generate a pressure differential that facilitates venous blood return to the heart. The importance of intrathoracic pressure differences in venous return should not be overlooked when assessing preload. When mechanical ventilation is employed, for example, this intervention leads to changes in intrathoracic pressure. Positive-pressure ventilation and use of positive end-expiratory pressure (PEEP) can significantly decrease preload and often require volume expansion to restore a normal preload state. Intrapericardial pressure changes resulting from cardiac tamponade, pericarditis, or pericardial effusions can also decrease preload. In these circumstances, the additional pressure being applied on the heart can dramatically decrease preload. Significant volume administration can be a lifesaving intervention by maintaining adequate preload while the patient is awaiting definitive care.

AV synchrony is variously reported to contribute to 10% to 20% of CO. Although this relationship is not well studied, the mechanism by which a well-synchronized atrial–ventricular contraction facilitates CO is preload. The ejection of a small bolus of blood from the atria into the ventricles moments before ventricular contraction provides a slight increase in ventricular volume, which then leads to an increase in ventricular SV. Maintaining AV synchrony in patients with advanced heart failure has been shown to extend their lives. Hence, medications and devices that keep these patients in sinus rhythm and ensure optimal AV contraction are key elements in the treatment of heart failure.

Frank–Starling Law

The **Frank–Starling law** is often referenced when assessing patients' fluid volume status. The premise of the Frank–Starling law, also referred to as the Starling curve **FIGURE 15-5**, is that SV (and hence CO) increases as the volume of blood filling the heart increases until a certain point, at which output declines as volume continues to increase.



Stroke volume
Preload
Increased cardiac function
Normal cardiac function
Decreased cardiac function

FIGURE 15-5 Frank–Starling law: the relationship between cardiac output (stroke volume) and preload.

© Jones & Bartlett Learning.

Description

As the ventricular preload increases, the force of contraction of the myocardium also increases, as a result of the increased stretch of the myocardial fibers. This relationship between increasing contraction and increasing stretching of the myocardium immediately before systole continues until a point is reached at which the force of contraction actually begins to fall off, with subsequent detrimental increases in preload. The Frank–Starling law describes how judicious administration of fluids results in improved CO up to a certain point, which varies between individual patients. Additional fluids given beyond the preload at which optimal CO is achieved result in worsened CO; such a patient is said to have "fallen off the end of the Starling curve."

The fundamental principle of the Frank–Starling law is often lost with use of static measurements of preload. The most important takeaway message from its application is that every patient has a preload point at which their CO is optimal. Should the patient's preload be less or greater than optimal, the CO will decline.

Measurement of Preload

Preload has conventionally been measured in several ways. Right ventricular preload is measured by central venous pressure (CVP), which closely matches RA pressure. LV preload is measured by pulmonary capillary wedge pressure (PCWP) or, in some patients, by pulmonary artery diastolic pressure. During cardiac operations, a left atrial pressure monitoring catheter is sometimes placed to continually monitor LV preload. In the past, the PCWP was considered the gold standard for LV preload measurement, with the definition of decompensated LV failure (heart failure) being a PCWP greater than 18 mm Hg. Today, critical care practitioners recognize that CVP and PCWP are static pressure measurements, which are significantly influenced by both vasodilation and constriction. As such, they tend to reflect circulating blood volume relatively poorly.

CONTROVERSIES

Conventional assessment of preload using static pressures measured in millimeters of mercury (mm Hg) is now known to be an extremely inexact reflection of right or left ventricular volume. Historically, it was believed that a linear relationship existed between right or left heart pressures and volume. More recently, it has become understood that changes in intrathoracic pressure from respirations and PEEP significantly influence venous return and preload. Today, as a more accurate means of measuring ventricular volume is sought, there is a deliberate shift toward use of dynamic parameters that account for the fluctuations in pressures resulting from respirations and PEEP. An example of this trend can be seen in the International Guidelines of the Surviving Sepsis Campaign, which previously recommended using CVP as a fluid resuscitation parameter, but now call for use of dynamic parameters.

Preload is increasingly being evaluated using dynamic parameters such as pulse pressure variation (PPV) **FIGURE 15-6**, stroke volume variation (SVV), and pleth variability index (PVI); all of these are proprietary algorithms that use either arterial pressure waveforms or pulse oximeter pleth waveforms to determine the percentage of change in SV resulting from respirations. The underlying premise of these dynamic parameters, which are measured over the course of a complete respiratory cycle, is that variations in blood pressure between inspiration and expiration reflect fluid volume status and fluid volume responsiveness. Normally, systolic BP (SBP) will decrease between 5 and 10 mm Hg during inspiration. Decreases exceeding 10 mm Hg are referred to as **pulsus paradoxus** and suggest the presence of significant hypovolemia or cardiac tamponade. Dynamic measurements calculate the percentage of change in either SBP using an arterial pressure waveform or the height of a pulse oximeter pleth waveform, with this percentage of change being displayed on a monitor.

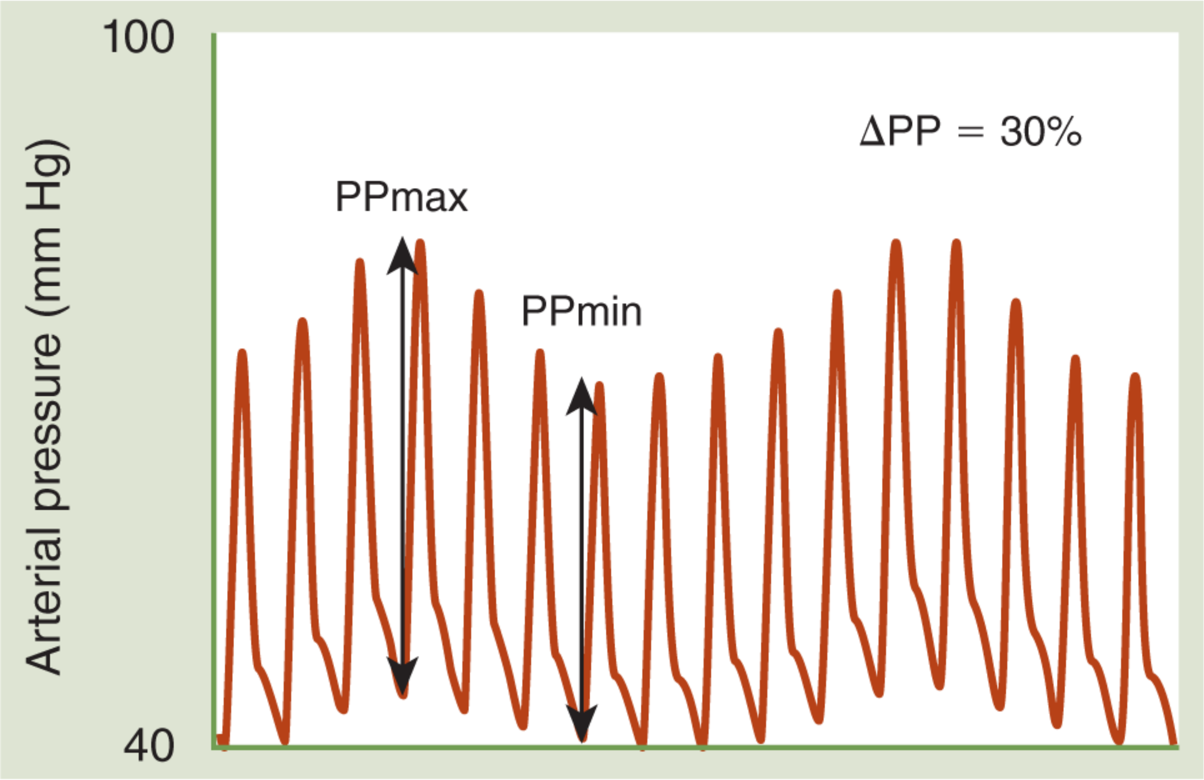


FIGURE 15-6 Respiratory changes in arterial pressure in a mechanically ventilated patient. The pulse pressure (PP; systolic minus diastolic pressure) is minimal (PPmin) three heart beats after its maximal value (PPmax). The respiratory changes in pulse pressure (ΔPP) can be calculated as the difference between PPmax and PPmin, divided by the mean of the two values, and expressed as a percentage: ΔPP (%) = 100 × (PPmax – PPmin)/([PPmax + PPmin]/2). In this case, the high value of ΔPP (30%) suggests that the patient would be potentially responsive to volume resuscitation.

Reproduced with permission from Lamia B, Chemla D, Richard C, et al. Clinical review: interpretation of arterial pressure wave in shock states. *Crit Care.* 2005;9:601. doi: 10.1186/cc3891.

Description

Early studies of volume expansion in patients with sepsis demonstrated that a PPV of 13% or greater was associated with a positive response to a fluid challenge, whereas a PPV of less than 13% was associated with no improvement in CO when fluids were given. More recent studies of PPV, SVV, and PVI have arrived at various values, ranging between 13% for PPV and 15% for SVV and

PVI, that can distinguish those patients with adequate preload or who will not respond to fluids from those patients with low preload who will be responsive to fluids. The mnemonic “high is dry” has been used to reflect the interpretation of these dynamic preload parameters.

One reason for caution in using PPV, SVV, and PVI as means to assess preload is that the majority of published evidence has evaluated their effectiveness in mechanically ventilated patients who are not overbreathing. Although data from spontaneously breathing patients suggest that these dynamic parameters have equal efficacy in this population, further studies are needed to confirm this finding.

A more simplistic and readily available test for fluid responsiveness is the passive leg raise (PLR). Passive leg raising evaluates the real-time effects of shifting a small amount (150 to 300 mL) of venous blood from the legs into circulating volume. To properly conduct a PLR test, the patient should initially be supine with the head elevated at a 45° angle. The head is then lowered to a flat position and the legs are elevated at a 45° angle. A response observed within 1 minute suggests that the patient is fluid responsive. PLR can also be used to confirm the reliability of PPV, SVV, and PVI measurements.

Many other variables can be observed to ascertain a response to fluid administration, including heart rate, BP, CO, and preload variables such as static or dynamic pressures.

Afterload

Afterload is the resistance the ventricles must overcome to eject blood. Afterload has an inverse relationship to ventricular function; that is, as afterload increases, ventricular function decreases. **Poiseuille’s law** is often used to explain the determinants of afterload. It is expressed by the following equation:

$$Q = \frac{\pi P r^4}{8 \eta l}$$

where

Q = Flow rate
P = Pressure
r = Radius
η = Fluid viscosity
l = Length of tubing

Poiseuille’s law states that flow varies directly with any increase in pressure. That is, as the radius (or diameter) of a tube increases, flow also increases to the fourth power of the increase in radius. When this concept is applied to IV fluid administration, it simply means that squeezing the IV bag or putting the bag into a pressure infuser will result in a faster flow. Using larger-diameter tubing or a large-size vascular access catheter, however, will increase the flow by a factor of four based on the increased-size catheter (a much greater increase than seen with pressure alone).

Poiseuille’s law also states that flow varies inversely with the length of the tubing or vessel and inversely with a coefficient of the viscosity of the fluid. When this concept is applied to the human body, it means that flow decreases as blood moves farther away from the heart (length) and as the hemoglobin level increases (viscosity). It is no wonder, then, that patients with polycythemia have decreased blood flow, whereas patients with anemia have increased CO.

Poiseuille’s law was developed based on the flow of fluid through a capillary tube. When evaluating afterload in the human body, however, pulsatile blood flow and the compliant vascular walls found in the blood vessels must also be taken into account. Early physiology textbooks were at a loss to explain timing differences between central and peripheral pulses, as it was believed that LV contraction was the force responsible for forward blood flow. With the advent of more sophisticated technologies for measuring physiologic parameters, such as magnetic resonance imaging, it is now understood that the LV ejects blood into the aorta, with the vascular compliance of the aorta and the expansion and contraction of subsequent vessels then helping to propel the blood forward throughout the body. As a result of this multistep process, a carotid pulse will be felt slightly earlier than a femoral or radial pulse. Patients with significant atherosclerotic disease, for instance, have a loss of elasticity of their blood vessels; as this disease process progresses, their blood flow can become significantly decreased. Conversely, vascular surgical procedures to improve blood flow in patients with significant peripheral vascular disease utilize the blood vessel radius part of Poiseuille's law to improve flow: Dilating a blood vessel or placing a stent to increase the radius of the blood vessel reduces afterload and improves blood flow.

Factors Affecting Afterload

Four factors typically determine afterload: outflow obstructions, vascular tone, blood viscosity, and ventricular dilation.

Outflow obstructions, such as aortic valvular stenosis, hypertension, and atherosclerosis, produce greater resistance and, therefore, increase afterload.

In terms of vascular tone, as is the case with preload, both vasoconstriction and vasodilation affect afterload: Vasodilation reduces afterload, and vasoconstriction increases afterload. Although vasodilation has many potential causes that can result in decreased afterload, including fever, exercise, and vasodilating drugs, only one shock state is associated with decreased afterload: distributive shock. This state can be an important finding when attempting to determine the cause of shock in a critically ill patient. Physiologically, it is important to understand the causes of afterload increases in the right heart versus those in the LV. Two conditions lead to pulmonary vasoconstriction, which then creates increased right ventricular afterload: hypoxia and hypercarbia. A newly observed increase in right heart afterload, then, should be attributed to one or the other of these conditions and interventions taken to address that imbalance (such as increasing the fraction of inspired oxygen [F_{IO_2}] level if hypoxia is suspected or increasing the minute volume if hypercarbia is suspected). Systemic vasoconstriction leading to increased LV afterload can result from hypothermia, administration of vasopressors, cardiogenic shock, or hypovolemic shock states.

Blood viscosity directly affects afterload. Increased afterload results from polycythemia, for example, because very viscous blood does not flow as readily as less viscous or very thin blood. This important concept explains why lowered hemoglobin levels are often tolerated and, in fact, sometimes considered beneficial in critically ill patients. Presuming that adequate hemoglobin is available to carry oxygen, values below those considered normal may well improve CO by decreasing afterload.

The relationship between ventricular dilation and afterload is a complex but important concept for the CCTP to understand. Without delving into the physics behind the interaction, suffice it to say that patients with dilated cardiomyopathies require a reasonable degree of afterload for LV ejection. Typically, heart failure is associated with elevated afterload. Indeed, almost all patients in cardiogenic shock exhibit extremely high afterload, usually requiring treatment to lower their vascular resistance. A significantly enlarged ventricle, however, has lost much of its ability to drive blood flow forward in conditions of very low resistance. This kind of disruption can occur in distributive shock states, with overzealous administration of vasodilators, or with large doses of sedatives, analgesics, or anesthetic agents.

Measurement of Afterload

LV afterload is measured by **systemic vascular resistance (SVR)**, and right ventricular afterload is measured by **pulmonary vascular resistance (PVR)**. In clinical practice, LV afterload is more often evaluated when addressing issues with CO because manipulations of SVR affect systemic circulation. Two instances when clinicians are interested in right ventricular afterload are when assessing a correlation between pulmonary artery diastolic pressure and PCWP, and when evaluating a patient for heart transplantation to determine if significant PVR is reversible. Patients with end-stage heart failure with elevated PVR that is not reversible will require heart and lung transplantation because a transplanted heart would fail in the face of significant right-side resistance.

Contractility

Contractility is defined as the inotropic state of the heart or the force with which the heart muscle contracts. Contractility is not directly measurable using conventional hemodynamic monitoring technology, but it can be assessed with the newer Doppler and ultrasonography devices that are increasingly being used to evaluate critically ill patients. Six factors influence contractility: myocardial muscle health, the autonomic nervous system, metabolic states, the ion environment, pharmacologic agents, and heart rate.

Myocardial muscle injury or ischemia can decrease contractility temporarily or permanently, although conditioning in a supervised cardiac rehabilitation program will normally improve contractility following injury. The parasympathetic and sympathetic arms of the autonomic nervous system responsible for increasing and decreasing heart rate simultaneously affect contractility. Metabolic states such as acidosis, hypoxemia, and sepsis decrease contractility.

Three ions have significant influence on contractility: calcium, sodium, and potassium. Hypocalcemia, hyponatremia, and hyperkalemia all decrease contractility, although the opposite changes in these ion levels do not seem to boost contractility above normal. In the critical care patient with suspected low CO, blood levels of ionized calcium are measured and treated as necessary with calcium replacement. Hyperkalemia has such a dramatic influence on contractility that IV potassium is used during cardiac operations to arrest cardiac motion after the patient is placed on cardiopulmonary bypass. This process allows the surgeon to sew grafts and valves. Potassium is also used in chemical executions to induce pulseless electrical activity.

Multiple pharmacologic agents influence myocardial contractility. Agents that increase contractility are referred to as positive inotropic agents; they include digoxin, dopamine, dobutamine, milrinone, calcium, epinephrine, and glucagon. Negative inotropic agents, or those that decrease contractility, include beta blockers, quinidine, procainamide, and calcium channel blockers.

Heart rate can influence contractility through its effect on diastolic filling time and coronary artery perfusion. Slower heart rates are associated with a longer diastolic time than are faster heart rates, allowing more time for coronary artery filling compared with very rapid heart rates. The shorter diastolic time seen with rapid heart rates may potentially diminish coronary artery perfusion and lower myocardial perfusion below the level needed for adequate contractility.

Contractility is inferred from the values for the **stroke volume index**, **left ventricular stroke work index**, and **right ventricular stroke work index**. When assessed using echocardiography, contractility is reported as the **ejection fraction**, representing the average percentage of blood ejected from the LV.

Blood Pressure

BP is one of the most often used, yet perhaps least understood assessments. Direct monitoring of BP is accomplished by the use of an arterial line. Indirect monitoring of BP is accomplished with a device that senses pulsatile flow, most commonly using a sphygmomanometer (BP cuff) to measure the systolic and diastolic pressures. **Systolic blood pressure (SBP)** is the measure of pressure on the arterial walls during systole, whereas **diastolic blood pressure (DBP)** is the measure of pressure on the walls of the arteries during diastole. The formula for BP is CO multiplied by SVR: BP = CO × SVR. Other methods that indirectly measure BP include assessment of pulses, electronic BP cuffs (also called noninvasive blood pressure [NIBP] units), and Doppler ultrasonography machines. It is extremely important to note that these indirect measurements assess flow, whereas direct monitoring devices (ie, arterial lines) measure pressure. Because pressure and flow are entirely different parameters, readings obtained by indirect and direct methods cannot be expected to correlate exactly.

Incorrect use of a monitoring device is the leading cause of erroneous measurements, whether the provider is using an indirect monitoring device such as a BP cuff or a direct monitoring device such as an arterial line or pulmonary artery catheter (PAC). The CCTP should be careful to avoid errors in measurement. BP cuff size and the position of the extremity during the measurement process are the two factors that most commonly contribute to inaccuracies.

The cuff bladder size should be matched to the size of the patient's extremity where BP is measured. Determining the bladder size is often difficult in the critical care setting; many practitioners instead choose a cuff that covers two-thirds of the extremity being measured. Using a cuff that is too large will result in readings that are lower than the actual pressures; a cuff that is too small will yield readings higher than the actual levels. The significant potential for error mandates that the transport unit carry various sizes of BP cuffs appropriate for the ages and sizes of the patient populations most commonly transported.

Depending on the patient's size and age, the CCTP may choose to measure BP in the lower arm, thigh, or leg. Regardless of the location used, an appropriate-size cuff should span two-thirds of the distance between the joints of the extremity where the cuff is applied. When using the lower arm, for example, the cuff should cover two-thirds of the area between the elbow and wrist. A cuff selected for an upper arm would be the proper size if it covered two-thirds of the distance from the elbow to the shoulder. On the lower leg, the cuff should cover two-thirds of the distance between the knee and ankle.

One exception to the two-thirds rule arises when using a conical radial artery BP cuff. These recently marketed cuffs, which are designed for patients with obesity, are applied to the forearm and cover a relatively smaller area. Because of their conelike shape, they can obtain BP values with accuracy similar to that achieved with conventional-size rectangular cuffs.

Positioning of the extremity in which BP is measured also affects accuracy. Proper assessment requires that the extremity be located at mid-heart level when BP is measured. Elevation of an arm (or leg, if that is where the cuff is placed) above mid-heart level will yield falsely low readings, whereas placing the extremity below mid-heart level will yield false high readings. This issue can be particularly problematic when measuring BP in side-lying patients or when measurements are taken in the lower leg of a patient who is seated or lying with the leg elevated above the heart.

Often, NIBP units are incorporated into transport monitors and used to obtain indirect BP measurements at predetermined intervals automatically. The NIBP units measure heart rate and mean arterial pressure (MAP) only. (MAP is discussed later in this chapter.) The NIBP software then calculates the patient's SBP and DBP values by using the measured parameters to determine the amount of time spent in systole and diastole computed against the MAP. If the NIBP unit fails to obtain an accurate heart rate, then an erroneous calculation will occur. Additionally, the formulas used by different manufacturers of NIBP devices vary. Notably, systolic and diastolic values calculated by different NIBP monitors for the same patient will vary, sometimes significantly. Because MAP is actually measured by the NIBP unit, this value should be used in making patient care and treatment decisions.

Outdated textbooks and literature suggest that pulses could be correlated with SBP. Current studies have failed to find any consistent correlation between SBP and the presence or absence of central or peripheral pulses. At present, the only setting where pulses may have some utility is in an austere environment such as the battlefield, where radial pulses help with decision making regarding fluid resuscitation.

Arterial Lines

Arterial lines (sometimes called A-lines) include a catheter that is inserted into the patient's arterial vascular system and connected to a transducer. The transducer is a biomedical device that converts the pressure waveform into an electrical signal. The electrical output of the transducer is connected by a proprietary electrical cable to the transport (or bedside) monitor, which then displays the waveform and its corresponding values. In the United States, pressure waveforms are usually measured in millimeters of mercury (mm Hg).

Arterial lines may be inserted in the radial, brachial, femoral, axillary, and dorsalis pedis arteries **FIGURE 15-7**. The radial artery is the preferred site because it is easily accessed and because the patient's hand can receive collateral circulation from the ulnar artery. It is best to use the patient's nondominant hand.

Description

In addition to offering the benefit of a continuously displayed BP reading while titrating vasoactive agents, the arterial line confirms the presence of pulsatile blood flow and allows access for arterial blood samples for arterial blood gas analysis. Commercial arterial line kits designed for insertion into the brachial artery have been gaining popularity in adult ICUs in recent years, because these lines are somewhat easier to insert and stabilize and may have longer patency than do radial catheters.

Indications

Direct BP measurement using an arterial line is indicated for patients who require constant BP measurement. The current indication for an arterial line is any patient in shock who is not rapidly responsive to therapy, including not only patients who are hypotensive, but also patients who are hypertensive and require powerful vasodilator therapy to reduce their vascular resistance. Arterial lines are also used routinely in patients receiving continuous vasoactive or antihypertensive infusions.

Studies comparing direct and indirect BP measurements have shown that SBP and MAP readings obtained from NIBP units closely approximate arterial line measurements in normotensive patients. However, as patients become hypotensive (SBP <110 mm Hg), SBP is increasingly overestimated by NIBP units. The greater the degree of hypotension, the larger the difference between directly measured (arterial line) and indirectly measured (NIBP) SBP readings will be. MAP readings obtained by arterial lines and NIBP units remain consistently correlated, however, regardless of the degree of hypotension. This finding suggests that clinicians using NIBP in hypotensive patients should base their treatment decisions on the NIBP-obtained MAP.

Contraindications

Contraindications to arterial lines include the following conditions:

- Ischemia of the extremity
- Infection at the puncture site
- Raynaud disease
- Prior vascular operation in the area of the insertion site

Complications

Complications from arterial line insertion include the following possibilities:

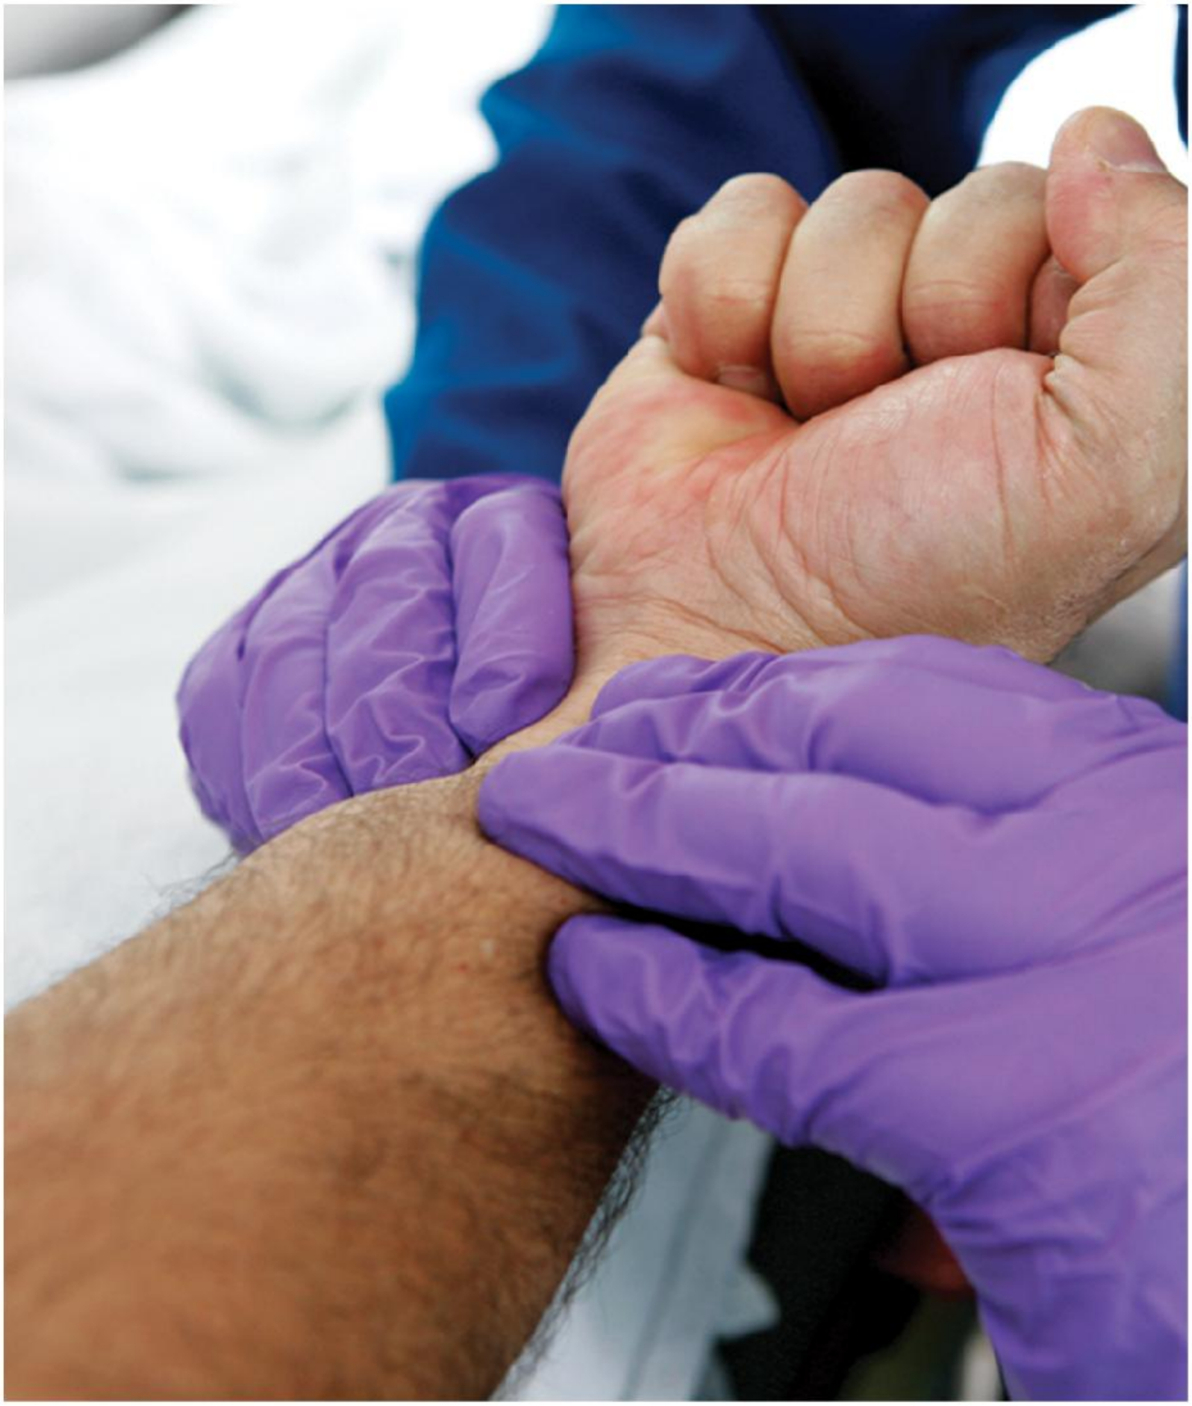
- Arterial line thrombosis
- Embolization
- Hematoma
- Insertion-site infection
- Median nerve neuropathy (radial artery insertion)
- Pseudoaneurysm of the artery
- Ischemic necrosis
- Digit, hand, leg, or foot ischemia
- Hemorrhage
- Arterial air embolism
- Arteriovenous fistula
- Arterial aneurysm

Arterial Line Placement

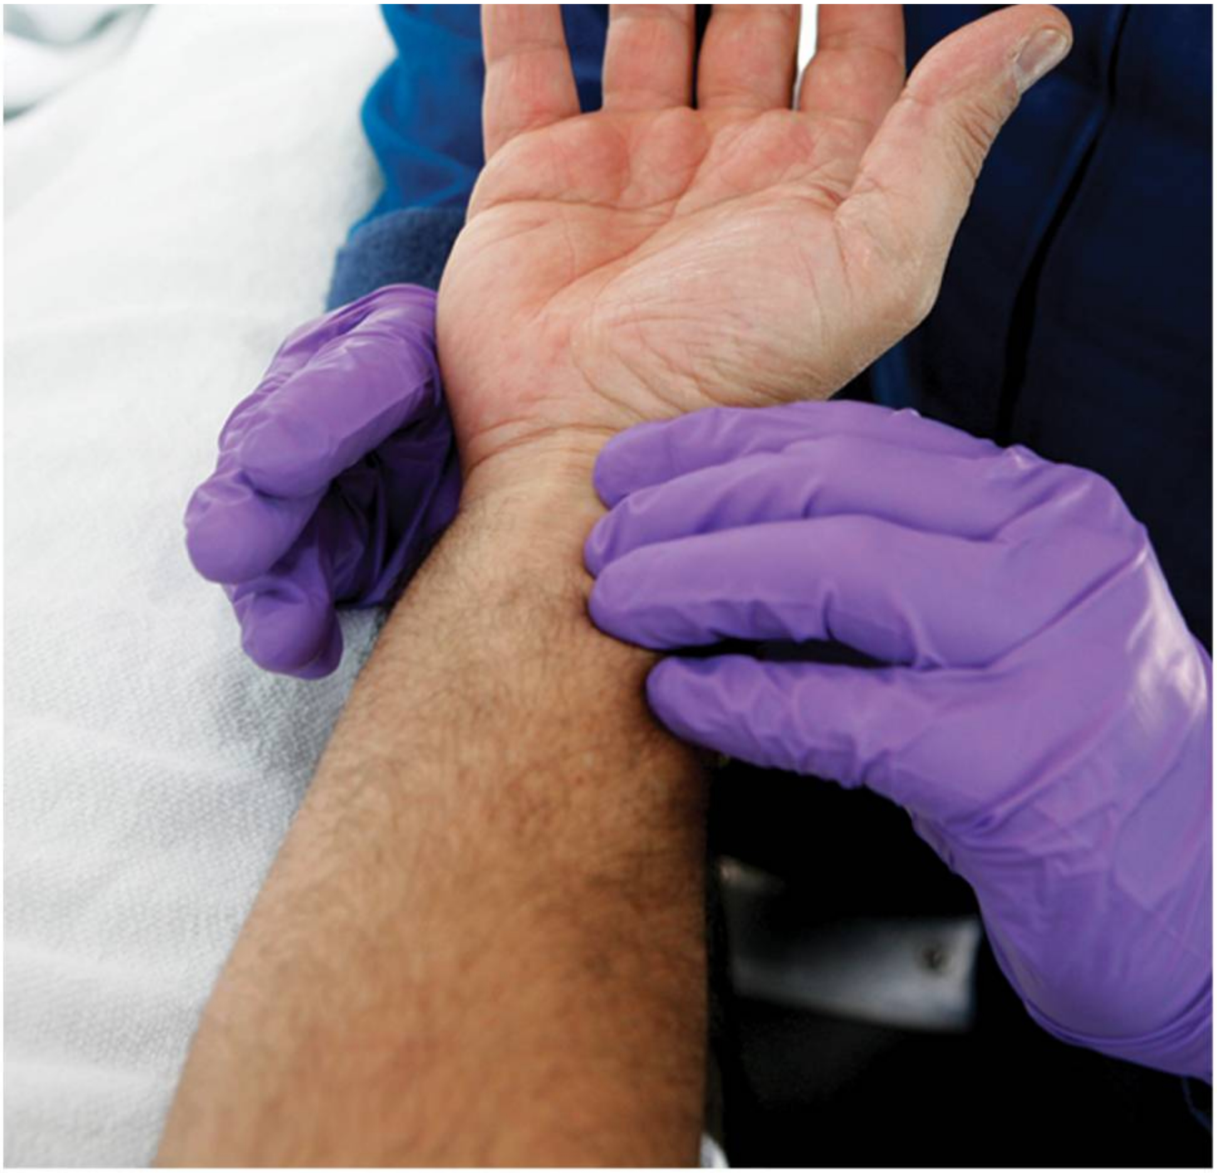
Although some CCTPs may be trained and credentialed to insert central venous catheters, they generally do not place arterial lines. They may, however, need to assist in the procedure. For the reader’s background knowledge, this section explains how arterial lines are placed. While traditional arterial line placement is performed blindly, using landmarks and tactile sensation, ultrasound-guided placement is increasingly common.

Allen Test

The **Allen test** can be used to assess extremity perfusion and ulnar artery function. With this technique, the patient’s radial and ulnar arteries are compressed while the fist is clenched **FIGURE 15-8A**. The fist is then opened **FIGURE 15-8B**. Pressure is kept on the radial artery, whereas ulnar pressure is released. After ulnar pressure is released, the color should return to the hand within 6 seconds.



A



B

FIGURE 15-8 The Allen test. **A.** The patient raises their hand above their head with the fist clenched. The CCTP compresses the radial and ulnar arteries. **B.** The patient lowers their hand with the fist open and the CCTP releases ulnar pressure while keeping pressure on the radial artery.

© Jones & Bartlett Learning.

Prior to insertion of a radial artery arterial line catheter, it is common practice to perform an Allen test to ensure collateral flow to the hand from the ulnar artery should the radial catheter occlude blood flow. Regardless of whether this test is conducted, development of signs of ischemia in any extremity following placement of an arterial catheter mandates immediate removal of the catheter.

Equipment

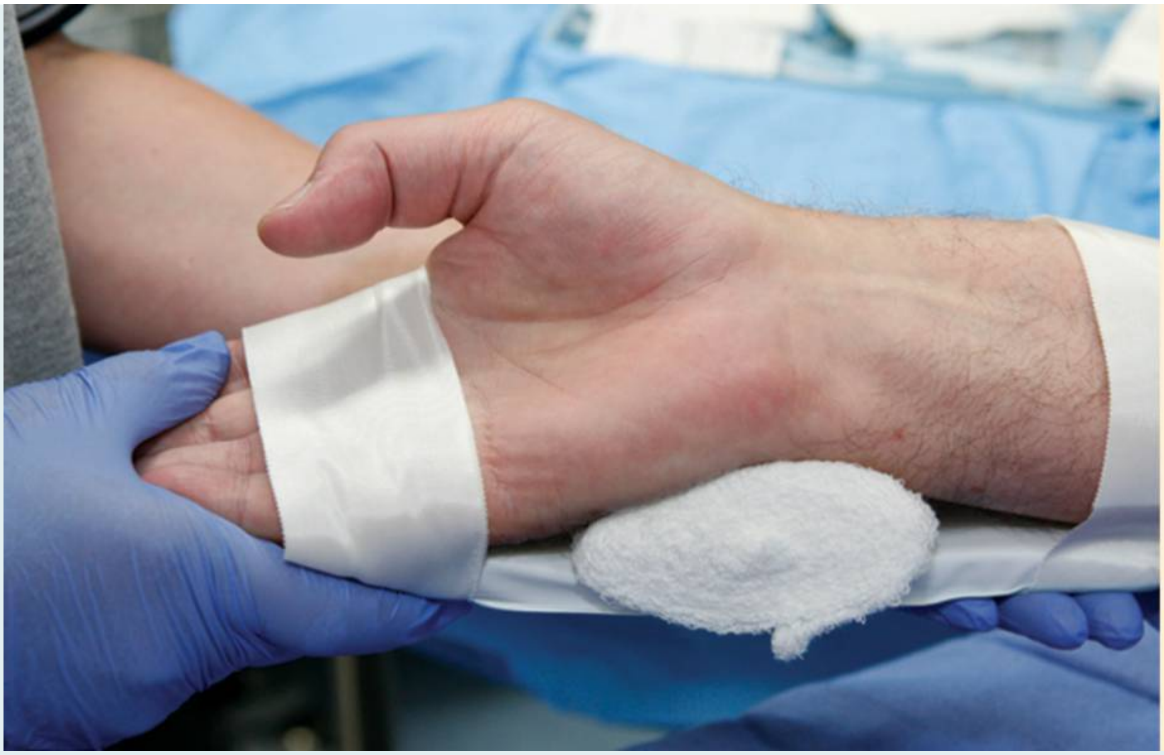
The following equipment is needed to insert an arterial line:

- 20-gauge radial over-the-needle catheterization kit with guide wire
- 18- to 20-gauge 6-inch (15-cm) femoral artery catheterization kit with guide wire
- Tape
- Sterile 2 × 2–inch (5.1 × 5.1–cm) gauze sponges
- Sterile 4 × 4–inch (10.2 × 10.2–cm) gauze sponges
- Local anesthetics
- Analgesic medications
- Sterile gloves, gown, mask, and drapes
- Chlorhexidine solution
- Pressure transducer
- Pressure tubing
- Pressure monitor
- Suture material or commercial suture kit

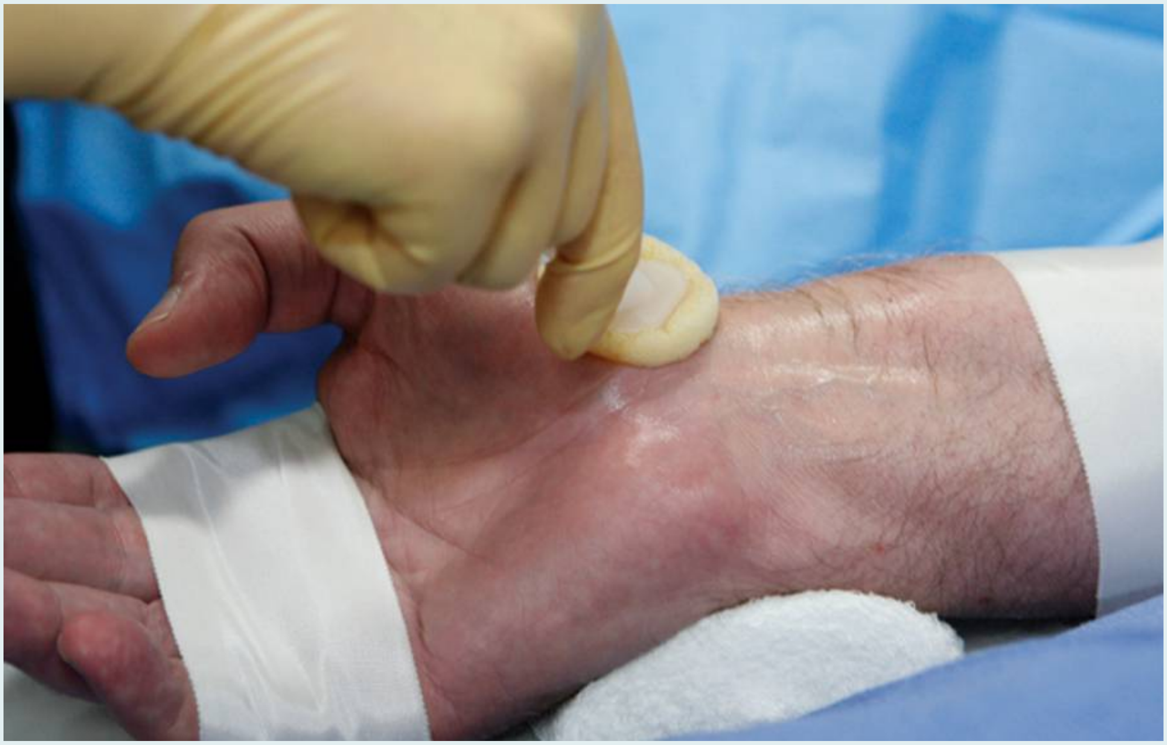
Steps

Skill Drill 15-1 outlines the steps for inserting an arterial line using the modified Seldinger technique (note that ultrasonography to assist with insertion is becoming commonplace):

SKILL DRILL 15-1 Inserting an Arterial Line

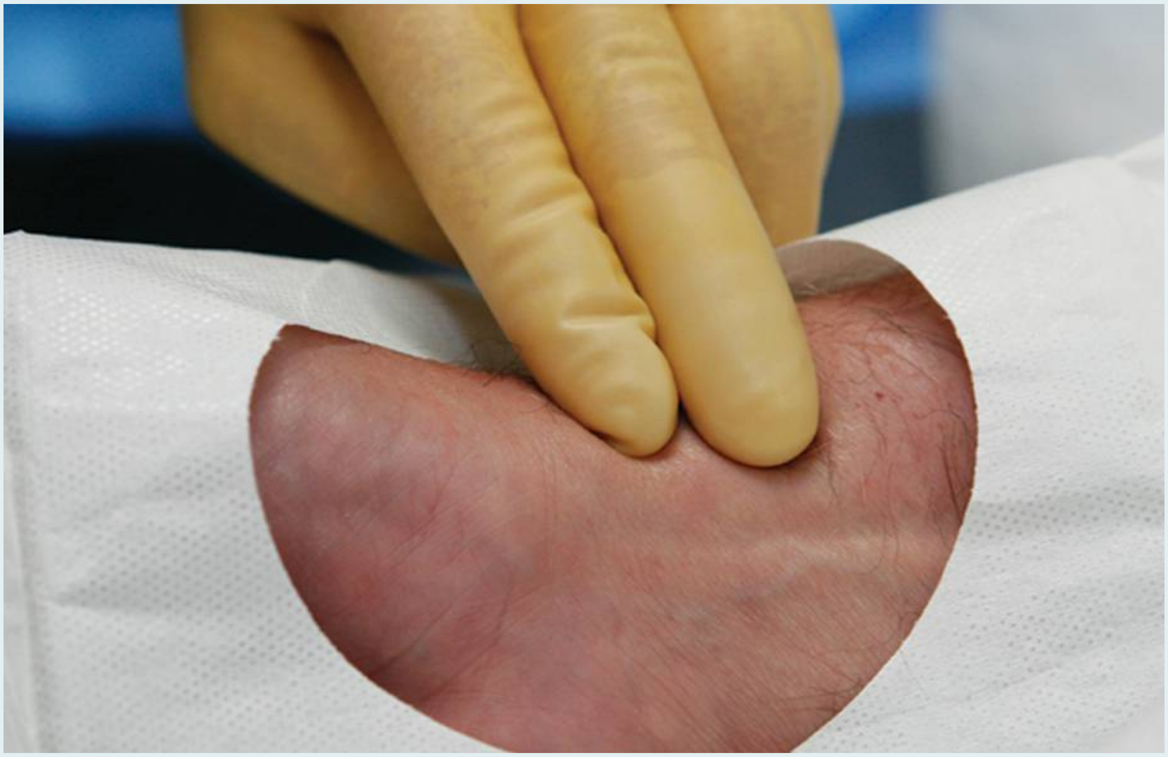


Step 1
Place rolled gauze under the wrist area, hyperextending the wrist.



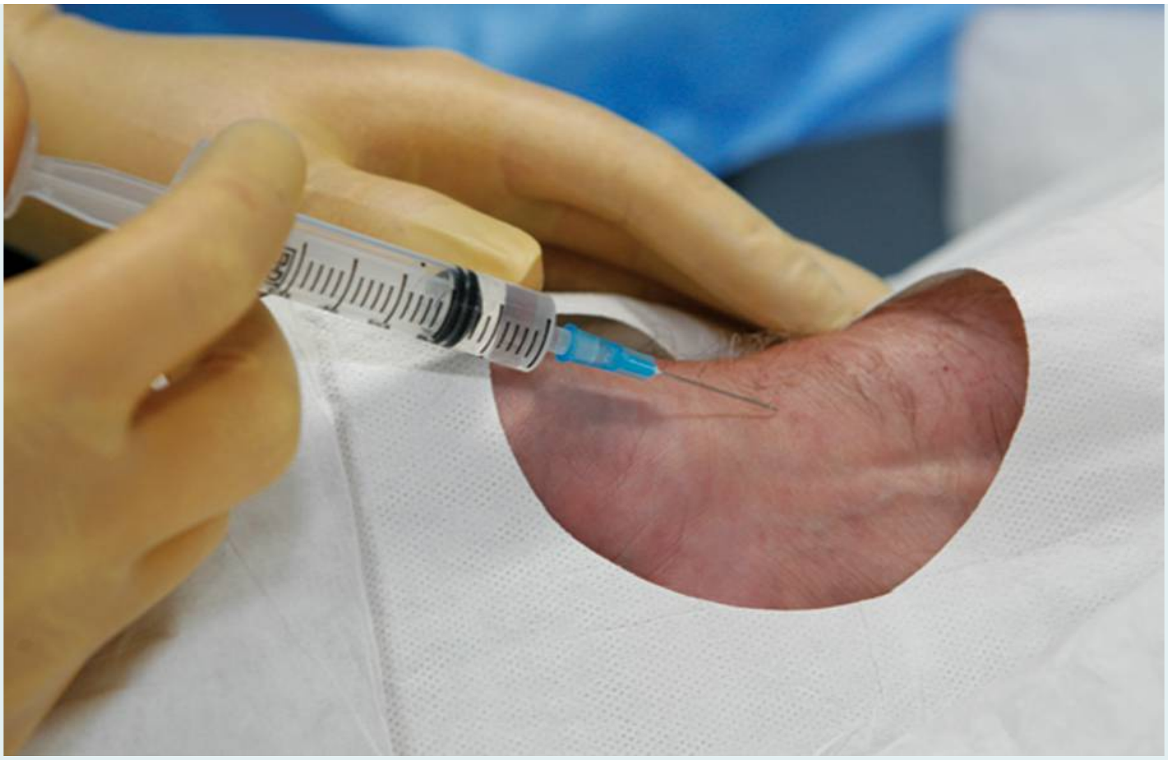
Step 2

Select and clean the insertion site; ensure IV access. Use sterile drapes to reduce infection risk.

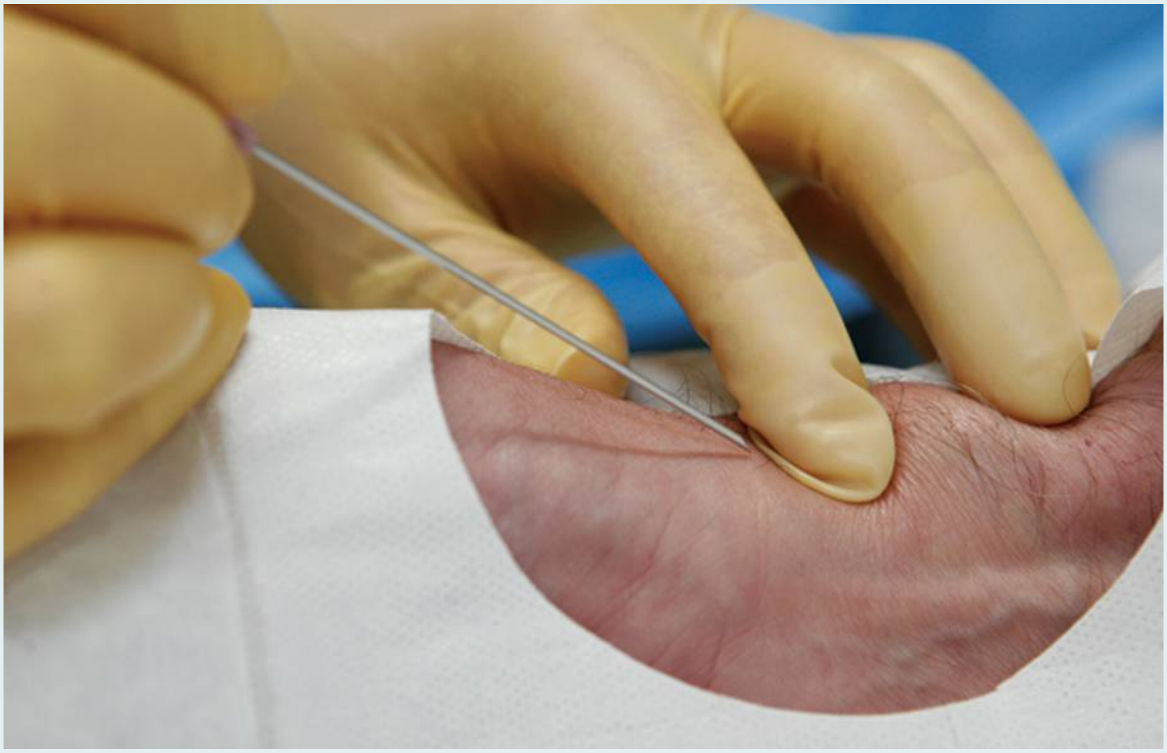


Step 3

Palpate the artery at the distal radius.

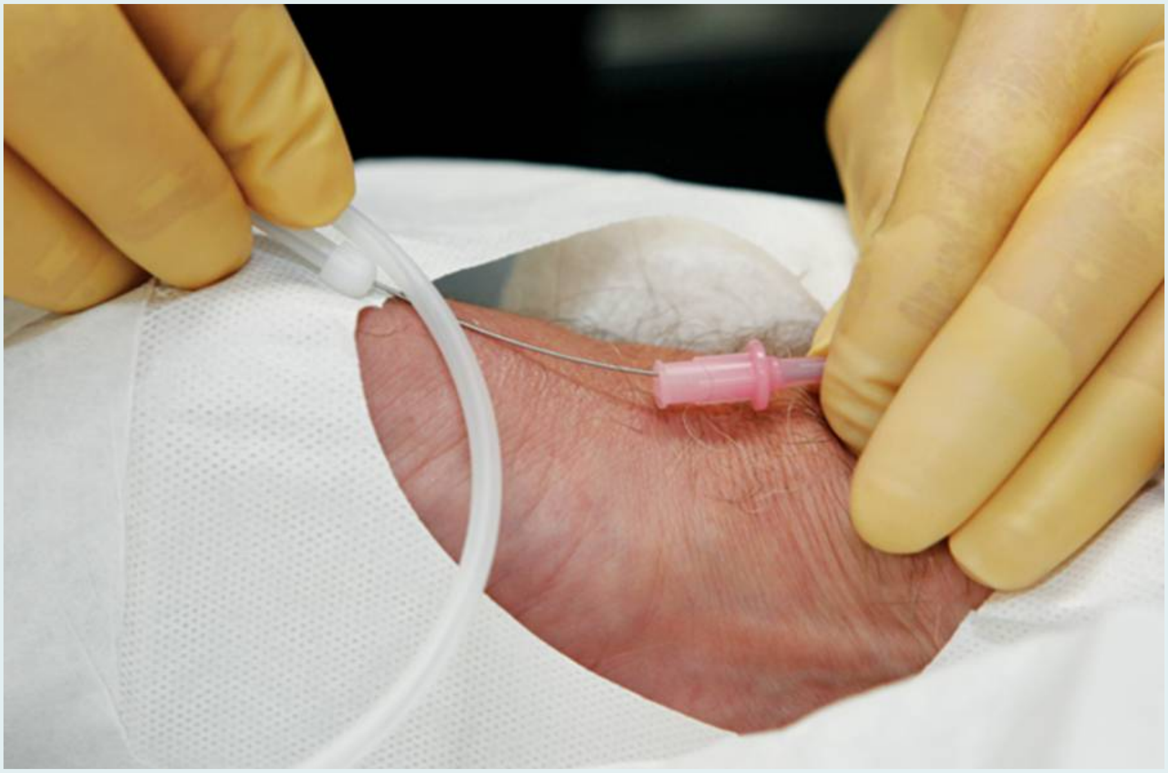


Step 4
Anesthetize the area.



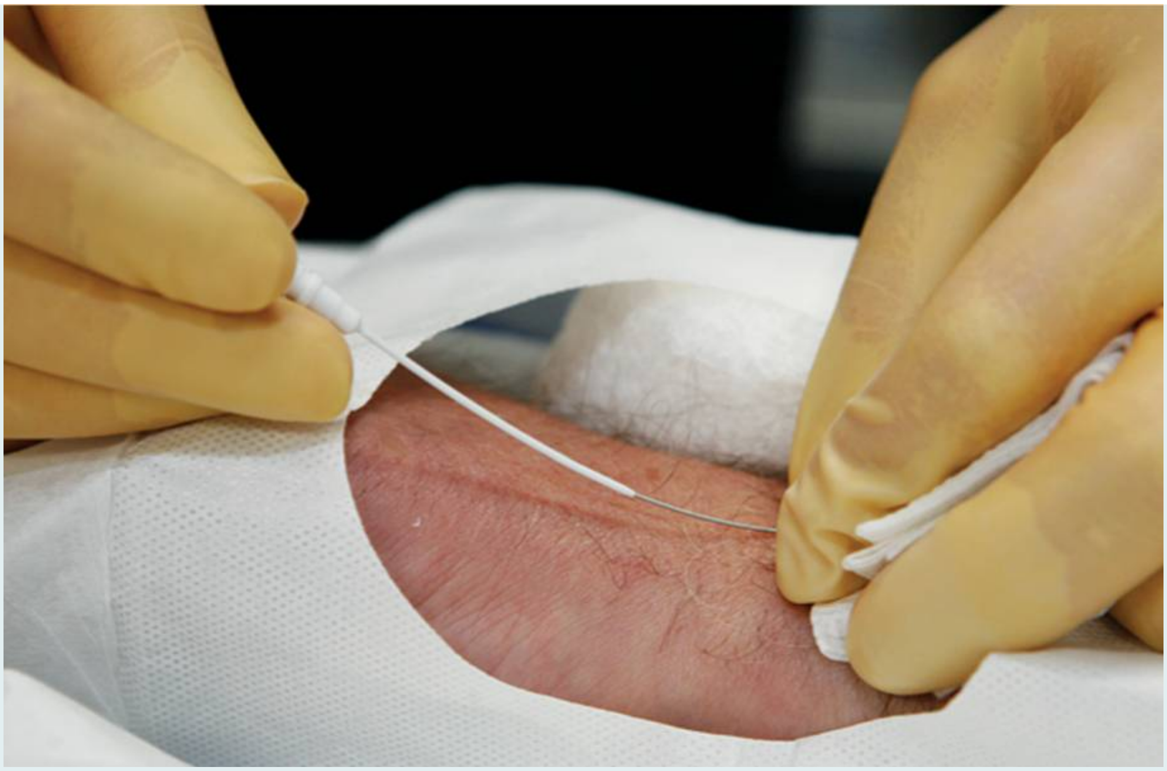
Step 5

Insert the needle over the radial artery approximately 0.5 inch (1 cm) distal to the wrist joint. Advance the needle at an approximately 20° to 45° angle, watching for entry into the artery, indicated by pulsating arterial blood.

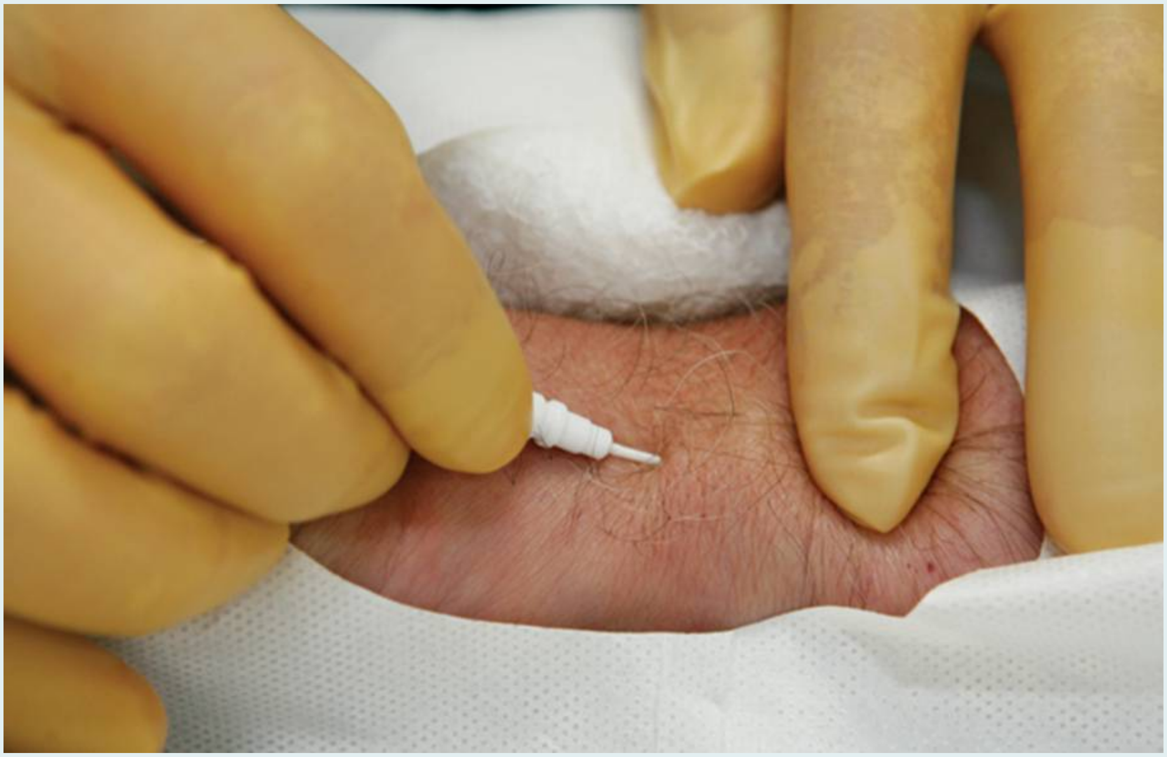


Step 6

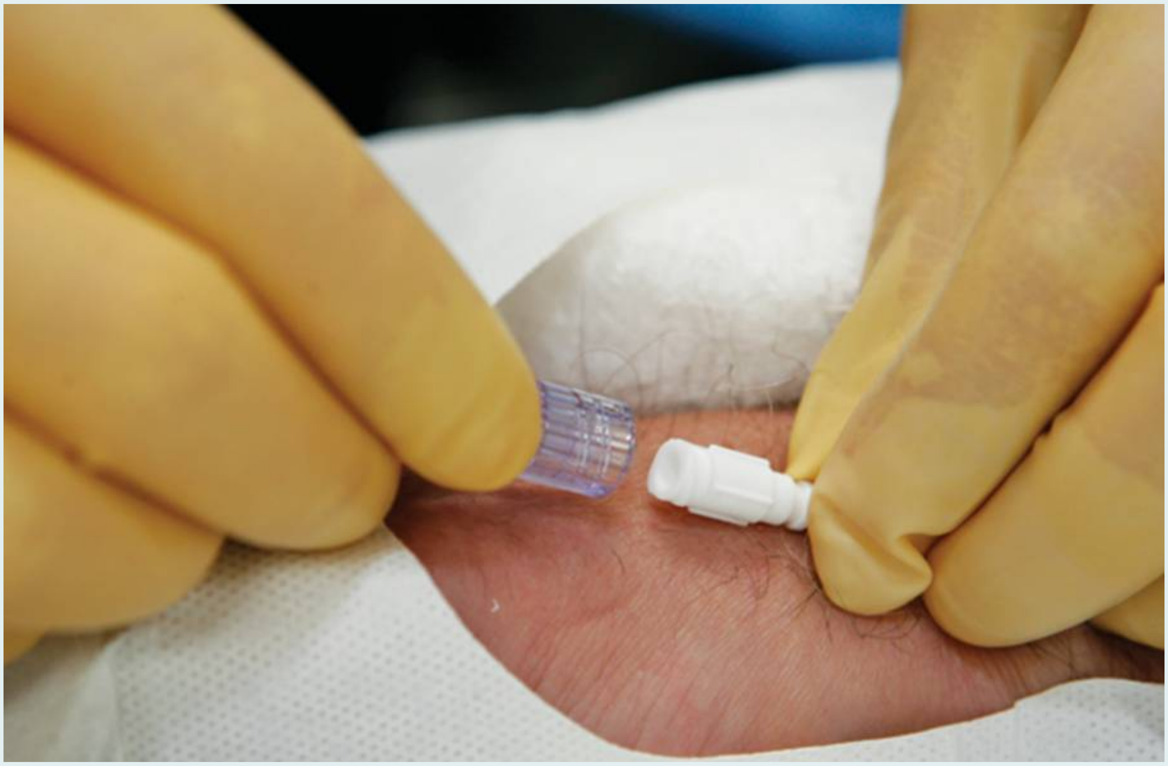
Immobilize the needle with your free hand. Advance the guide wire, and then remove the needle, leaving only the guide wire in the artery.



Step 7
Place the arterial catheter over the guide wire.



Step 8
Remove the guide wire, leaving only the cannula in place.



Step 9
Connect the tubing to the pressure transducer. Secure the catheter to the skin with sutures and apply a sterile dressing to the insertion site.

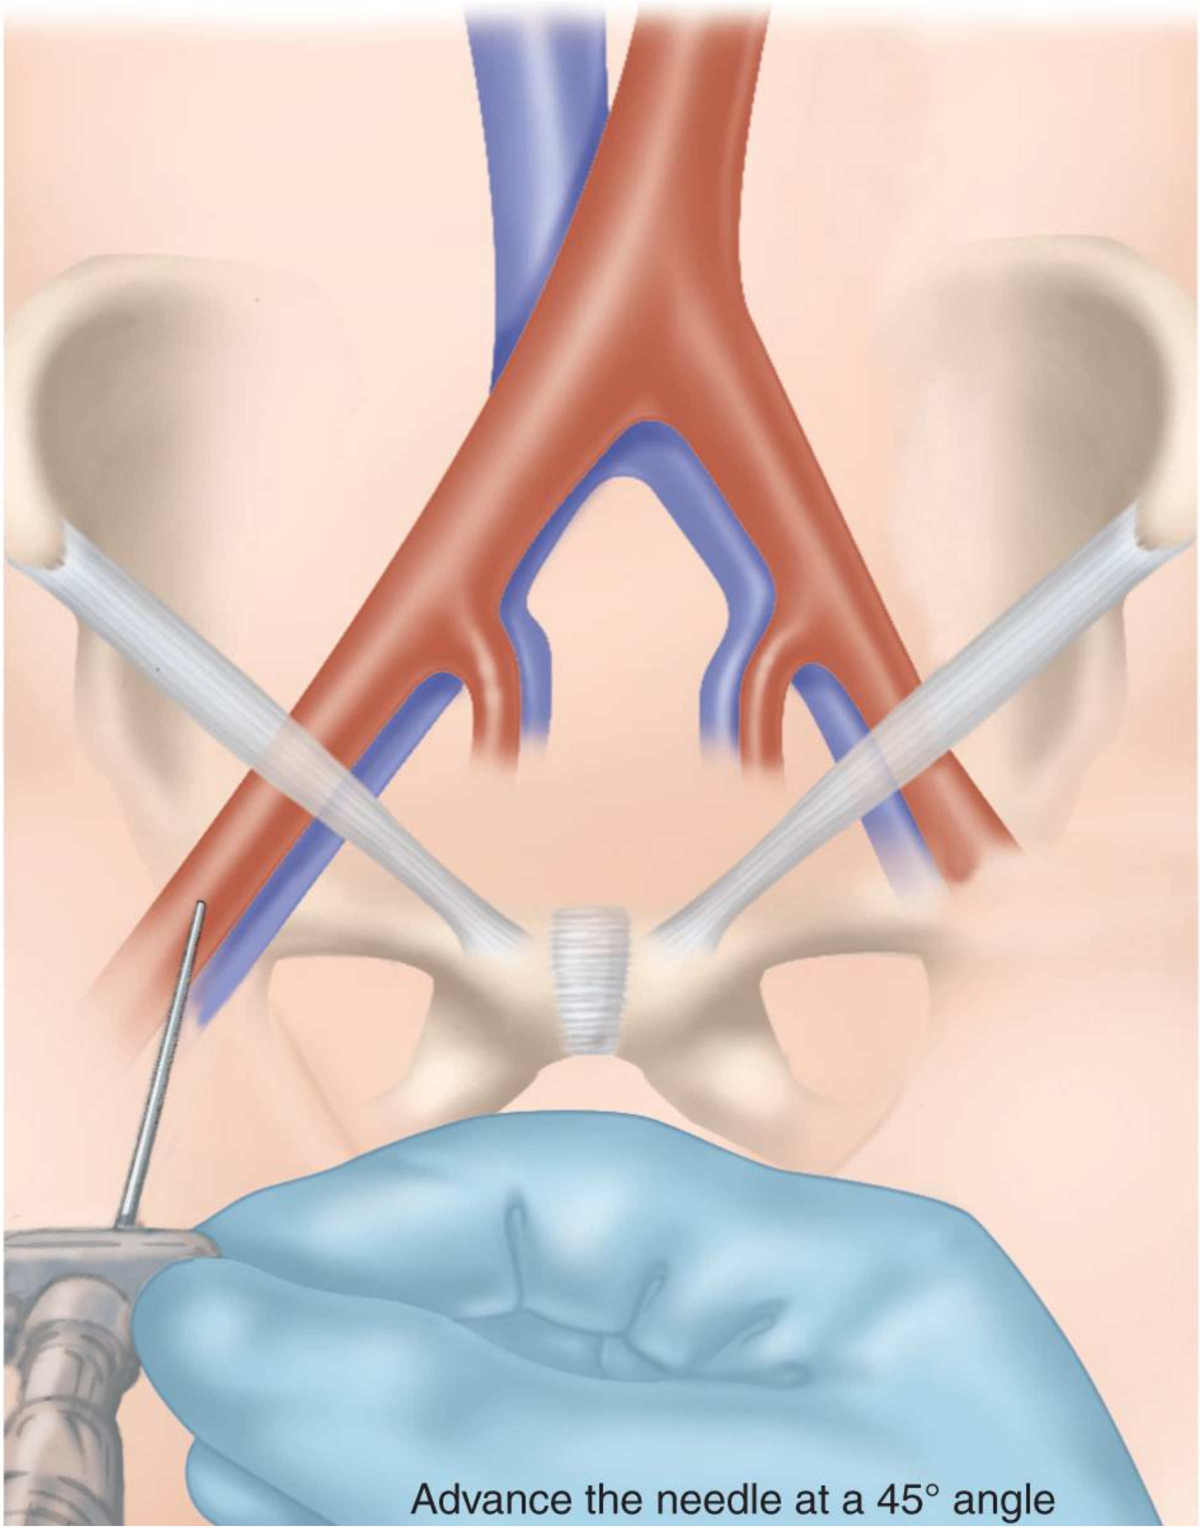
1. Take standard precautions.
2. Prepare all equipment using a sterile technique.
3. Position the patient by placing rolled gauze under the wrist area, hyperextending the wrist **STEP 1**.
4. Select and clean the insertion site; ensure IV access. Use sterile drapes to reduce infection risk **STEP 2**.
5. Palpate the artery at the distal radius **STEP 3**.
6. Anesthetize the area **STEP 4**.

7. Insert the needle over the radial artery approximately 0.5 inch (1 cm) distal to the wrist joint **STEP 5**.
8. Advance the needle at an approximately 20° to 45° angle. Entry into the artery will be indicated by pulsating arterial blood.
9. Immobilize the needle with your free hand.
10. Advance the guide wire, and then remove the needle, leaving only the guide wire in the artery **STEP 6**.
11. Place the arterial catheter over the guide wire **STEP 7**.
12. Remove the guide wire, leaving only the cannula in place **STEP 8**.
13. Connect the tubing to the pressure transducer **STEP 9**.
14. Secure the catheter to the skin with sutures and apply a sterile dressing to the insertion site. It is imperative that line placement be radiographically confirmed before departing with the patient.

The steps for femoral artery cannulation are also listed here for reference:

1. Prepare the equipment.
2. Use a complete aseptic technique.
3. Ensure IV access.
4. Palpate the femoral artery below the inguinal ligament.
5. Anesthetize the area.
6. Enter the skin over the femoral artery approximately 0.5 to 0.75 inch (1 to 2 cm) below the inguinal ligament **FIGURE 15-9**.
7. Advance the needle at an approximately 45° angle. Entry into the artery will be indicated by pulsating arterial blood.
8. Immobilize the needle with your free hand.
9. Advance the guide wire through the needle. Remove the needle, leaving the guide wire in place.
10. Pass the arterial catheter over the guide wire; remove the guide wire.
11. Connect the tubing to the pressure transducer.

12. Secure the catheter with sutures and apply a sterile dressing. Line placement must be radiographically confirmed before departing with the patient.



Advance the needle at a 45° angle

to the skin toward the ischial tuberosity

Description

Obtaining Invasive Hemodynamic Measurements

After an arterial line is placed, it is connected to a pressure-monitoring transducer by using rigid pressure-monitoring tubing. This tubing is filled with an isotonic solution, usually normal saline. Historically, heparinized saline was used, but its lack of demonstrated benefit and the potential for harm to patients have all but eliminated its use as a flush solution. The difference between pressure-monitoring tubing and IV extension tubing is important because the latter will absorb much of the pressure waveform generated by the patient before it reaches the transducer.

To maintain the patency of the pressure-monitoring line and fluid-filled system, a continuous flush solution system is used. Most often, the flush solution used to fill the monitoring system is placed into a disposable pressure bag. After the monitoring system is connected to the patient, free of bubbles, and functioning properly, the pressure bag is inflated to 300 mm Hg, or a pressure higher than the patient's BP. Whenever the pressure in the monitoring system exceeds the patient's BP, each transducer will flow 3 mL/h of flush solution into the patient. Such a continuous flush system maintains the catheter's patency and prevents blood backflow into the catheter and monitoring system. In cases in which less than 3 mL/h of flow through each transducer is necessary (such as in a neonate), the flush solution can be delivered to the transducer(s) by using an infusion pump.

If the patient transfer will involve air medical transport, then all of the air left in the fluid bag, which has been placed inside the pressure bag, should be expelled to prevent its expansion during flight. As mentioned earlier, the pressure bag itself must remain at 300 mm Hg; in fact, it may have a pressure indicator that will display a green color when inflated near 300 mm Hg and a red color when the pressure exceeds 300 mm Hg. After the pressure bag is properly inflated, the air to it should be turned off to prevent deflation **FIGURE 15-10**. The pressure bag should be periodically checked during transport to verify that it is still inflated.

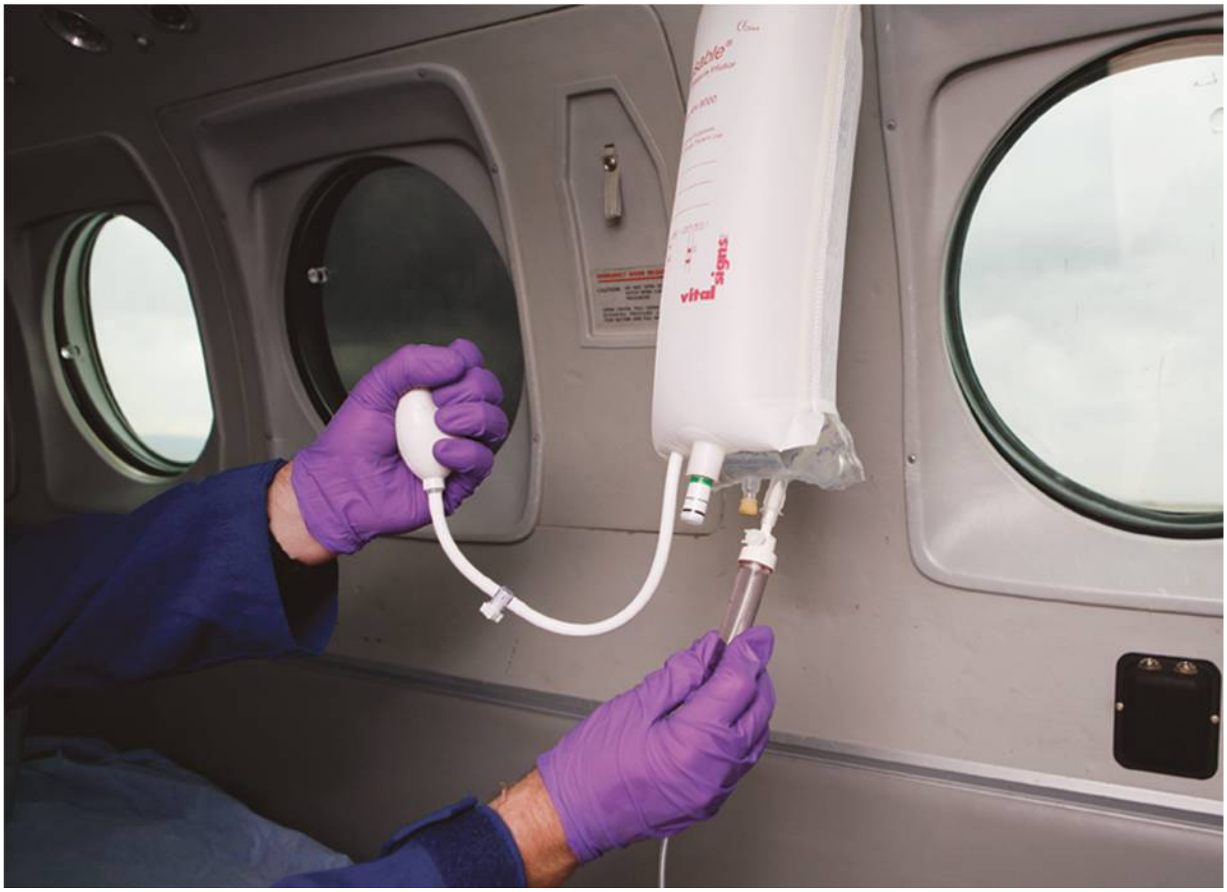

FIGURE 15-10 An inflated pressure bag with proper inflation.

© Jones & Bartlett Learning.

Before moving a patient with hemodynamic monitoring equipment already in place, the CCTP should examine the equipment, note the values currently being displayed, and trace the tubing from each transducer to the pressure-monitoring catheter to which it is connected. The catheter site should be examined and documented to be visibly clean, dry, and covered by an occlusive dressing. The CCTP should be familiar with the operation of the stopcocks and catheters in use or should ask the clinician at the bedside for a review of their proper use.

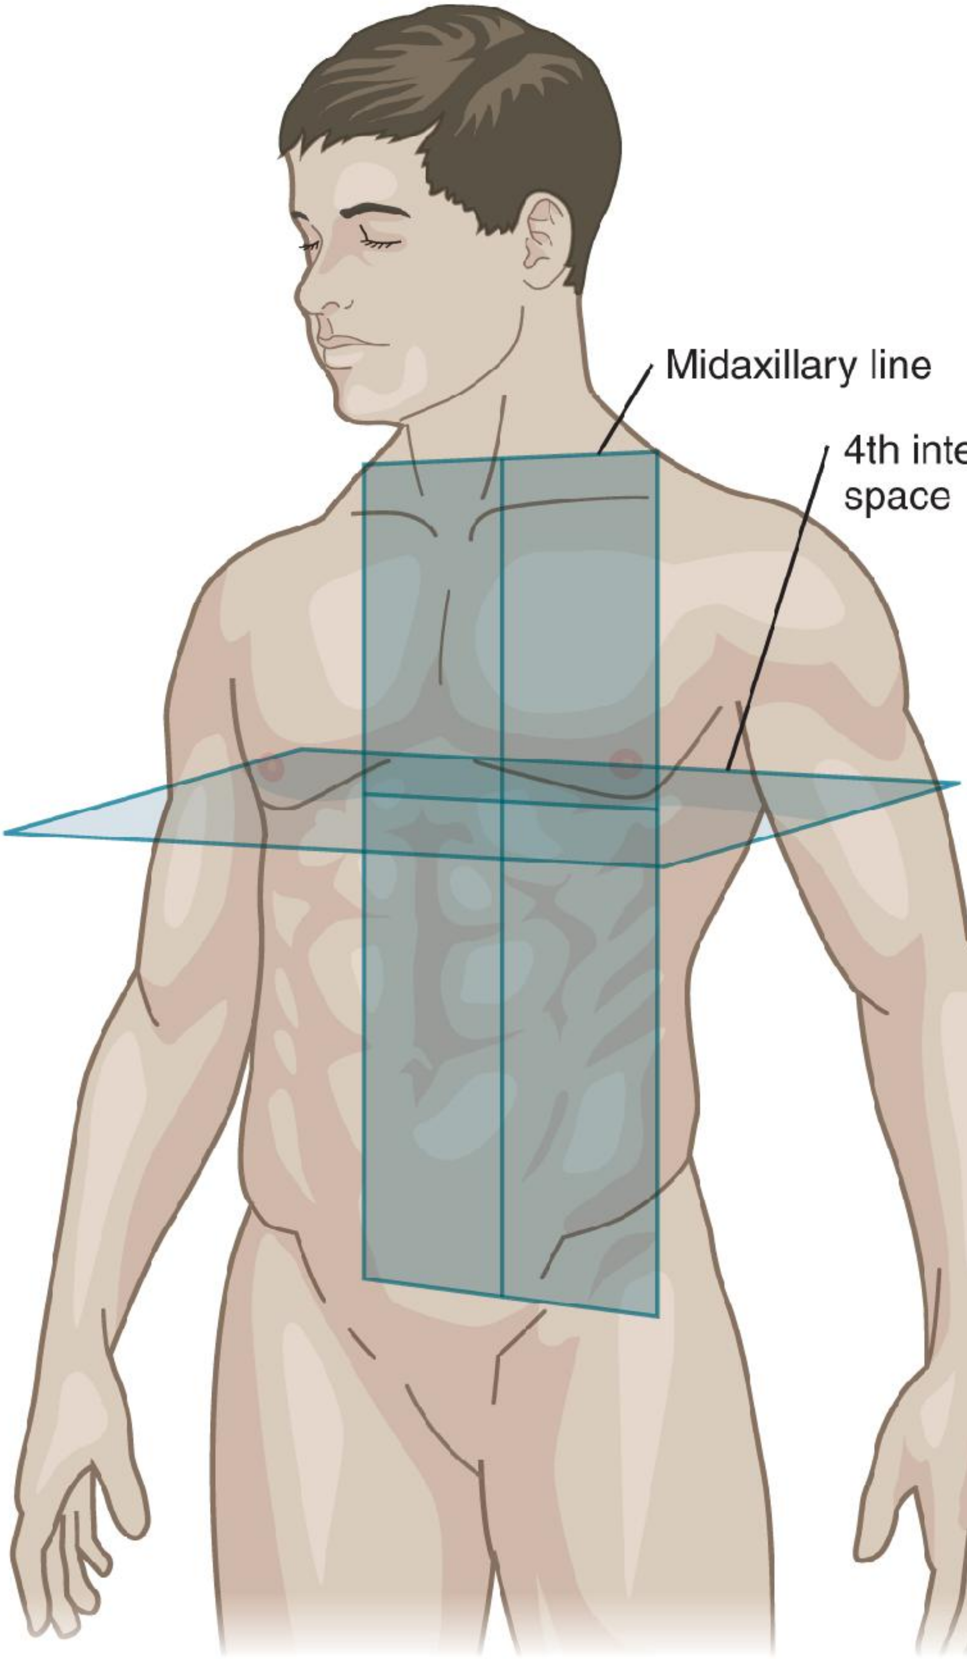
A CCTP may elect to transfer a patient to the transport stretcher before connecting transducers to the transport monitor or may make the connections to the transport monitor before moving the patient. In either case, one pressure cable is moved at a time to the transport monitor, with the CCTP ensuring that waveforms and values similar to those displayed on the hospital monitor appear on the transport equipment before transferring additional lines and pressure channels. Proceeding in such a deliberate, stepwise manner avoids periods in which the patient is not connected to any monitoring equipment, when changes may not be readily detected.

Extra caution is needed when moving a patient with hemodynamic monitoring equipment in place because catheters can easily become dislodged or pulled out if they are not adequately secured. Agency or service policy for securing monitoring lines and catheters during transport should be followed. The most reliable hemodynamic waveforms and pressure readings will be obtained from tubing that spans less than 48 inches (122 cm) from transducer to invasive catheter, with no more than one stopcock between the transducer and the invasive catheter.

The best protection against accidental dislodgement or dislocation of invasive monitoring catheters is to carefully set monitoring alarms. The transport environment is no exception to the need for monitoring alarm parameters designed to alert the CCTP if hemodynamic parameters are outside of reasonable thresholds. Disconnected catheters will invariably register less than physiologic levels that can be readily detected if alarms are properly set by the CCTP. Despite the provider’s singular focus on the patient, care of a critically ill patient is a task-intensive endeavor, meaning the CCTP cannot continuously observe the transport monitor for changes. Consequently, alarms must be set for each parameter being monitored during transport. Failure to do so increases the risk of missing sudden or transient events with important patient safety implications.

Leveling and Zeroing the Pressure Transducer

The most common cause of error in obtaining direct hemodynamic pressure measurements is incorrect leveling of the transducer. The fluid used to fill the rigid pressure tubing that connects the monitoring catheter between the patient and the transducer will interfere with pressure readings if the pressure transducer is lower or higher than mid-heart level, commonly located at the patient’s atrium. This reference point, which is referred to as the **phlebostatic axis**, is located at the fourth intercostal space, mid-chest position **FIGURE 15-11**. **Leveling** is the process of ensuring that the hemodynamic pressure transducer is at the level of the atrium, which also corresponds to the level of the aortic root. Having the transducer at this level eliminates the influence of hydrostatic pressure from the fluid in the tubing from the measured pressures. The transducer must be releveled with every change in the patient’s position; therefore, this point is often marked on the patient’s skin. The simplest way to ensure proper placement during transport is to secure the transducer at the phlebostatic axis, although this step is not always practical in the critical care setting. The point on the transducer that is leveled is the air–fluid interface, or the location that was opened to air so as to perform the zeroing procedure described later in this section.



Midaxillary line
4th intercostal space

FIGURE 15-11 The phlebostatic axis.

© Jones & Bartlett Learning.

Description

The phlebostatic axis moves with the patient, and transducers can be adjusted to obtain accurate readings in almost any sitting or lying position. Transducers must be releveled with any change in patient position. For each inch that a transducer is leveled above the phlebostatic axis, readings will be 1.86 mm Hg less than actual pressures in the patient. For each inch that a transducer is leveled lower than the phlebostatic axis, values obtained will be 1.86 mm Hg greater than the actual pressures. Inches of error in leveling can have significant implications if treatment decisions are based on erroneously obtained values. For this reason, all leveling should be performed with a carpenter's level or a leveling tool specifically designed for hemodynamic monitoring applications.

In addition, any pressure transducer must be "zeroed" to eliminate the effects of atmospheric pressure on the measurements obtained. **Zeroing** is the process in which a transducer connected to the transport monitor is opened to atmospheric air to obtain a baseline reading of environmental atmospheric pressure. Once opened to air, the monitor is zeroed to eliminate the effects of atmospheric pressure on the transducer **FIGURE 15-12**. The procedure to zero the transducer includes the following steps:

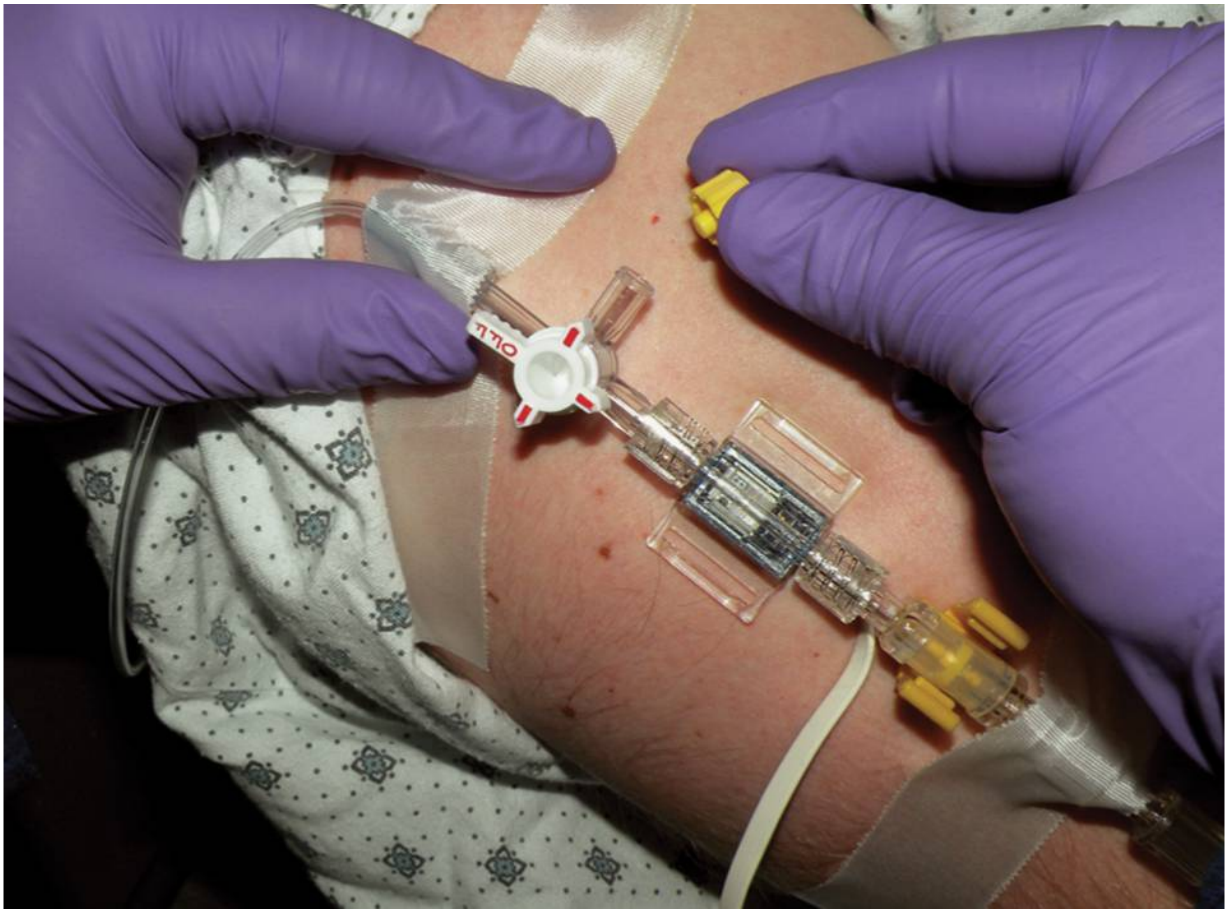


FIGURE 15-12 Zeroing the transducer.

© Jones & Bartlett Learning.

Description

1. Ensure that the cable is connected (or reconnected) to the monitor.
2. Close the stopcock to the patient, and open the stopcock to the air.
3. Press the zero button on the monitor. Confirm that the monitor has accepted the zero value and actually indicates zero on the pressure and waveform displays.

Zeroing should be performed in the following circumstances:

- Immediately after connecting the transducer to the transport monitor
- Once the transducer is reconnected to the monitor following any disconnection

- Whenever displayed values are in question

Depending on flight patterns and altitudes, zeroing is often performed at the initial connection of the transducer to the transport monitor, at cruising altitude, and again on arrival at the destination.

Transducers and Cables

Several transducer brands are available, each of which has its own fast-flush system. The two most commonly encountered types are the squeezable style and the pull style. The squeezable-style device includes two pieces of plastic on either side of the transducer that, when squeezed, will fast-flush the closed fluid-filled system **FIGURE 15-13A**. The pull-style (or pigtail) device has a small piece of rubber that resembles a pigtail **FIGURE 15-13B**. To flush the system, the CCTP pulls the tail straight out (away from the transducer).

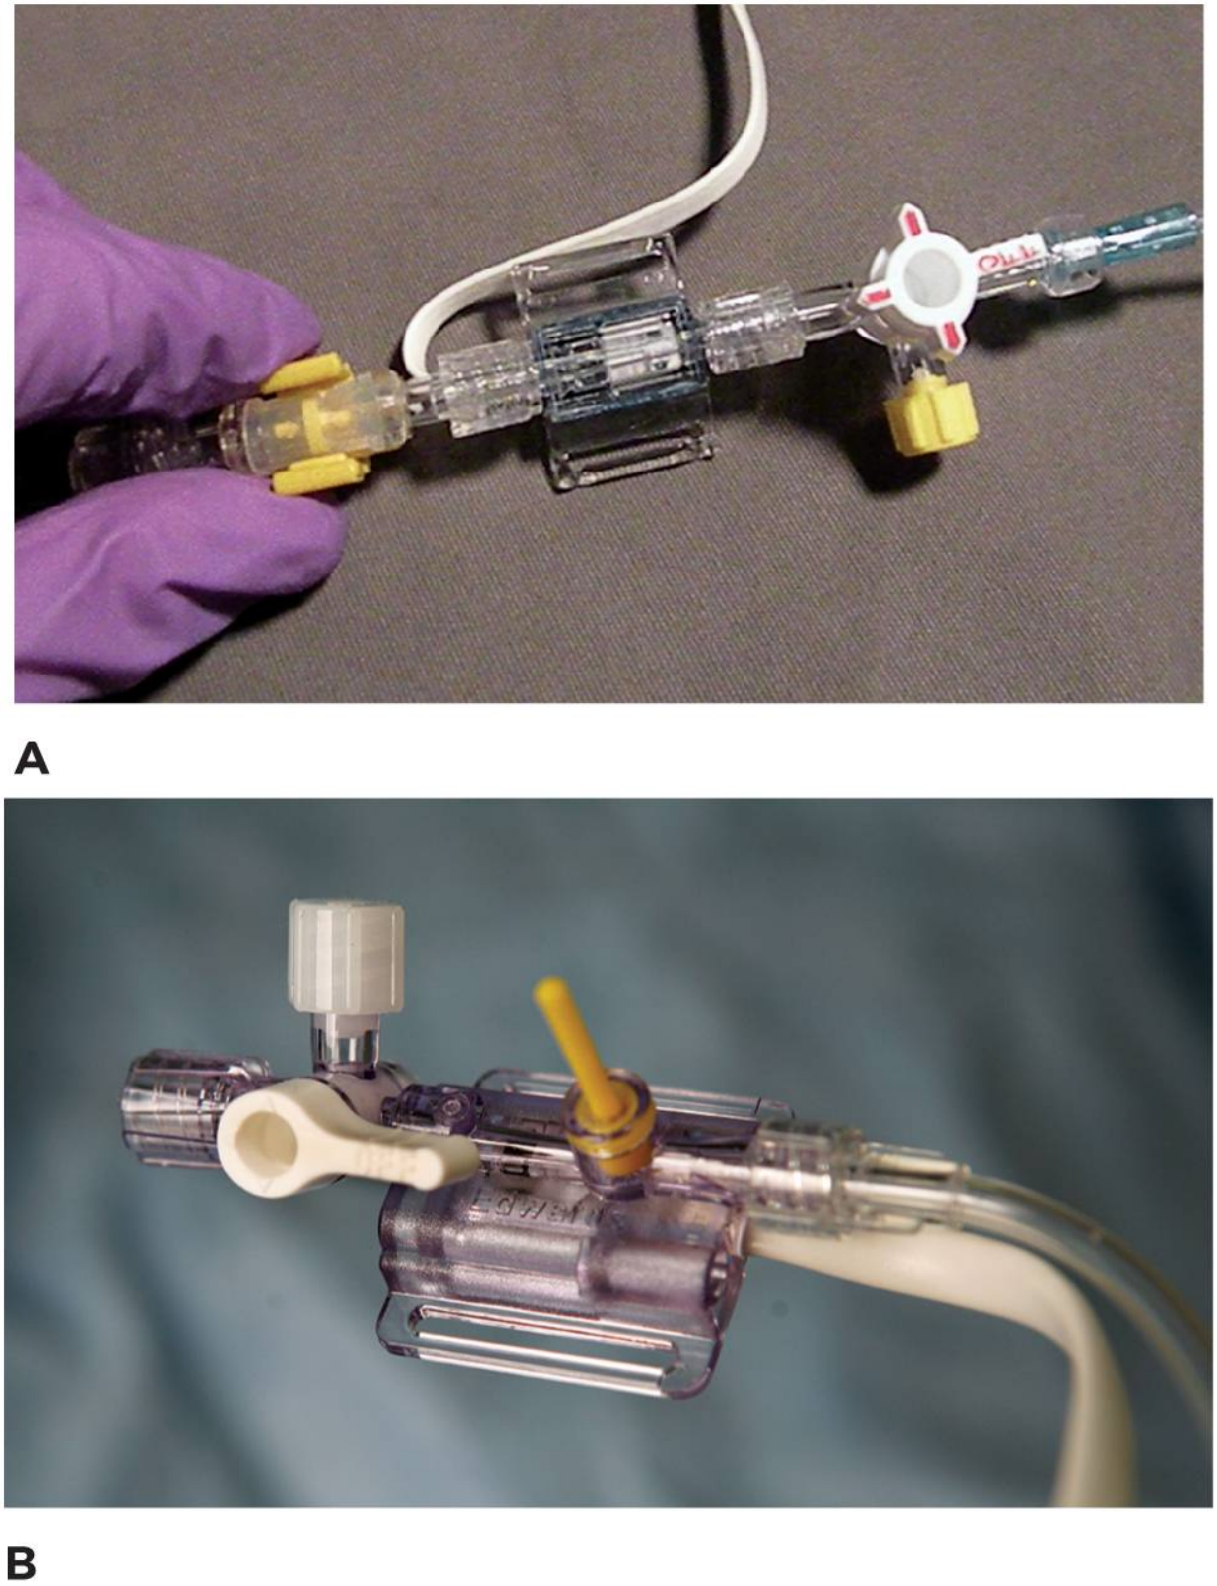

FIGURE 15-13 The two most common transducer flush system devices. **A.** Squeezable style. **B.** Pull style.

© Jones & Bartlett Learning.

Fast flushing overrides the normal delivery of 3 mL/h of flush solution through the transducer into the patient and allows free flow of the pressurized flush solution through the system for as long as the fast-flush assembly is activated. It is useful as an initial technique to troubleshoot a **dampened waveform** or absent waveform in a system that had previously been functioning normally.

The CCTP should become familiar with transport monitors and the cables needed to connect them to pressure-monitoring equipment and transducers. Transport monitors are often limited to monitoring two pressure channels; thus, it may be necessary to decide which pressures will be observed during transport. Any patient with a PAC must have the distal port (pulmonary artery) continuously monitored in case the catheter spontaneously wedges (ie, migrates into a wedged position without manipulation by a clinician). Unmonitored or undetected spontaneous wedging can result in pulmonary infarction.

The cables that connect patient transducers to the monitor that an agency uses must be compatible with the equipment in use at both the referring and receiving hospitals. Two main cable types are available. In the most commonly used version, one end of the cable that attaches to the transducer resembles a phone line connection; the other is best described as a half-moon connection **FIGURE 15-14**. All patient monitors have a standard pressure cable receptacle. Because the transducer end of the monitoring cable is specific to the transducer manufacturer and the cables are extremely costly, many transport services elect to carry several spare transducers in case the transferring facility transducers are from a different manufacturer than those ordinarily used by the transport service.

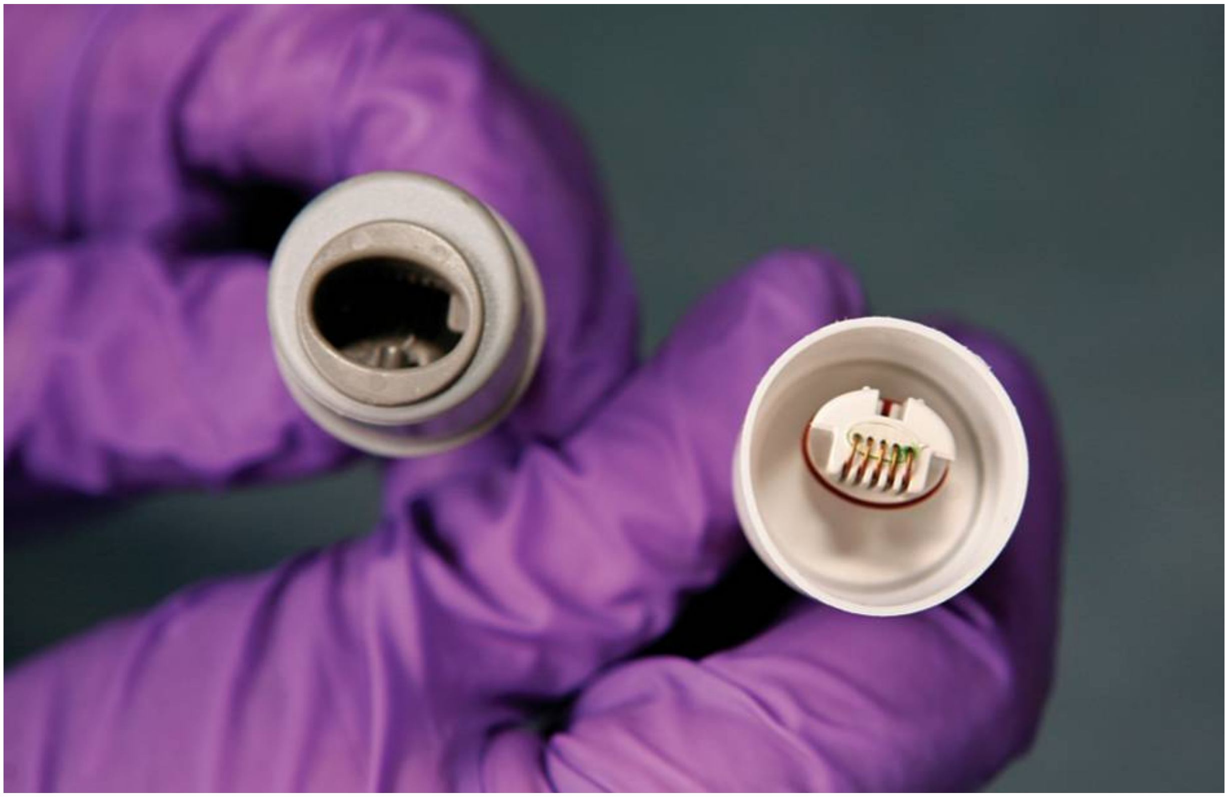

FIGURE 15-14 Two types of cables that connect the transducer to the monitor are a phone line–type connection and a half-moon connection (shown here).

© Jones & Bartlett Learning.

Asepsis

The importance of asepsis cannot be overemphasized as an element of care for patients with central lines and hemodynamic monitoring equipment. The Centers for Disease Control and Prevention's National Healthcare Safety Network uses the term **central line–associated bloodstream infection (CLABSI)** to describe and track primary bloodstream infections (meaning that there is no infection present or suspected at another site) that develop in a patient who had a central line in place within the 48-hour period prior to the onset of the bloodstream infection. Preventing CLABSI is a major focus of critical care practitioners worldwide. Because central venous catheters disrupt the integrity of the skin, they provide a pathway for bacteria and fungi to enter the bloodstream. Critically ill patients are at greater risk for such infection. CLABSIs have serious implications for patients, typically causing prolonged hospital stays and increased costs and risk of mortality. Although the incidence of CLABSIs declined in US hospitals from 2008 through 2019, they continue to occur in ICUs and wards of acute care facilities. Notably, increased volumes of critically ill patients and the complexities born of the COVID-19 pandemic were associated with a 28% increase in CLABSIs in US hospitals in 2020 versus 2019.

With application of evidence-based practices, all CLABSIs are considered preventable. Indeed, several key practices can assist the CCTP in preventing such infections. If the CCTP is involved in catheter insertion, then CLABSI prevention includes meticulous hand hygiene, strict adherence to aseptic technique, use of maximal sterile barrier precautions (eg, removal of any unnecessary people from the room; wearing of masks, caps, gowns, and sterile gloves; full-body draping), use of chlorhexidine for skin antisepsis, site selection to minimize infections, and use of an appropriate dressing after the catheter has been inserted.

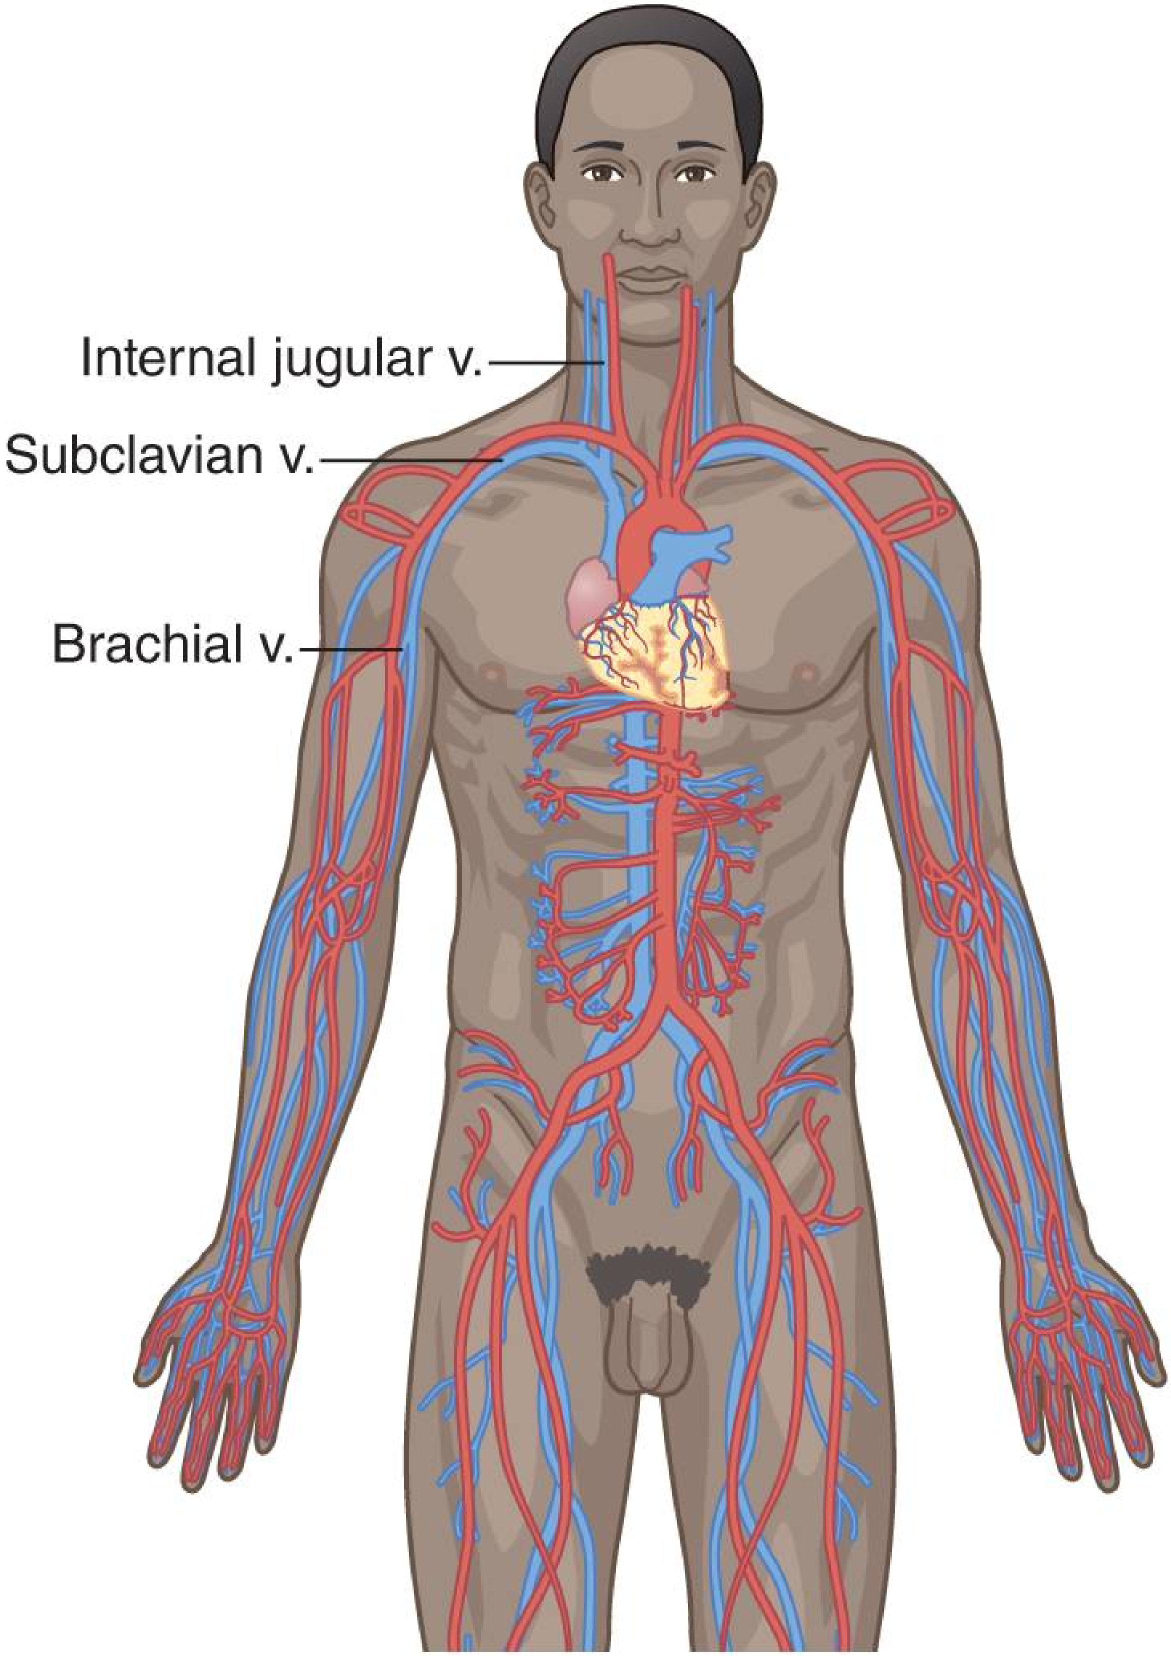
When central line placement is implemented, the patient’s skin should be prepared with a chlorhexidine antiseptic using a back-and-forth friction scrub lasting at least 30 seconds. The antiseptic solution should not be wiped off or blotted from the skin, but rather must be allowed to dry completely (for approximately 2 minutes) before puncturing the site. Older antiseptic solutions, such as povidone–iodine solution, are no longer considered effective skin antisepsis.

CCTPs caring for patients with previously established central lines should strictly adhere to hand hygiene requirements, using an alcohol-based hand gel or other appropriate hand sanitizer frequently during transport. They should scrub the catheter hub or access port immediately before each use with an appropriate antiseptic, and use only sterile devices to access the catheter or fluid path. In addition, they should replace any wet, soiled, or damaged central line dressings using aseptic technique, including wearing clean or sterile gloves and placing face masks on the patient (unless intubated) and all providers in the vicinity.

The frequency with which central lines are accessed is directly related to the risk of CLABSIs. Interventions that reduce the need to connect, disconnect, and reconnect IV tubing and medication syringes help to reduce this risk. Such measures include use of tubing with multiple ports and adding multiple port adapters to catheter hubs that allow tubing to remain connected continuously, thereby eliminating the need to repeatedly connect and disconnect tubing when infusions are started and stopped. Prompt removal of unnecessary central lines is also a key practice in CLABSI prevention, and the CCTP should discuss the need to remove unnecessary central lines with referring staff.

Central Venous Lines

Central venous lines are invasive catheters placed inside the central venous system that provide access to the core vessels of the body. The right internal jugular vein **FIGURE 15-15** is the easiest site to access and in which to insert a central venous line because of the desirable surrounding anatomy and a relatively low rate of complications. Subclavian sites are preferred because they best minimize infection risks. Femoral and brachial veins are also commonly used sites, although femoral lines are strongly discouraged in adults because they have the highest risk for infection of any central venous line location.



Internal jugular v.
Subclavian v.
Brachial v.

FIGURE 15-15 The right internal jugular vein is the easiest site to access and insert a central venous line. The subclavian, brachial, and femoral veins are also common sites.

© Jones & Bartlett Learning.

Description

The catheter of a central venous line is inserted until the tip resides just outside the RA (in the superior vena cava). This position allows for CVP readings (also known as right atrial readings). CVP reflects right ventricular preload, intravascular volume status, and right heart function. The normal range for CVP is 2 to 6 mm Hg in a critically ill patient. In healthy patients, CVP often ranges between 0 and –2 mm Hg, because this pressure draws venous blood back to the right heart. This phenomenon is the rationale for use of the Trendelenburg position when placing a central line in a patient with an unknown CVP. It also explains why a laceration of a jugular vessel is likely to be more lethal than a similarly lacerated carotid artery: The former injury carries a greater risk of air embolism.

The CVP waveform is subject to fluctuations during spontaneous and assisted respirations. For this reason, the CCTP should obtain a CVP measurement during end expiration to ensure its accuracy. Most monitors designed for use with critical care patients measure the CVP with a presumption that the patient is being mechanically ventilated.

Indications

In addition to their role in hemodynamic monitoring, central venous lines often include ports for obtaining blood specimens and for delivery of IV fluids and medications. These lines are frequently used when providers are unable to establish adequate peripheral vascular access or require access to the patient’s central circulation to administer medications that cannot safely be given through peripheral sites. In summary, central venous lines provide a means to perform the following care:

- Rapid fluid replacement
- Medication administration
- Rapid access to central circulation
- Invasive monitoring

Contraindications

Some of the relative contraindications to central venous access include the following:

- Significant coagulopathy
- Local trauma to the site of insertion
- Infection at the site of insertion

Complications

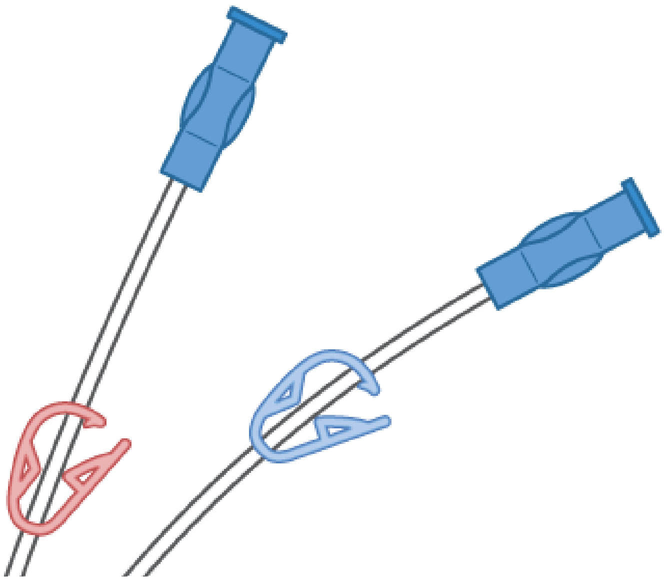
Insertion of a central line carries some risks to the patient, including infection or bleeding at the insertion site. The most common complication is pneumothorax or hemothorax from an unsuccessful attempt at subclavian insertion. Additional complications include the following:

- Air embolism
- Infection
- Thrombosis
- Phlebitis
- Limb ischemia
- Arterial puncture
- Improper placement
- Myocardial perforation (resulting in tamponade)
- Thoracic duct injury (with left internal jugular or subclavian approaches)
- Nerve injury

- Catheter occlusion
- Sluggish infusion
- Catheter damage with resultant air embolism or infection
- Blood withdrawal problems (inability to obtain specimens)
- Retained guide wire

Types of Central Venous Catheters

The most commonly used central line in critical care has three lumens and is simply referred to as a **triple-lumen catheter** **FIGURE 15-16**. All three lumens can be used for phlebotomy or fluid and drug administration; alternatively, two lumens can be used for fluid administration and the other for CVP monitoring. In some cases, one port of a triple-lumen catheter may be reserved for total parenteral nutrition and should not be used during transport, except in an emergency. Other types of central venous catheters include those that have one or two access ports and those that are tunneled under the skin, a design appropriate for long-term use for IV medications, hemodialysis, or parenteral nutrition. Emergency use of these catheters should be guided by direction from the receiving facility and local protocols.



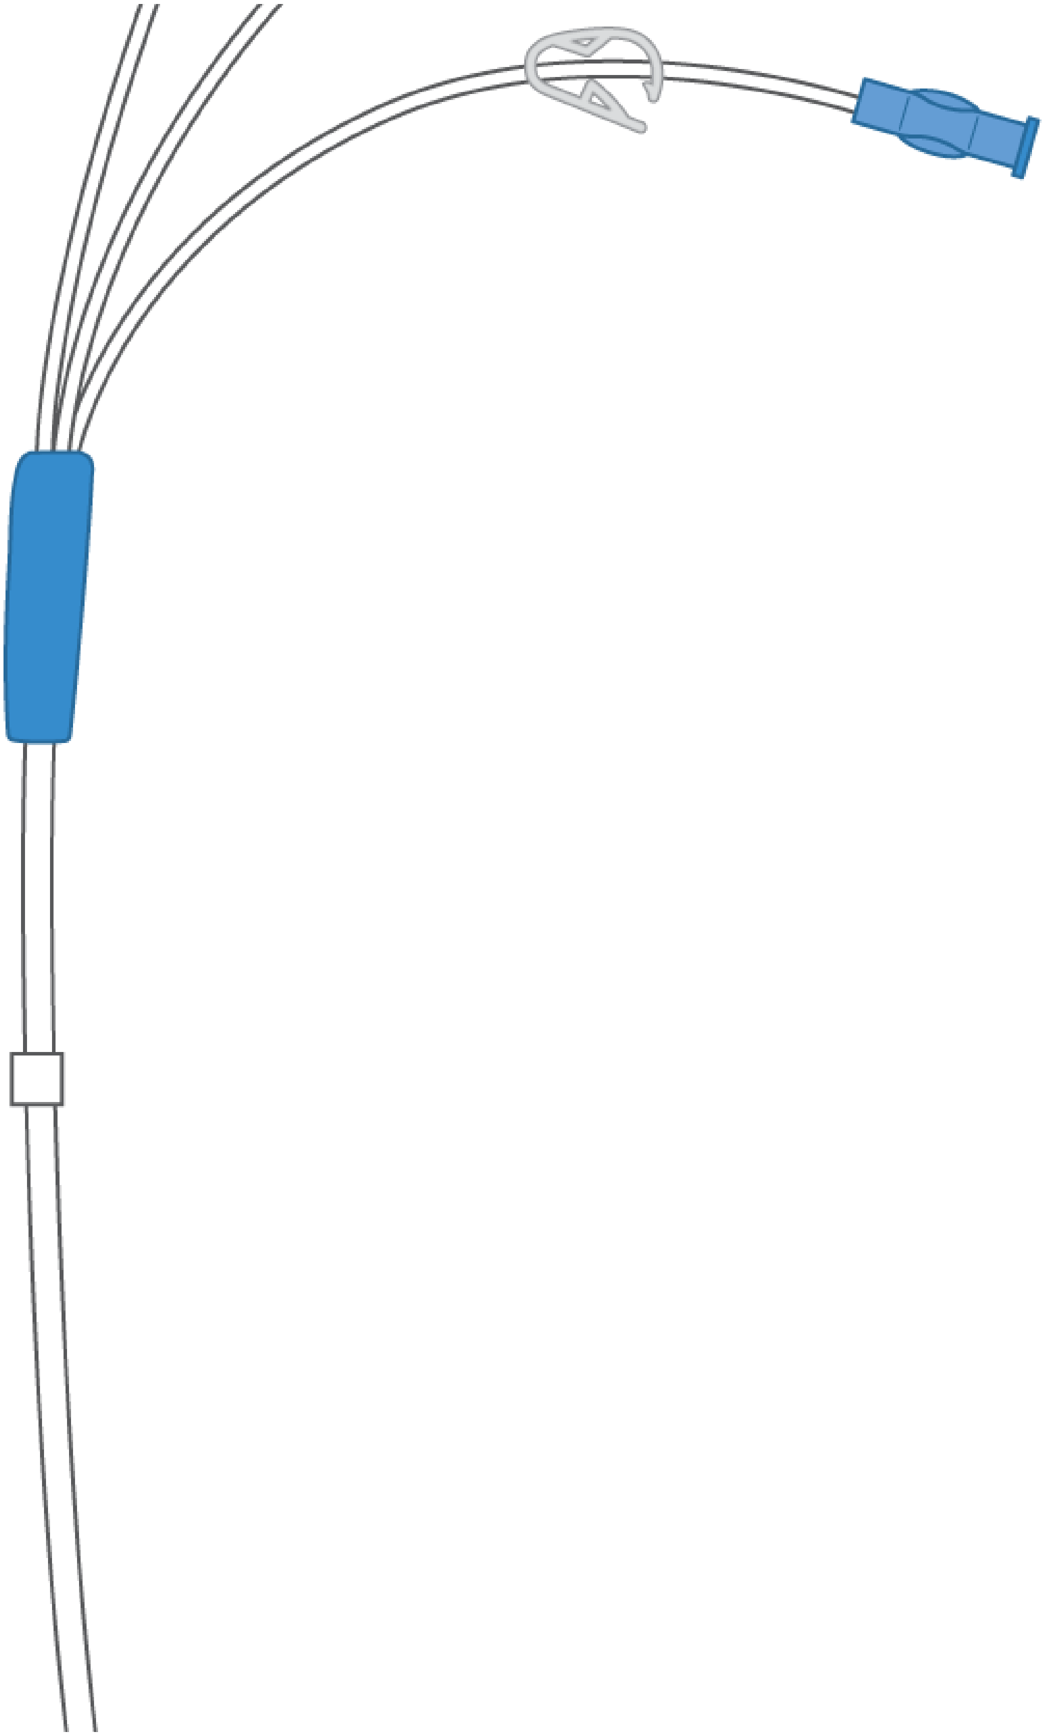


FIGURE 15-16 Hickman triple-lumen catheter.

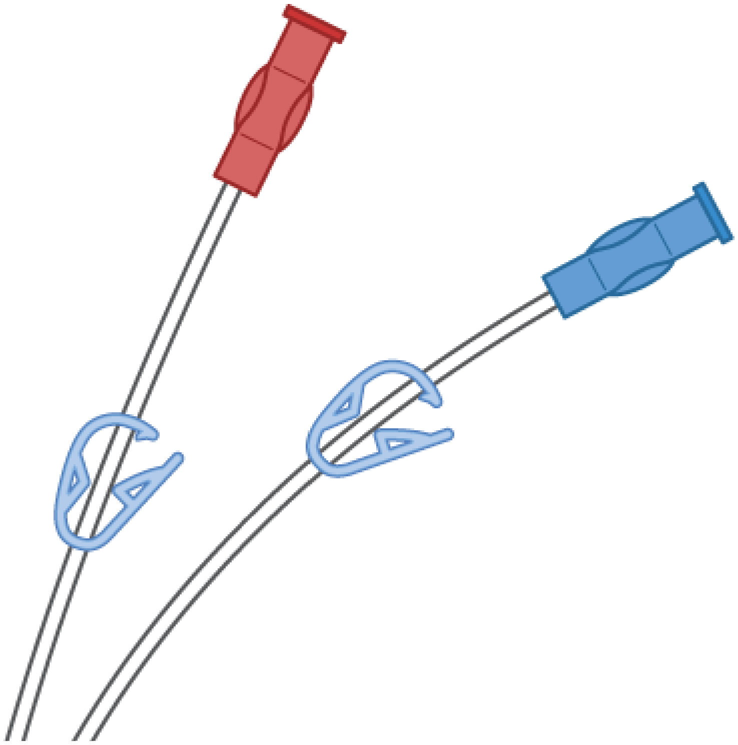
© Jones & Bartlett Learning.

The Hickman catheter **FIGURE 15-17** is a long-term central venous catheter used for venous access and for drawing blood. This line can be placed into the cephalic, subclavian, or external or internal jugular vein, with the distal tip advanced to just above the RA. The proximal end of the catheter exits from the lower portion of the anterior chest wall via a subcutaneous tunnel. Daily flushing of this line is necessary to prevent it from clotting and is also required every time the line is used to draw blood.



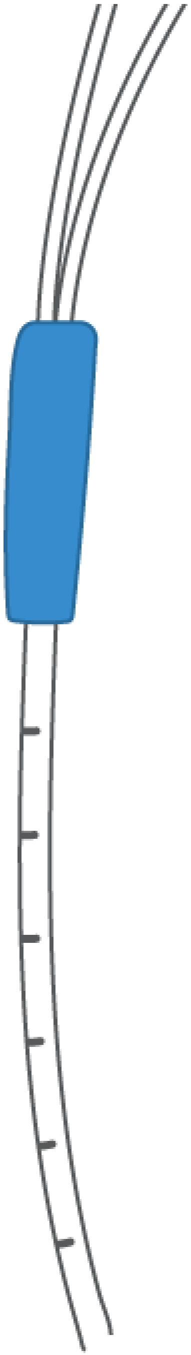


FIGURE 15-17 Hickman catheter.

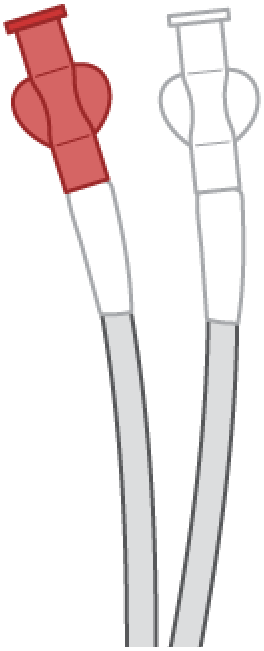
© Jones & Bartlett Learning.

Complications associated with the Hickman catheter include clotting of the line, catheter breakage, and infection of the catheter or insertion site. If the line becomes clotted, it should not be force-flushed because the catheter could rupture and, more importantly, a thrombus could be released into the circulatory system. If catheter breakage does occur, a soft clamp should be placed between the break and the patient’s skin until repair of the catheter can be accomplished. If a soft catheter clamp is unavailable, the CCTP should fold the distal end of the catheter over itself several times and wrap it with a rubber band. Infection at the insertion site is evidenced by erythema, edema, or discharge. Catheter infection is often apparent as bacteremia, with fever and chills progressing to septic shock if not recognized and promptly treated. All complications should be reported to the receiving facility on arrival.

The Groshong catheter **FIGURE 15-18** is thinner, is more flexible, can have up to three lumens, and is equipped with a subcutaneous cuff. This catheter usually exits the skin near the nipple. A pressure-sensitive, two-way valve on its adjacent lateral wall allows for the tip of the catheter to be closed. Because venous pressure maintains the valve in the closed position, minimal backflow of blood into the catheter occurs. The advantages of this design are that clamping and frequent flushing are not necessary, although a saline flush is needed after each use or once daily.



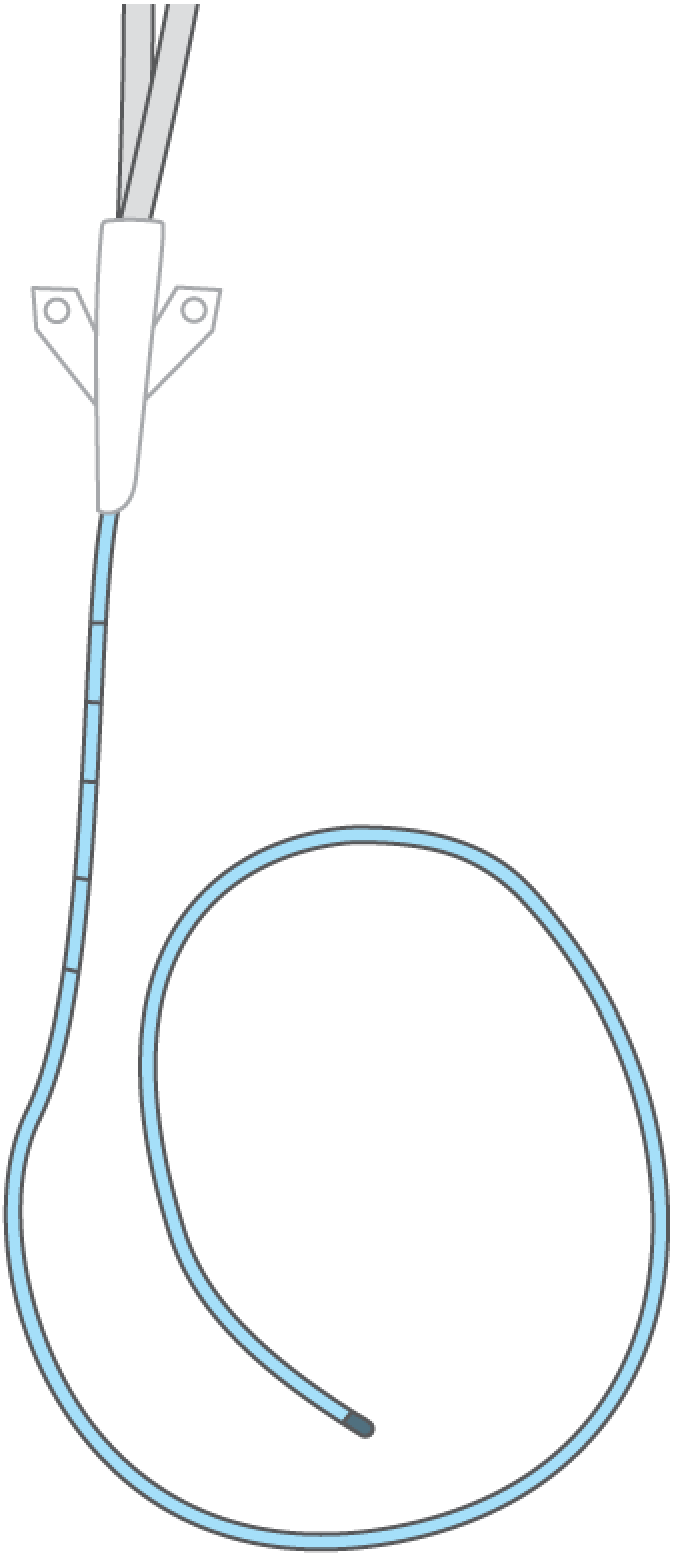


FIGURE 15-18 Groshong catheter.

© Jones & Bartlett Learning.

The Port-A-Cath is a titanium chamber with a catheter that threads under the skin into the subclavian vein to the RA **FIGURE 15-19**. The titanium chamber is 1 × 1 × 0.5–inch (2.5 × 2.5 × 1–cm) in dimension and has a self-sealing rubberlike top, which is implanted under the skin of the anterior part of the chest in the pectoral region. This kind of catheter can be used for the infusion of fluid or medications and for blood draws. It is accessed using a Huber needle, which is inserted through the skin and into the rubber top of the portal. A Huber needle is a specially designed noncoring needle that minimizes damage to the port and bends at a 90° angle, allowing it to be secured to the chest wall after its insertion into the port. The advantages of a Port-A-Cath are that it may remain in place for years with proper care, it allows the patient to be active, and it does not require daily care. The catheter must be flushed with saline (or heparin) once every 4 to 6 weeks if not in use. The risks of the Port-A-Cath are similar to those associated with external catheters and include kinks, ruptures, and, rarely, infections.

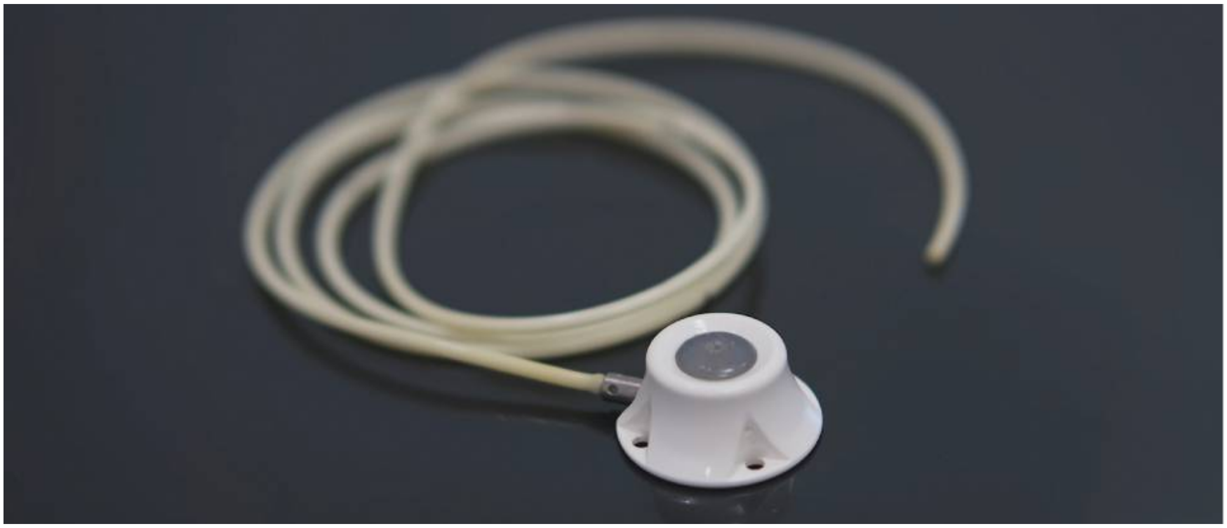

FIGURE 15-19 Port-A-Cath.

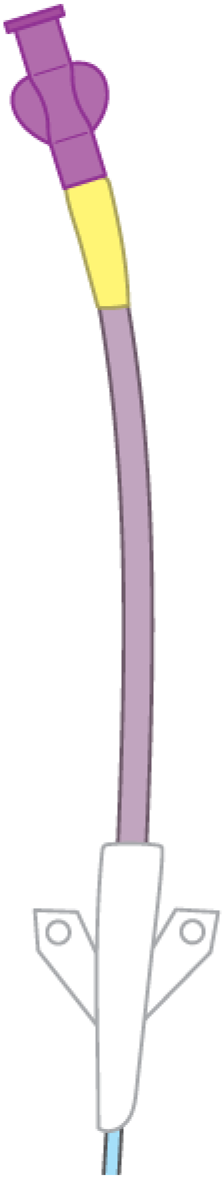
© NINUN/Shutterstock.

A peripherally inserted central catheter (PICC) **FIGURE 15-20** is used when medium-duration, long-term access is needed (usually limited to several months). This catheter can be used in ways similar to other centrally placed lines. It is inserted via the brachial or other arm vein and is advanced to the superior vena cava, with the tip of the line located just outside the atrium. The PICC requires regular flushing with saline solution to prevent clotting. Low-dose warfarin may be added to the patient's daily medications to augment line patency if clotting problems have occurred in the past. The disadvantages of a PICC include limited arm mobility and limitations on aggressive exertion (eg, swimming), in addition to other risks associated with placement of centrally placed catheters.



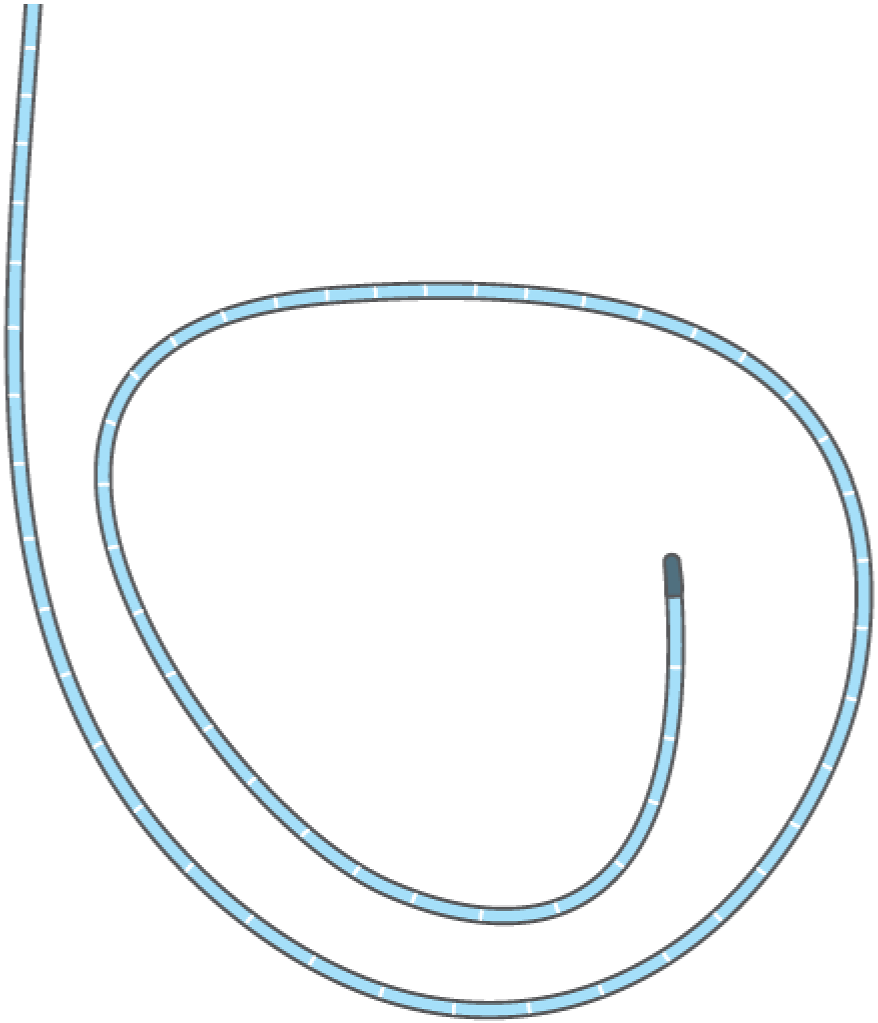


FIGURE 15-20 Power-injectable peripherally inserted central catheter.

Central Venous Catheter Placement

Although central venous catheters are rarely placed by CCTPs, the steps are useful to understand as background knowledge. This section explains how such lines are placed.

Equipment

The following equipment is needed to insert a central venous line:

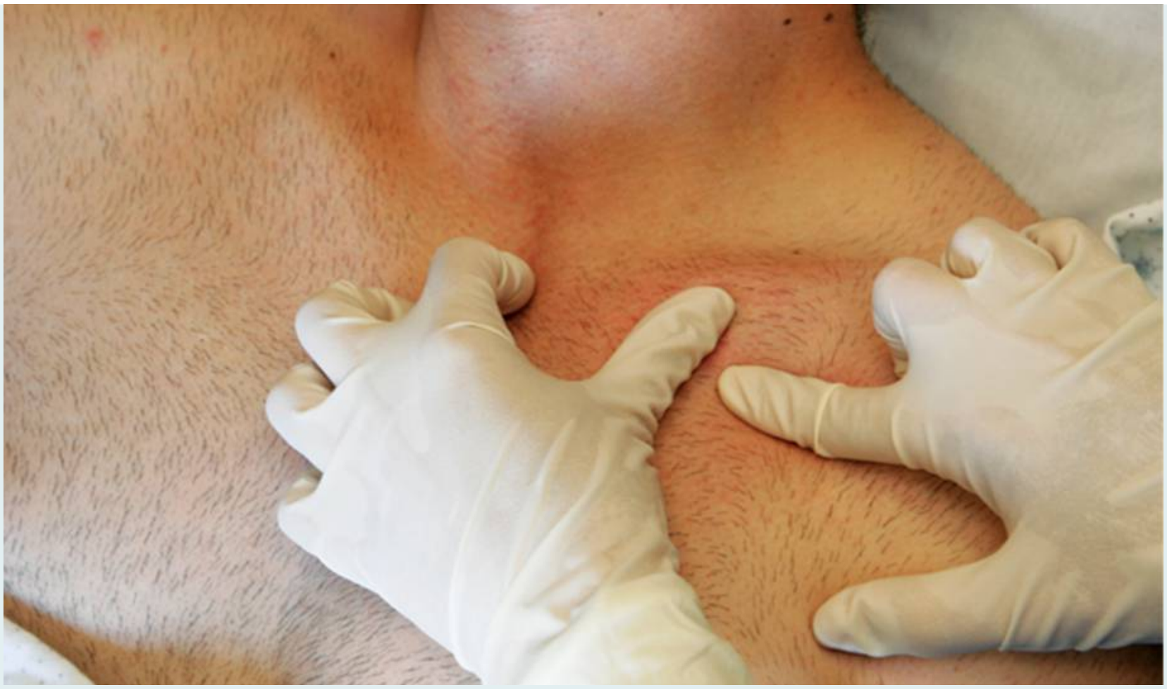
- Catheters (various sizes and lengths)

- 5- and 10-mL syringes
- Saline flush solution
- Chlorhexidine solution
- J-tipped guide wire
- IV tubing
- IV fluids
- Suture materials
- Occlusive dressing
- Sterile drapes
- Tape
- Local anesthetic

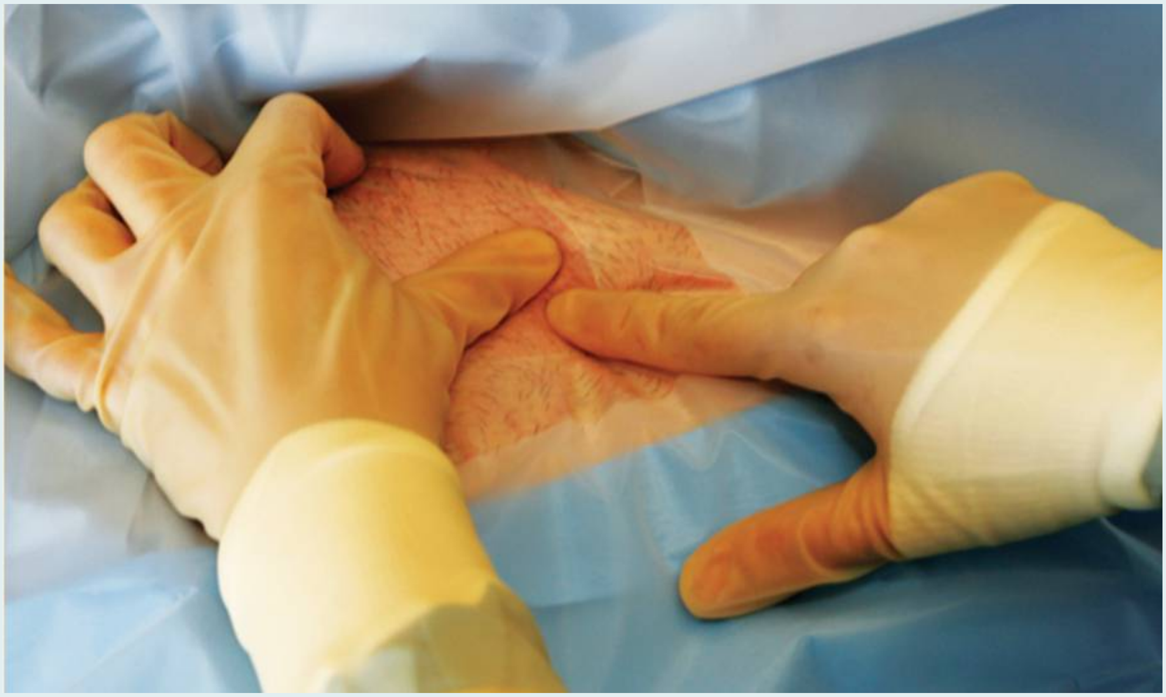
Steps

The most common technique for line insertion is the **Seldinger technique**. **Skill Drill 15-2** outlines the steps for inserting a central venous line using this technique (note that ultrasonography to assist with insertion is becoming commonplace):

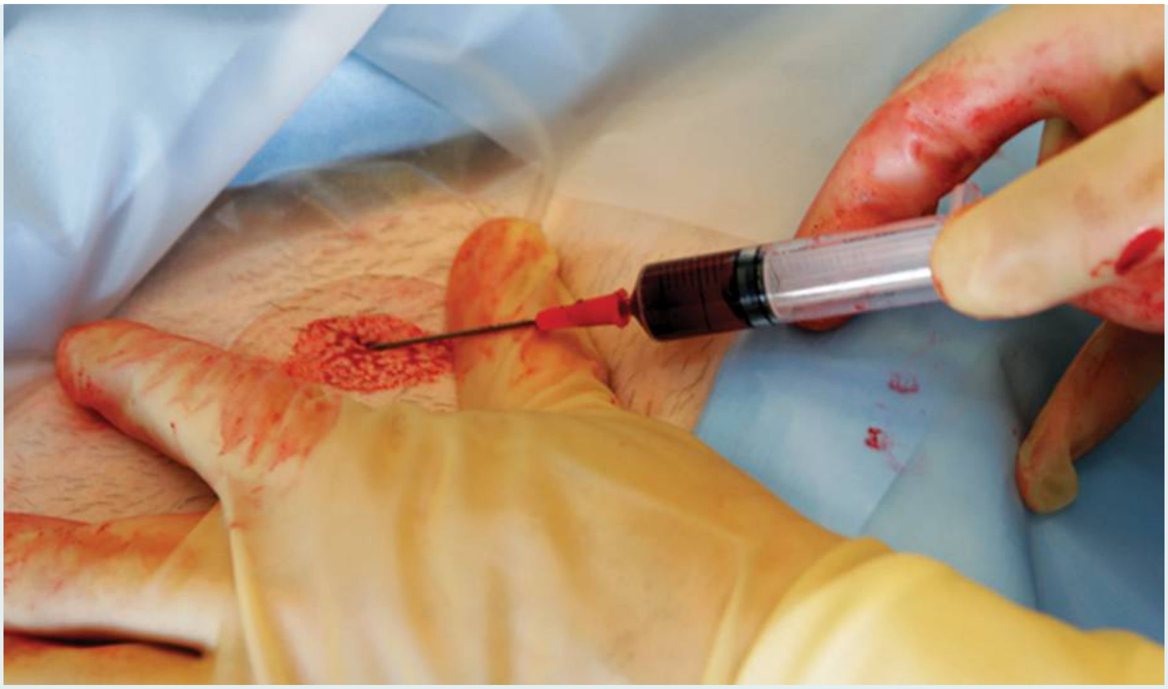
SKILL DRILL 15-2 Inserting a Central Venous Line



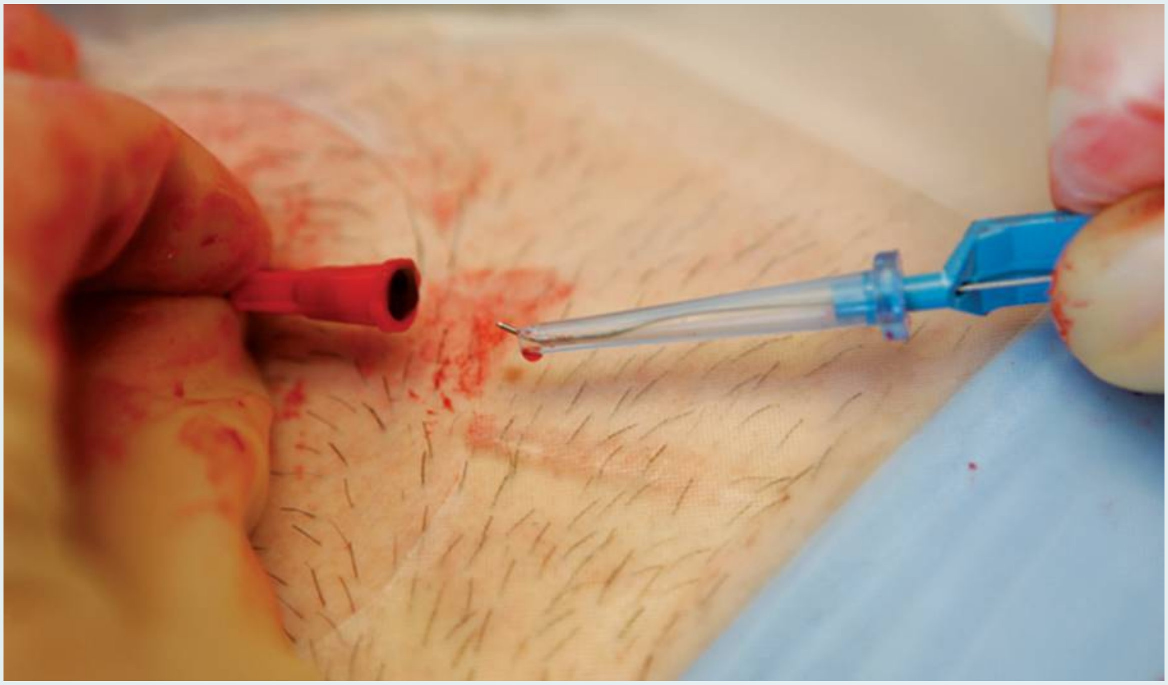
Step 1
Locate the appropriate landmarks.



Step 2
Palpate for the entry location.

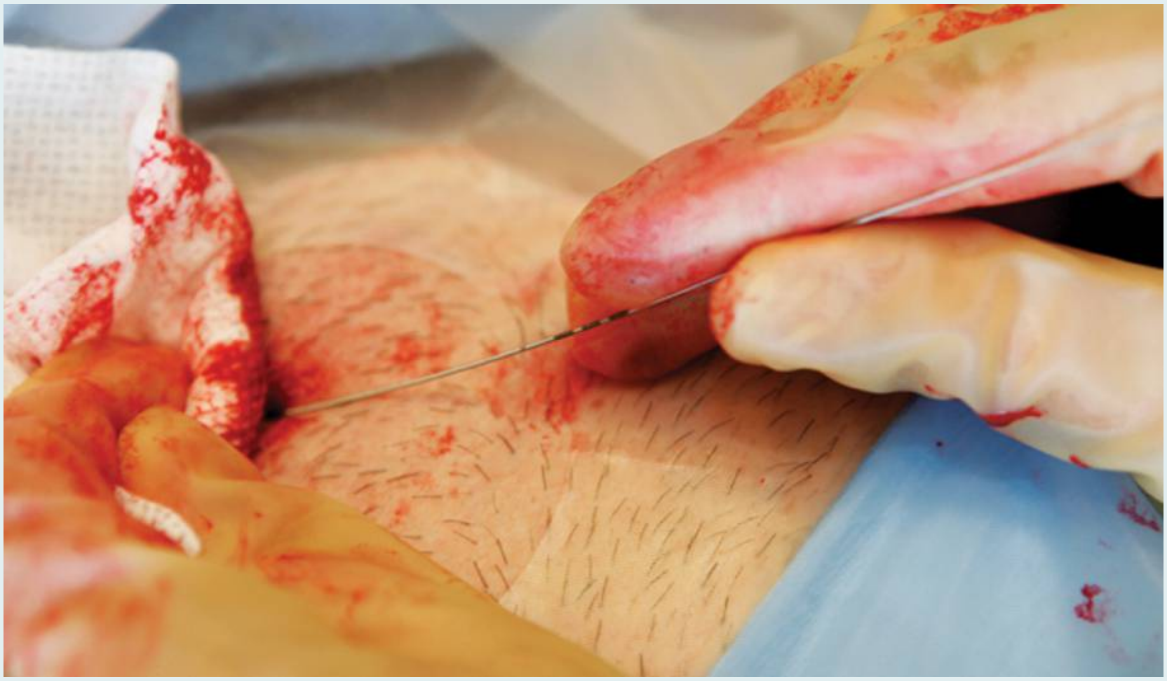


Step 3
Insert the needle with the connected syringe at the site, aspirating until blood is drawn into the syringe.

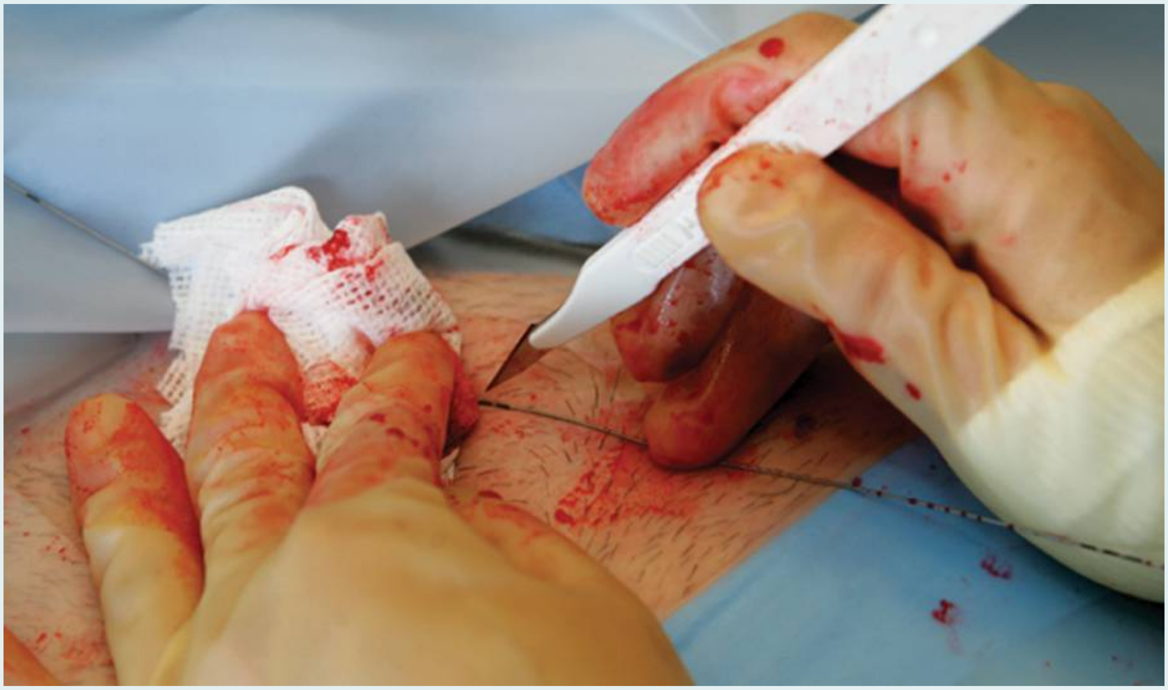


Step 4

Remove the syringe, insert the guide wire into the needle, and feed the guide wire into the vein.

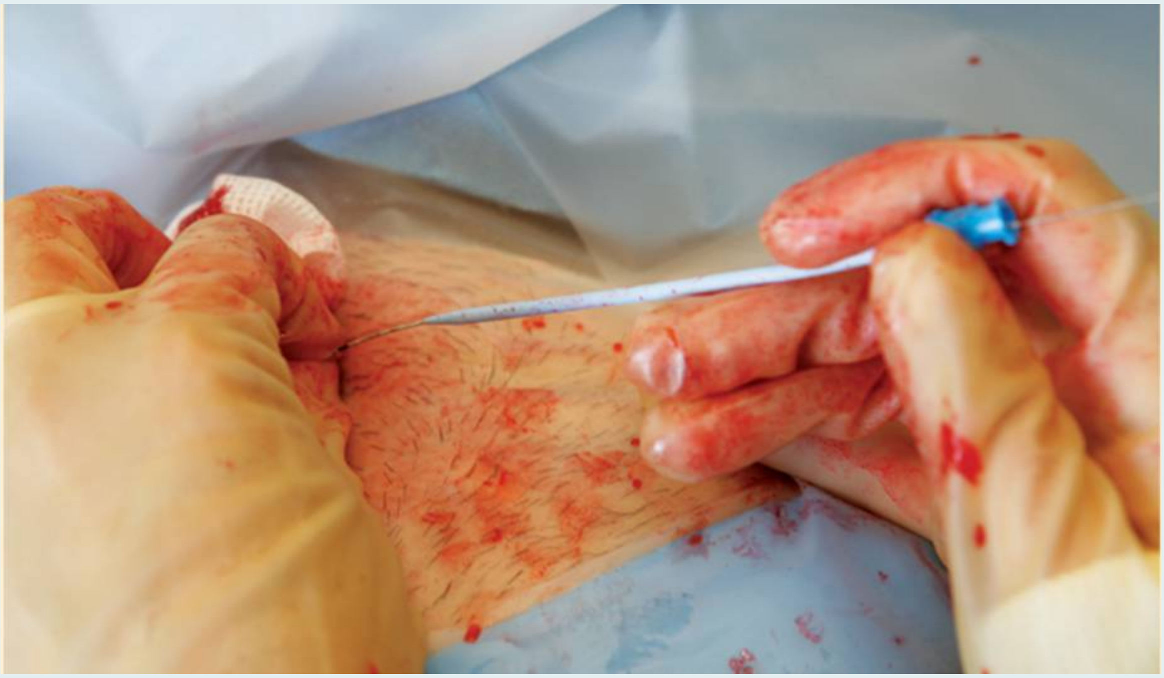


Step 5
Remove the needle while holding the guide wire in place.



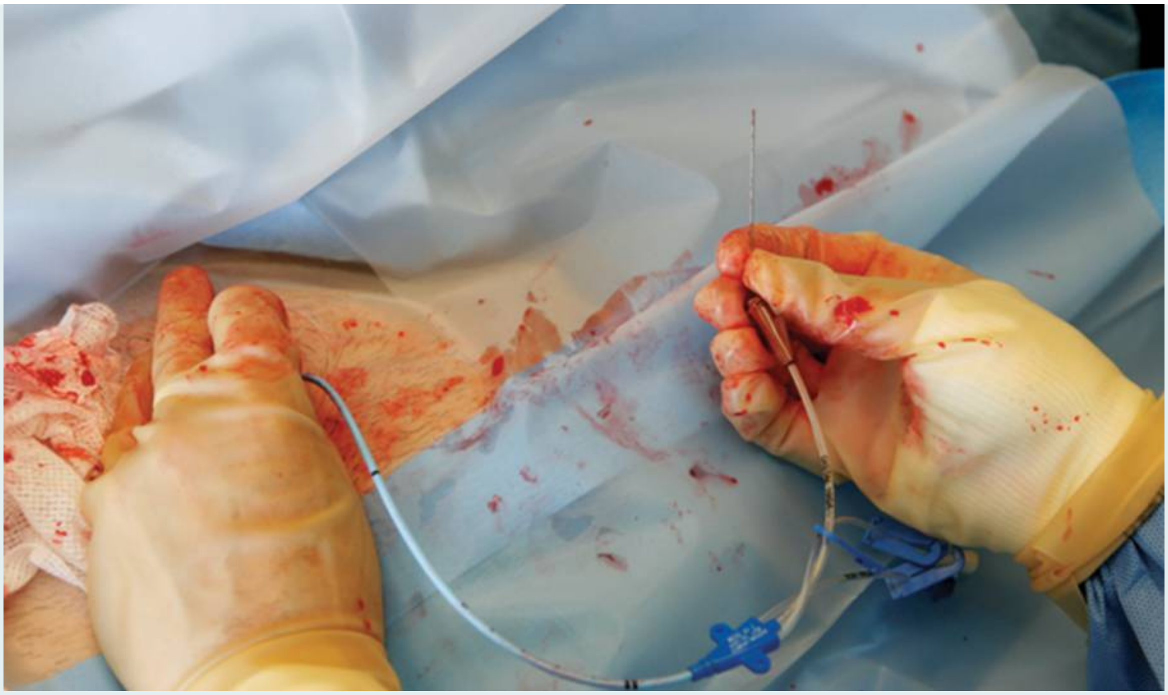
Step 6

Pass the dilator over the guide wire to the skin. Use a scalpel to make a small (approximately 0.25- to 0.5-inch [0.5- to 1-cm]) incision in the skin.

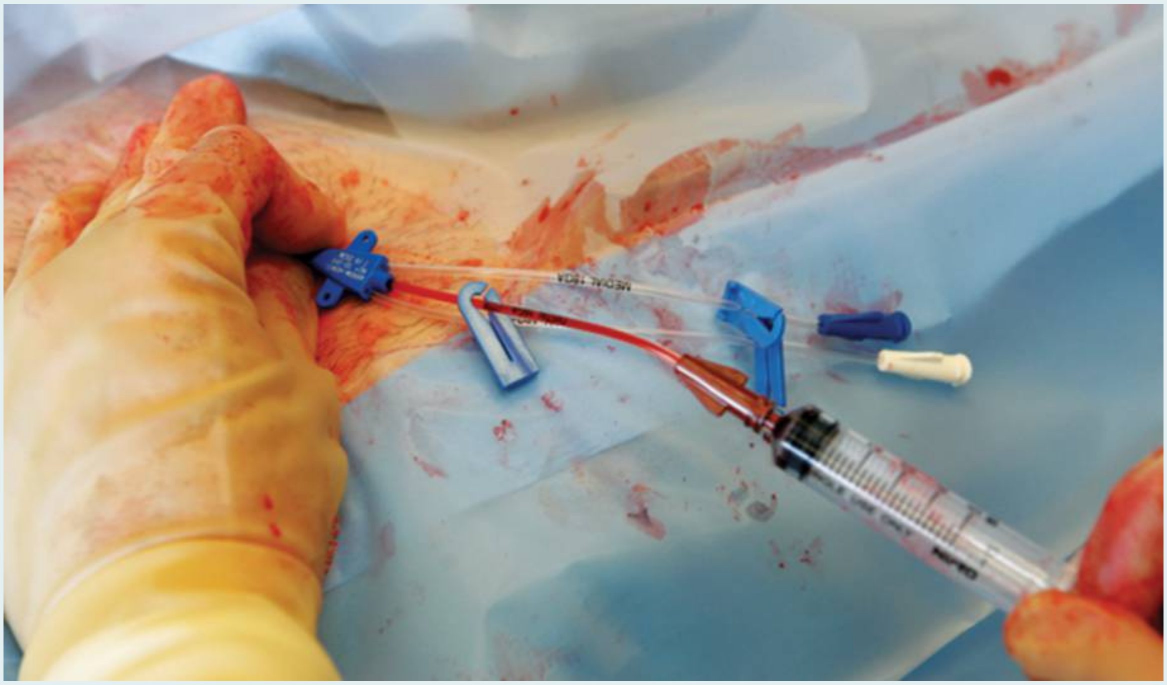


Step 7

Remove the dilator, while maintaining contact with the guide wire.

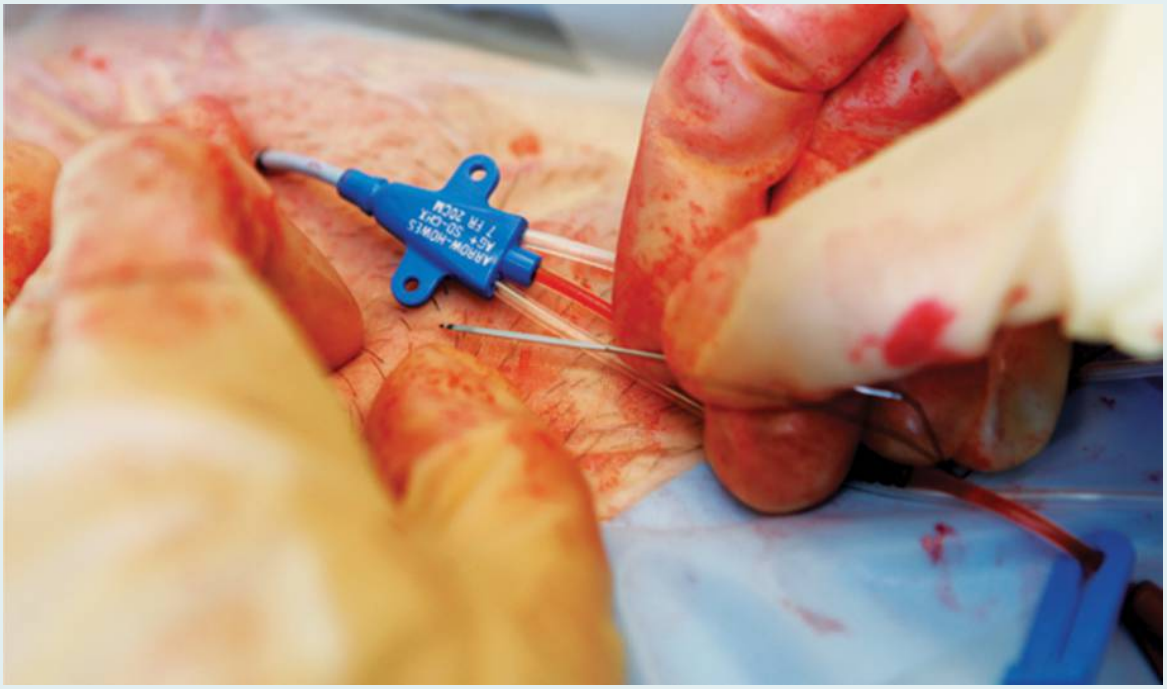


Step 8
Insert the catheter over the guide wire and into the vessel, removing the guide wire as the catheter advances.



Step 9

Aspirate blood and flush all ports to ensure patency.



Step 10
Secure the line to the patient’s skin using sutures or staples.

All images © Jones & Bartlett Learning.

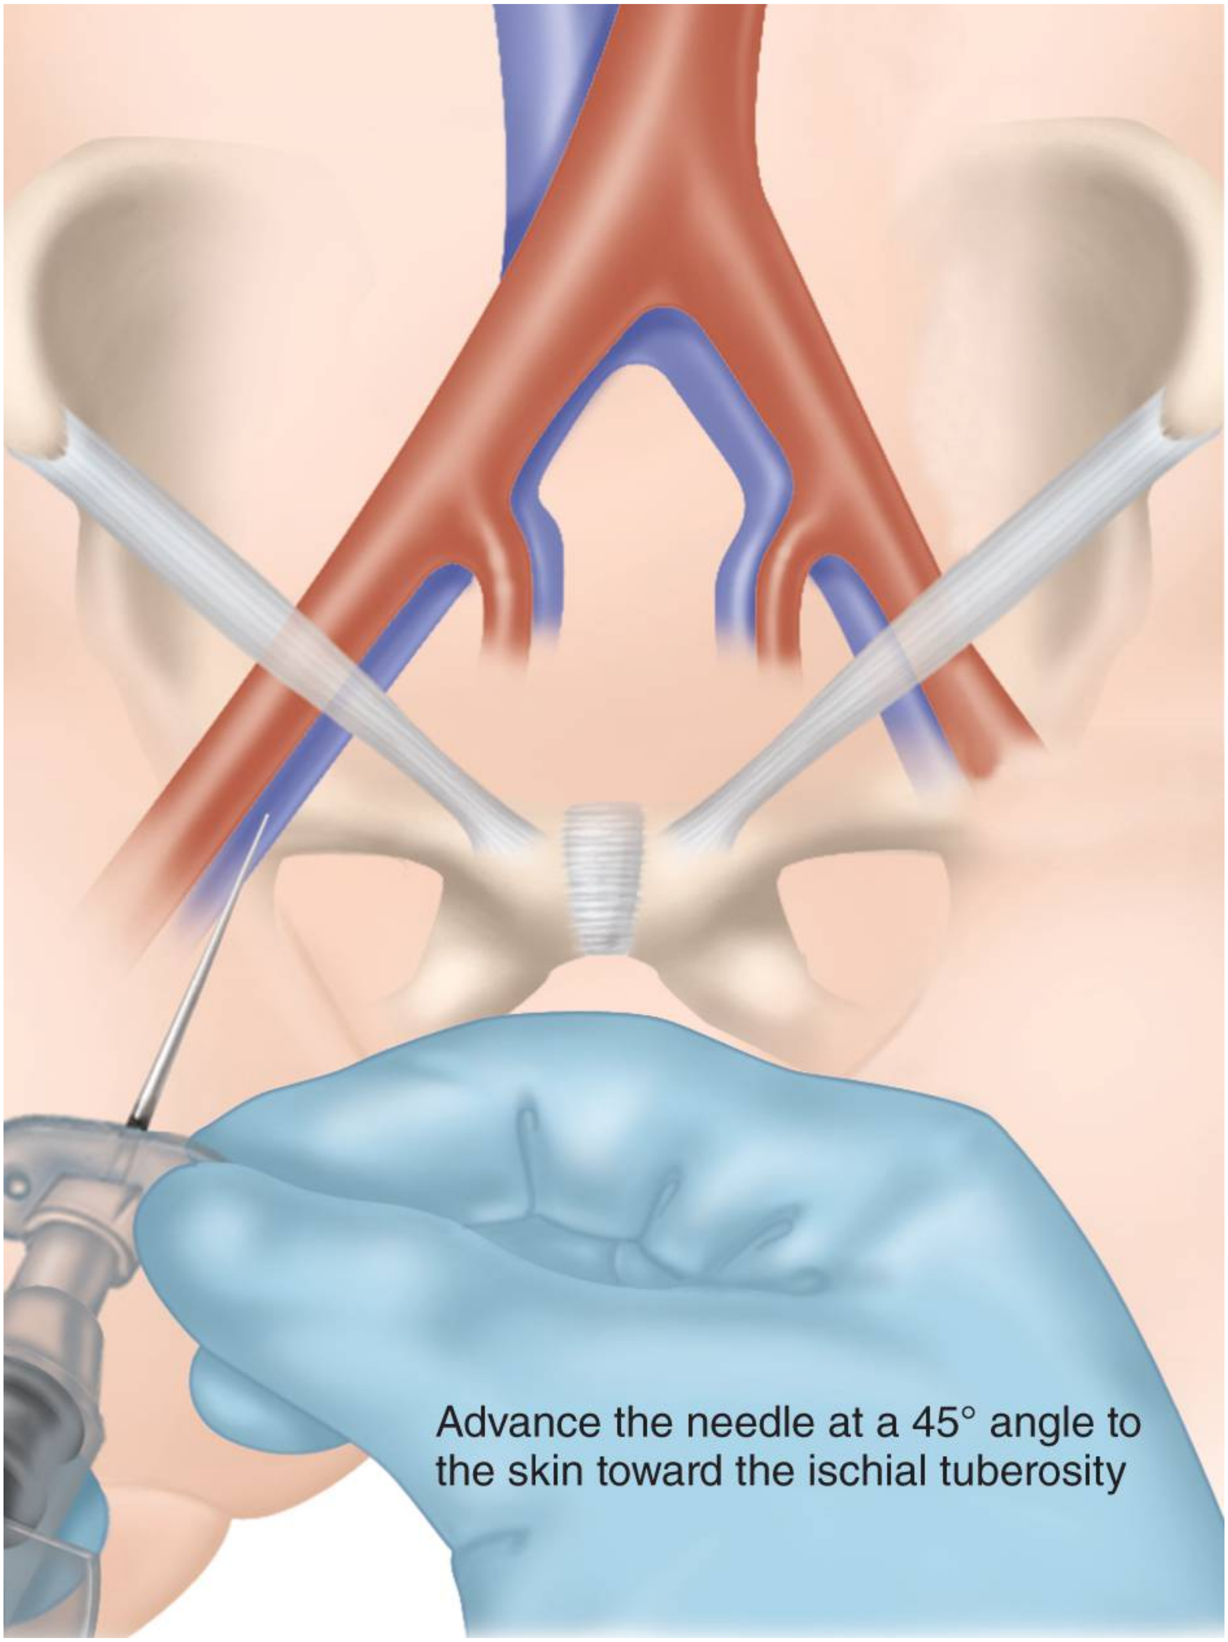
1. Take standard precautions.
2. Prepare all equipment and flush all lumen ports.
3. Locate the appropriate landmarks **STEP 1**.
4. Palpate for the entry location **STEP 2**.
5. Clean and prepare the site using a sterile technique.
6. Administer a local anesthetic.
7. Insert the needle with the connected syringe at the site, aspirating until blood is drawn into the syringe **STEP 3**.
8. Remove the syringe and insert the guide wire into the needle. Feed the needle into the vein, while continually maintaining contact with the guide wire **STEP 4**.
9. Remove the needle while holding the guide wire in place **STEP 5**.

10. Pass the dilator over the guide wire to the skin. Use a scalpel to make a small (approximately 0.25- to 0.5-inch [0.5- to 1-cm]) incision in the skin to facilitate passing of the dilator **STEP 6**.
11. Remove the dilator, while maintaining contact with the guide wire **STEP 7**.
12. Insert the catheter over the guide wire and into the vessel, removing the guide wire as the catheter advances **STEP 8**.
13. Aspirate blood, and flush all ports to ensure patency **STEP 9**.
14. Secure the line to the patient’s skin using sutures or staples **STEP 10**.
15. Dress the site, and follow up with a radiograph to ensure proper line placement. It is imperative that line placement be radiographically confirmed before departing with the patient.

The following lists outline specific procedures for insertion of central lines in the femoral, internal jugular, and subclavian veins.

Steps for femoral vein insertion include the following:

1. Prepare the equipment.
2. Clip hair from the area, and, if necessary, drape the area.
3. Cleanse the area with chlorhexidine antiseptic.
4. Locate the femoral artery.
5. Numb the area using a local anesthetic.
6. Puncture the area two fingerbreadths below the inguinal ligament, medial to the artery, directing the needle cephalad at a 45° angle with the skin until the needle can no longer be advanced **FIGURE 15-21**.
7. Maintain suction on the syringe, and pull the needle back slowly until blood appears in the syringe.
8. Lower the needle so that it is more parallel to the frontal plane. Remove the syringe and insert the catheter.



Advance the needle at a 45° angle to the skin toward the ischial tuberosity

FIGURE 15-21 Femoral vein insertion.

Data from Henretig FM, King CC, eds. *Textbook of Pediatric Emergency Procedures*. Baltimore, MD: Williams and Wilkins; 1997.

Description

Steps for internal jugular vein insertion include the following:

1. Prepare the equipment.
2. Determine the depth of catheter placement by measuring from the point of insertion to the following surface markers on the chest wall **FIGURE 15-22**:
    a. Sternoclavicular joint to the subclavian vein
    b. Midmanubrial area to the brachycephalic vein
    c. Manubriosternal junction to the superior vena cava
    d. 2 inches (5 cm) below the manubriosternal junction (the RA of the heart)
3. Place the tip of the catheter above the RA for administration of fluids.
4. Place the patient in a supine, head-down position at a 15° angle. Extend the patient’s head and turn it away from the side of venipuncture.
5. Cleanse the area with chlorhexidine antiseptic and drape the area. Maintain sterility.
6. Administer a local anesthetic.
7. Insert the needle at a 45° to 60° angle directed caudally **FIGURE 15-23**. Advance to a depth of 1 to 2 inches (3 to 5 cm), depending on the patient’s size.
8. If the vein is not entered, then redirect the needle tip slightly more medially and repeat; do not direct the needle across the midline because the carotid artery may be punctured.
9. After entering the vein, advance the guide wire through the needle; minimal to no resistance should be met. Monitor the ECG during insertion for atrial ectopy.

10. With the guide wire in place, withdraw the needle and advance the catheter to the predetermined depth.

Description

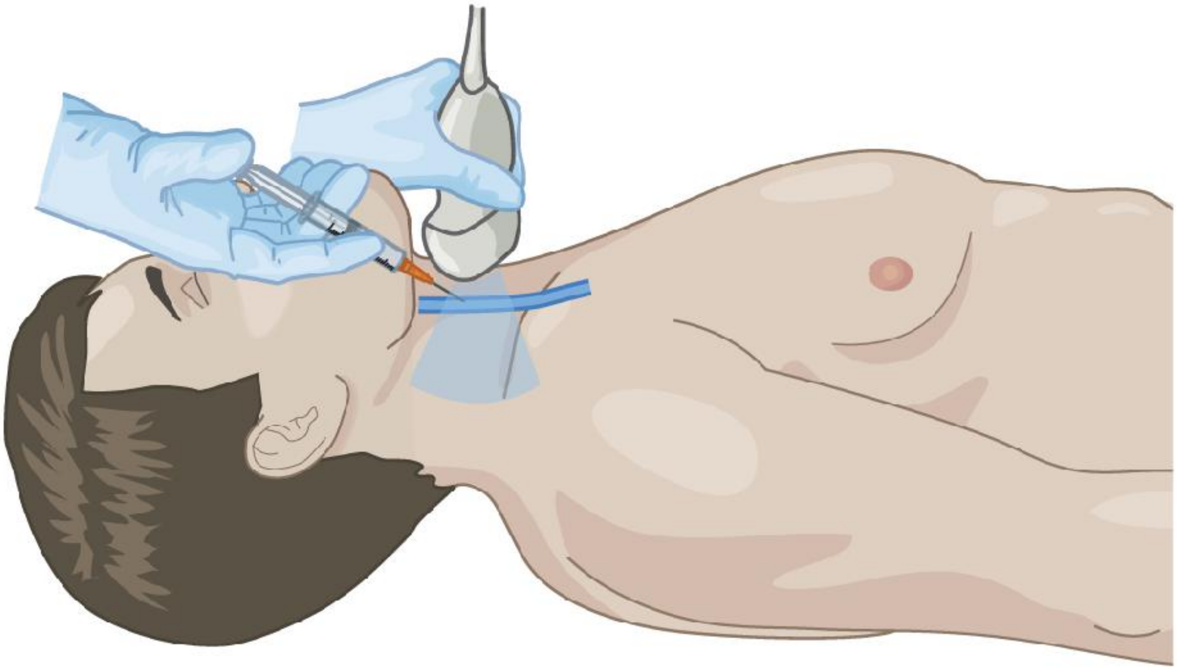

FIGURE 15-23 Internal jugular vein insertion with ultrasonographic guidance.

© Jones & Bartlett Learning.

Steps for subclavian vein insertion include the following:

1. Position the patient in a 15° angle head-down position.
2. Stand at the side of the bed.
3. Turn the patient’s head away from the side to be cannulated.
4. Puncture the skin at the junction of the medial (middle of the clavicle) and middle third of the clavicle **FIGURE 15-24**.
5. Advance the needle beneath the clavicle toward the sternal notch to a depth of 1 to 2 inches (3 to 5 cm).
6. After the lumen of the vein has been entered, rotate the needle cephalad and clockwise 90° and proceed to insert the guide wire and catheter.

Troubleshooting

The problems that most commonly occur when inserting a central venous line are listed in **TABLE 15-2**. The table also identifies potential solutions to these problems.

TABLE 15-2 | **Common Problems Encountered When Inserting a Central Venous Line**

Problem	Possible Actions to Resolve the Problem
Sluggish infusion	Check for kinks in the catheter. Reposition the catheter. Remove the injection cap and check for clots. Flush vigorously with 10 mL of normal saline.
Inability to withdraw blood	Check for kinks in the catheter. Make sure the catheter is not clamped. Flush vigorously with 10 mL of normal saline. Use repositioning maneuvers. Remove the injection cap and attach the syringe. Flush with saline.
Catheter damage	Clamp the catheter between the damaged area and the skin with a soft clamp or fold the distal end of the catheter over itself several times and apply a rubber band. Cover the damaged area with a sterile dressing. Do not attempt to repair.

© Jones & Bartlett Learning.

Pulmonary Artery Catheters

The **pulmonary artery catheter (PAC)** is a flow-directed catheter with a balloon at the tip that allows blood flow to carry the catheter through the heart and into the pulmonary artery, where it terminates. A PAC is also known as a Swan–Ganz catheter (or simply a “swan”) after Harold Jeremy Swan and William Ganz, who invented this catheter in 1970.

Much of our current knowledge of hemodynamics came from frequent use of PACs in patients being treated in the ICU. Overuse of these catheters became a concern in the mid- to late 1990s; during that era, the majority of clinical studies suggested that routine use of PACs was not indicated, because this intervention was associated with a variety of complications, including mortality.

The PAC is a diagnostic, not therapeutic, device. Considerable knowledge and experience are required to properly interpret the hemodynamic data obtained from a PAC. Today, use of PACs is infrequent, but valuable in select situations. These cases include patients with cardiogenic shock, patients being evaluated and treated for pulmonary arterial hypertension, certain patients with severe systolic or diastolic heart failure, patients being assessed for heart and/or lung transplantation, patients undergoing some high-risk operations such as cardiothoracic procedures, patients with acute respiratory distress syndrome (ARDS) who require high levels of PEEP, and other situations where the data derived from a PAC are valuable for diagnostic or therapeutic purposes.

Use of a PAC is outside the scope of practice of most CCTPs and, as described in the following discussion, is not without risks to the patient. When a CCT team is transporting a patient with a PAC in place, a licensed provider such as a critical care registered nurse should accompany the crew. If this is not possible, given the risks and inability of the PAC to provide significant and clinically useful information to the transport team, it may be advisable to discuss removal of this catheter from the patient prior to transport. Because PACs are placed through an introducer, inserting a new one at the destination facility is a relatively simple procedure.

A PAC uses the same access routes as any other central line and can be placed at the bedside within minutes. The catheter is fed into the vena cava and then through the RA **FIGURE 15-25**. Once past the lumen of the introducer sheath, the catheter tip balloon is inflated with as much as 1.5 mL of air to facilitate further placement. With the balloon inflated, the catheter is "floated" through the RA into the right ventricle and ultimately wedges into a proximal branch of the pulmonary artery. After the PAC is in place, the balloon is deflated to allow blood flow around the catheter.

Description

A PAC is 43 inches (110 cm) long and contains multiple lumens that terminate at various points along the length of the catheter, corresponding to different locations in the heart. The PAC is marked at 10-cm intervals beginning at the distal tip of the catheter, with one thin black line representing 10 cm, two thin black lines representing 20 cm, three thin black lines representing 30 cm, and so on, up to one thick black line representing 50 cm, one thick black line accompanied by a thin black line representing 60 cm, one thick black line and two thin lines representing 70 cm, and so on. During the initial assessment, the CCTP should note the centimeter measurement of the PAC at the introducer. This information will help to determine whether the catheter has moved into or out of the patient during transport.

Two of the lumens are connected to pressure transducers that continuously display measurements. The first pressure reading is the RA pressure, and the second pressure reading is the pulmonary artery pressure. The RA pressures are displayed as mean pressures, whereas pulmonary artery pressures are displayed as systolic, diastolic, and mean values. After the PAC is properly placed in the pulmonary artery, inflation of the PAC balloon results in blockage of blood flow from the right ventricle behind the balloon tip and the appearance of a PCWP waveform on the monitor. The PCWP waveform, like the RA pressure, is measured as a mean value.

Complications of PAC insertion are nearly the same as complications of central line insertion, with the addition of pulmonary artery perforation or rupture, pulmonary infarction, arrhythmias, tricuspid and pulmonic valve injury, tamponade, and knotting of the catheter. The greatest potential complication of PAC use is misinterpretation of the data by clinicians, resulting in inappropriate therapy and potentially worsening outcomes.

A **thermistor** used for thermodilution CO measurement is connected to the distal end of the PAC **FIGURE 15-26**. This thermistor provides continuous readings of pulmonary artery temperature, considered the gold standard for core body temperature measurement. Some PACs also have a fiberoptic oximetric catheter at the distal tip for continuous monitoring of mixed venous oxygen saturation.

Description

Although PACs vary in terms of their size and number of lumens, manufacturers have standardized the coloring of the primary PAC lumens. All PACs have a blue RA (proximal) port, a yellow pulmonary artery (distal) port, a red balloon inflation port, and a yellow temperature thermistor port. Some PACs have additional RA and/or right ventricular ports that can be used for infusions or pressure monitoring. Specially designed PACs with integrated pacing wires are available that can be used for transvenous cardiac pacing, as well as PACs with an integrated thermal filament that allows for continuous CO measurement using pulse-coded electrical signals.

Indications

Commonly accepted indications for pulmonary artery catheterization have little or no evidence supporting them and are largely determined by clinician experience, expertise, and preference. As mentioned earlier, a PAC may be warranted when clinicians have a specific question about a patient's hemodynamic status that has not or cannot be readily answered by noninvasive assessment. Use of bedside ultrasonography has greatly diminished the uncertainties that had previously led to insertion of a PAC. Despite common use of these catheters in cardiac operations and frequent insertion of PACs for management of end-stage heart failure, as yet no studies have demonstrated improved outcomes with their use in critically ill patients. Conversely, no clear data prove that a moratorium should be placed on use of PACs. Instead, clinicians need to carefully consider the risks and benefits in critically ill patients on a case-by-case basis.

Some situations in which the use of a PAC might be considered include the following:

- Differentiation among causes of shock
- Determination of the mechanisms responsible for pulmonary edema
- Evaluation or diagnosis of intracardiac shunt(s)
- Evaluation and treatment of pulmonary hypertension
- Perioperative and postoperative care of patients with unstable cardiac status
- Management of complex myocardial infarction (MI)
- Care of patients undergoing cardiac operations
- Guidance for titration of inotropic, vasopressor, or vasodilator therapy
- Complex fluid volume status management
- Assessment of cardiac performance
- Evaluation of patients for heart, lung, or heart and lung transplantation

Contraindications

As with central venous catheterization, few absolute contraindications exist to pulmonary artery catheterization, although the risks of PAC use are greater than those associated with the use of central venous catheters alone. Relative contraindications to the use of PACs include the following:

- Significant coagulopathy
- Local trauma to the site of insertion
- Infection at the site of insertion
- Inability to float the PAC into the pulmonary artery

Pulmonary Artery Catheter Placement

Equipment

The following equipment is needed to insert a PAC:

- The PAC
- A PAC introducer kit (must be 0.5F to 1F larger than the PAC)
- Sterile gowns and drapes for complete draping of the patient and bedside area
- ECG and pulse oximetry monitoring
- Transducer setup
- Patient monitor and cables to connect to transducers
- Thermodilution CO set **FIGURE 15-27**
- Appropriate antiseptic solution (usually chlorhexidine)
- 2% lidocaine and atropine (to treat arrhythmias during the procedure)

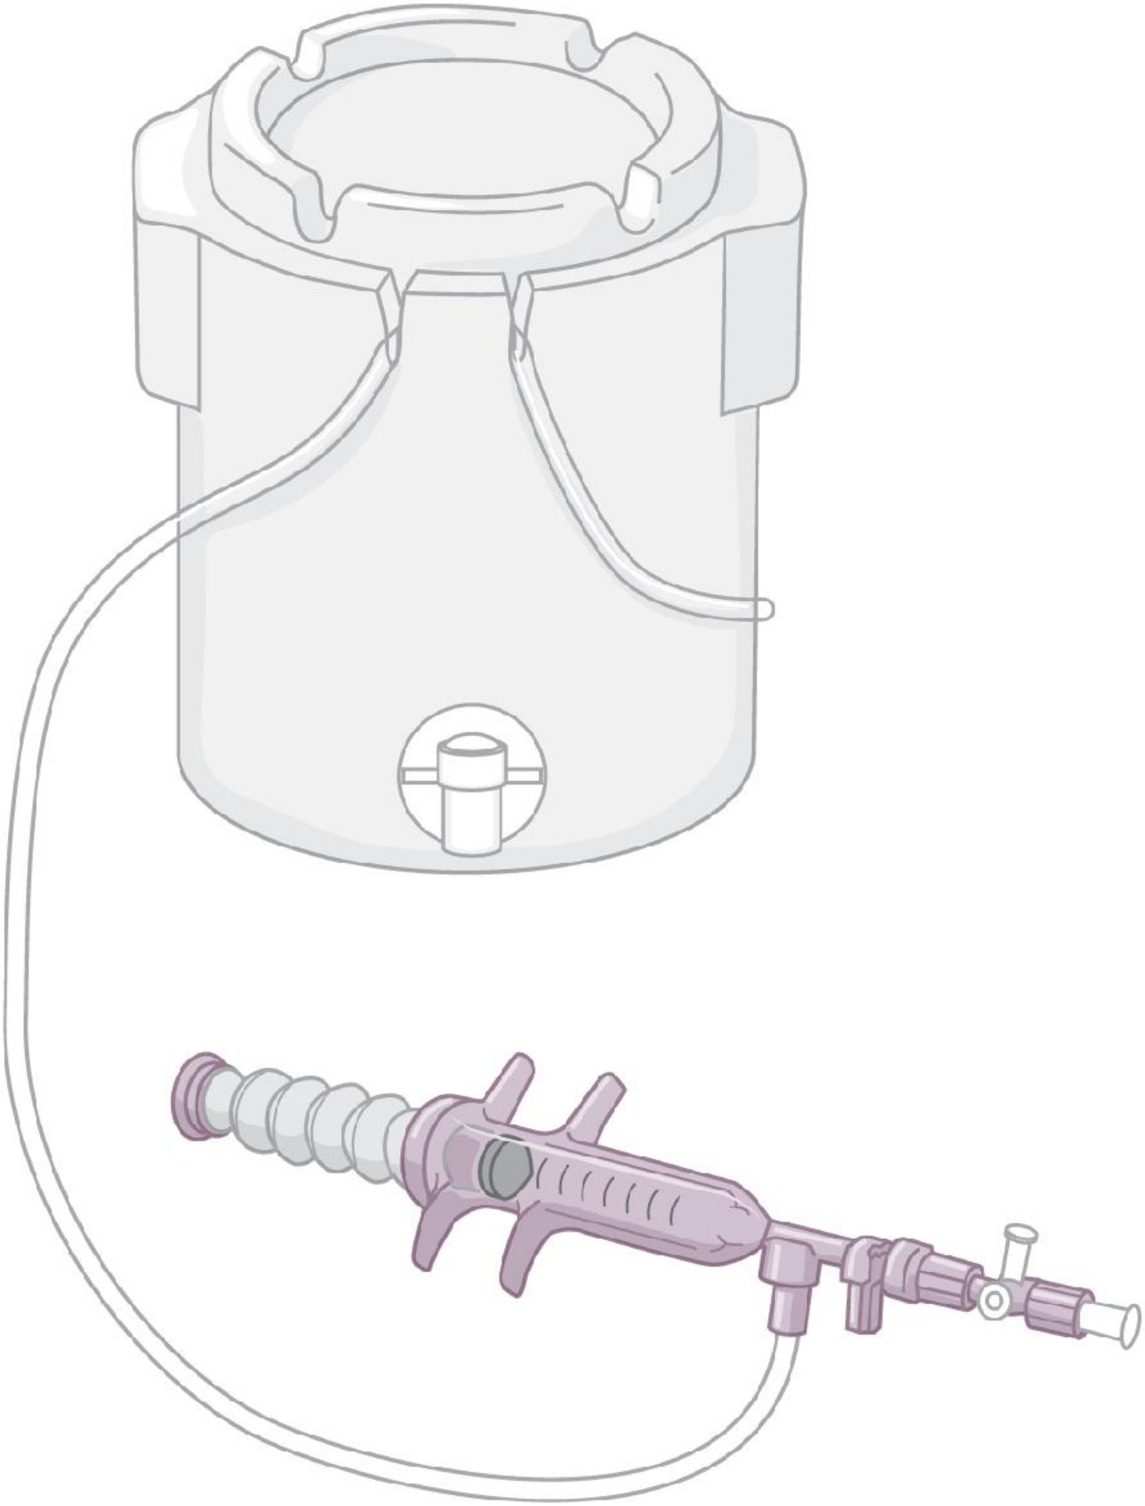

FIGURE 15-27 A thermodilution cardiac output set.

© Jones & Bartlett Learning.

Steps

Although the CCTP would not insert a PAC, the steps are listed here to provide useful background knowledge:

1. Assemble and connect the transducers to the monitor.
2. Zero the transducers (described previously in the section “Leveling and Zeroing the Pressure Transducer”).
3. Assemble the equipment.
4. Position the patient in reverse Trendelenburg (head-down) position, arms by their side, with their head turned in the opposite direction of the intended cannulation site.
5. Ensure that cardiac and pulse oximetry monitoring devices are in place and functioning.
6. Establish a sterile field. Open the introducer supplies.
7. Prepare the insertion site.
8. Administer a local anesthetic agent.
9. Prepare the introducer equipment while awaiting the onset of anesthetic effects.
10. Cannulate the vein at the selected insertion site using an 18-gauge or larger needle that is attached to an empty 10-mL syringe.
11. After the vein has been entered and the IV position of the needle has been confirmed, pass a Seldinger wire (included in the introducer insertion supplies) through the needle.
12. Remove the needle.
13. Widen the skin opening using a scalpel.
14. Using a dilator, pass the PAC introducer over the wire into the vein. Remove and discard the wire.
15. Aspirate and flush the side port of the introducer with sterile saline.
16. Secure the introducer to the skin with suture(s).
17. Prepare the PAC by flushing the ports. Connect it to the transducer(s) and slide the sterile sleeve over the catheter.

18. Test the PAC balloon and distal port to ensure that the waveform appears on the monitor.
19. Advance the PAC through the introducer.
20. Inflate the balloon after the PAC is past the distal end of the introducer (usually 6 inches [15 cm]).
21. Advance the PAC to the wedge position, by observing the waveforms on the monitor, through the RA, right ventricle, and pulmonary artery.
22. If arrhythmias occur while the PAC is in the right ventricle, quickly advance the PAC into the pulmonary artery.
23. After the pulmonary artery wedge tracing is observed, deflate the balloon to check for return of the pulmonary artery pressure waveform.
24. With the balloon deflated, pull back the catheter 0.5 to 0.75 inch (1 to 2 cm) and recheck wedge function.
25. Wedging the catheter should require 1 to 1.5 mL of air. If the catheter wedges with less than 1 mL of air, it has been inserted too far and should be pulled back slightly.
26. Secure the sterile sheath to the introducer and attach the PAC to the patient to prevent accidental dislodgement.
27. Obtain an anterior–posterior chest radiograph to check for pneumothorax and proper catheter position.

Invasive Pressure Measurements

By placing invasive catheters into the vasculature, several hemodynamic parameters can be continually monitored, and others can be periodically assessed. Pressure measurement in hemodynamic monitoring is measured in millimeters of mercury (mm Hg) in the United States; outside the United States, the units for these measurements are torr and kilopascals.

Common hemodynamic parameters are listed here. The line from which the measurement is obtained is shown in parentheses after each item, and the values that are calculated by a provider (rather than obtained from the device) are noted.

- CVP (central line, large-bore antecubital line, or PAC)
- SVV, PPV, PVI (arterial line or pulse oximeter pleth, measured)
- SBP (arterial line, calculated when using an electronic cuff)
- DBP (arterial line, calculated when using an electronic cuff)
- MAP (arterial line or electronic cuff, calculated or computed if using a manual cuff measurement)
- Pulse pressure (arterial line, calculated)
- Pulmonary artery pressure (systolic, diastolic, and mean) (PAC)
- PCWP (PAC)
- CO (PAC)
- PVR (PAC, calculated)
- SVR (PAC, calculated)
- SV (PAC, calculated)
- Mixed venous oxygen saturation (PAC)
- Central venous oxygen saturation (central line)
- TBSA (calculated using height and weight)
- CI (PAC, calculated)

- Ejection fraction, left heart (ultrasonography, calculated)

Normal ranges and values for invasive and noninvasive measurements are given in **TABLE 15-3**.

TABLE 15-3 **Normal Ranges and Values for Hemodynamic Measurements**

Assessment Parameter	Normal Range/Value
CVP	2 to 6 mm Hg
PPV	9% to 13% (>13% suggests fluid responsiveness)
SVV/PVI	10% to 15% (>15% suggests fluid responsiveness)
SBP	100 to 120 mm Hg
DBP	60 to 80 mm Hg
MAP	70 to 105 mm Hg
Pulse pressure	40 to 60 mm Hg
Heart rate	60 to 100 mm Hg
Pulmonary artery pressure, systemic	15 to 30 mm Hg
Pulmonary artery pressure, diastolic	8 to 15 mm Hg
PCWP	4 to 12 mm Hg
CO	4 to 8 L/min
CI	2.2 to 4 L/min/m^2
PVR	100 to 250 dyne-sec/cm^{-5}
SVR	800 to 1,200 dyne-sec/cm^{-5}

Assessment Parameter	Normal Range/Value
SV	60 to 100 mL/beat
SvO_2	60% to 80%
$ScvO_2$	70% to 90%
SV index	30 to 50 mL/beat/m^2
EF	55% to 75% (mean normal 65%)

Abbreviations: CI, cardiac index; CO, cardiac output; CVP, central venous pressure; DBP, diastolic blood pressure; EF, ejection fraction; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; PPV, pulse pressure variation; PVI, pleth variability index; PVR, pulmonary vascular resistance; SBP, systolic blood pressure; $Scvo_2$, mixed central venous oxygen saturation; SV, stroke volume; Svo_2, mixed venous oxygen saturation; SVR, systemic vascular resistance; SVV, stroke volume variation

Measurements From an Arterial Line

Pressure Waveforms

The following pressure changes occur in the LV during the cardiac cycle:

1. At the beginning of the cardiac cycle, aortic pressure is at its lowest (ie, diastolic) level. The elastic state and vascular resistance of the arteries determine this pressure. During diastole, the AV valves are open and blood flows passively from the atria into the ventricles. The pressures in the ventricles and atria are nearly equal and significantly lower than the pressure in the aorta.
2. The SA node depolarizes, causing the atria to contract. This contraction causes the pressure in the atria and ventricles to rise. As the impulse is conducted through the ventricles, the pressure rises sharply.
3. When the pressure in the LV exceeds that in the LA, the mitral valve snaps closed. The pressure continues to rise until the pressure in the aorta is exceeded, causing the aortic valve to open.

As the aortic valve opens and blood enters the aorta, the pressure rises to the peak systolic level and then begins to fall as ventricular ejection tapers.

4. The aortic pressure begins to decrease. As the pressure in the LV drops, the pressure in the aorta becomes greater than that in the LV. This change in pressure causes a slight backward flow of blood into the ventricle, and the backward flow causes the aortic valve leaflets to be forced outward and into the closed position, much like the opening of a parachute.
5. As the aortic valve leaflets are forced outward into place, the pressure gradient across the valve increases significantly because the ventricle continues isovolumetric relaxation. The valves bulge slightly under the pressure of the blood from the aorta and then spring back slightly. This springing back causes a slight bump in the aortic pressure waveform, referred to as the **dicrotic notch**, signaling the onset of diastole. With the valve closed and the ventricles continuing to relax, the ventricular pressure decreases rapidly **FIGURE 15-28**.
6. When the pressure in the ventricle is less than the pressure in the atrium, the mitral valve opens and blood begins to flow passively into the ventricle from the atrium.

Description

Arterial BP

Direct BP measurement using an arterial line provides continuous assessment of arterial (or systemic) pressure. Because hemodynamic status can change by the minute, continual BP monitoring can help the CCTP more closely observe patients during transport. An arterial line connected to the transport monitor provides constantly updated SBP, DBP, and MAP values and an arterial waveform **FIGURE 15-29**. Components of the arterial waveform include the dicrotic notch, mean pressure, systole, diastole, systolic pulse pressure, and diastolic pulse pressure. The dicrotic notch represents a brief increase in aortic pressure reflected as a notching of the wave. It is caused by the sudden closure and springing back of the aortic valve leaflets and signals the start of diastole.

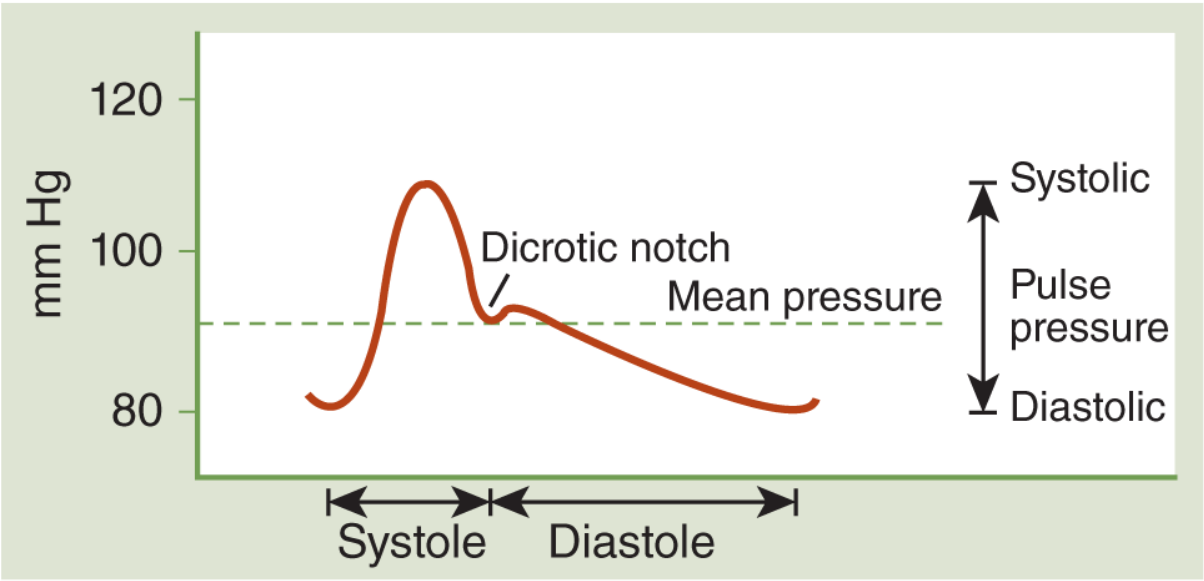

FIGURE 15-29 A blood pressure waveform from an arterial line.

© Jones & Bartlett Learning.

Description

BP readings from an invasive arterial catheter, when properly obtained, have less potential for inaccuracies in measurement compared with BP cuff measurements. Specifically, they are less likely to be associated with problems such as operator error, inappropriate size or placement, and effects of low-flow or high-SVR (shock) states.

Mean Arterial Pressure

An important calculation, sometimes done by the CCTP and sometimes by the machine, is **mean arterial pressure (MAP)**. The MAP is a function of heart rate, SBP, and DBP. It represents the average (ie, constant) pressure that the arterial vasculature feels from the pulsatile nature of the heartbeat.

The MAP is calculated by the transport monitor software, which measures the mean area under the arterial pulse pressure waveform. The reverse calculation is used by NIBP software to derive the SBP and DBP for display. If precisely one-third of the cardiac cycle was spent in systole and two-thirds was spent in diastole, then the MAP could be calculated by using the following formula:

$$\text{MAP} = \text{DBP} + 1/3\ (\text{SBP} - \text{DBP})$$

Because a heart rate of 70 beats/min is typically required to spend one-third of the cardiac cycle in systole and two-thirds of the cycle in diastole, this formula is relatively inaccurate in practice. In contrast, the MAP measured by a transport monitor connected to an arterial line or by an NIPB is the most precise of the pressure measurements available to CCTPs.

The location of an arterial line's placement significantly affects the SBP. The farther out from the heart that an arterial line is placed, the more pressure that will be needed to flow blood and, therefore, the higher the SBP will be. The MAP, however, is unaffected by the location of line placement and is the best parameter to use when making treatment decisions. Usually, a person needs a MAP between

70 and 105 mm Hg to satisfactorily perfuse the tissues. The organs most sensitive to hypotension are the kidneys, which typically require a MAP of 60 mm Hg or higher and are likely to sustain irreversible injury when faced with a MAP of less than 60 mm Hg for more than 20 minutes. For that reason, most medical orders for BP parameters require titration of drugs or administration of fluids to maintain a MAP of 70 mm Hg or greater.

A long-standing debate in critical care has focused on the accuracy of NIBP-obtained BP measurements versus those obtained using an arterial line. Clearly, the NIBP measures flow, whereas the arterial line measures pressure. Nevertheless, there are times, especially when critically ill patients become hypotensive, when clinicians have questioned the accuracy of the arterial line, choosing instead to rely on NIBP readings.

A large study published in 2013 examined data from 4,957 patients in a university teaching hospital whose BP measurements were taken from both an arterial line and an NIBP. When 27,022 simultaneous readings were compared, the researchers found that the NIBP overestimated SBP in patients with hypotension. Moreover, beginning at systolic pressures less than 100 mm Hg, the more hypotensive the patient became, the greater the overestimation by the NIBP was. Despite the difference in SBP, measured MAPs by both arterial line and NIBP consistently correlated down to a MAP of 40 mm Hg. This very large study and many smaller studies like it have fairly conclusively demonstrated that, regardless of whether direct monitoring with an arterial line or indirect monitoring with an NIBP is performed, the MAP is the value that should be used to make treatment decisions. One additional finding in the large 2013 study was that a MAP of less than 60 mm Hg closely correlated with increased incidence of acute kidney injury and death.

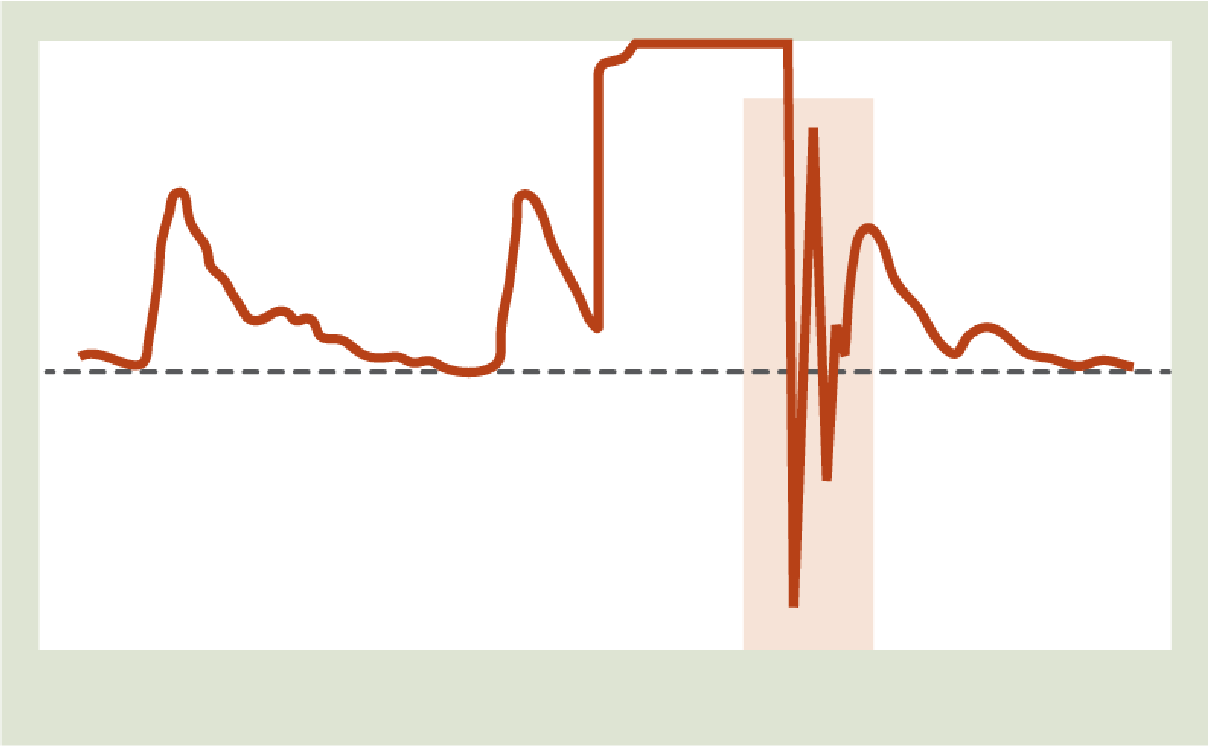
Pulse Pressure

Pulse pressure is the mathematical difference between the SBP and the DBP. Values of 40 to 60 mm Hg are seen in healthy people, but may be altered in critically ill patients.

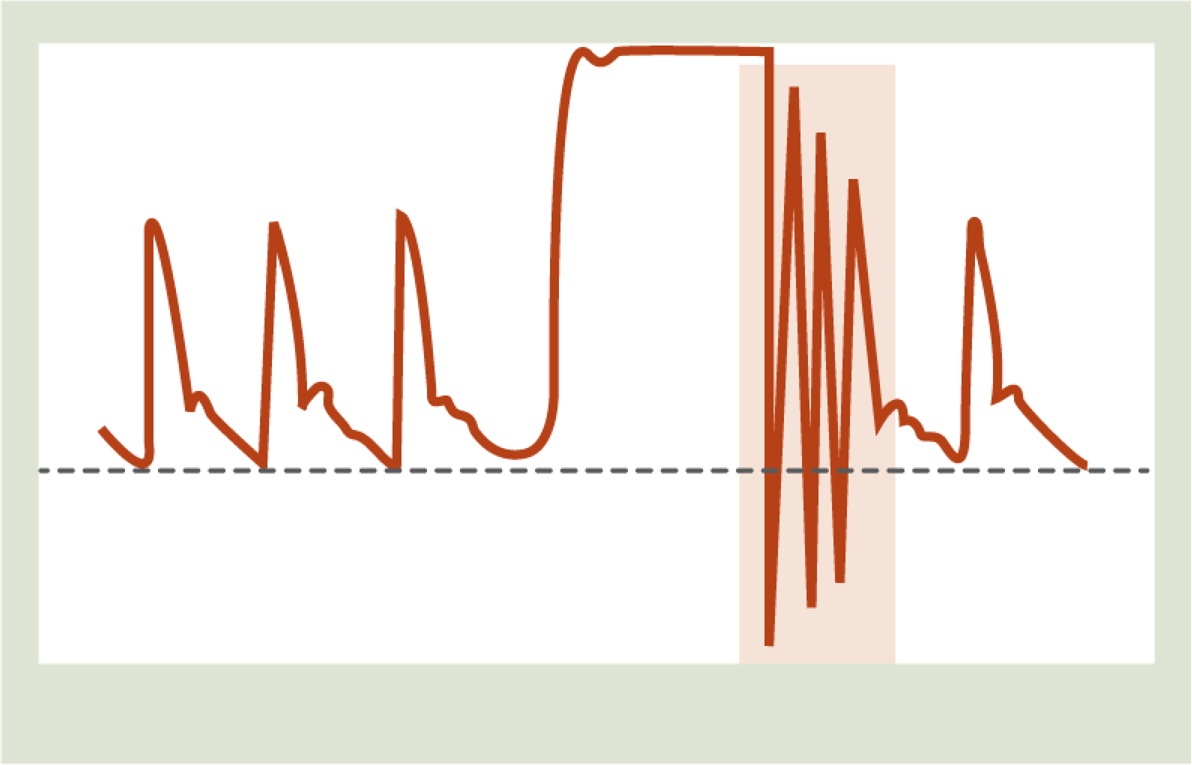
Both SV and vascular compliance affect the pulse pressure. An elevated pulse pressure can be indicative of high SV states (eg, hypervolemia) or low vascular compliance (eg, arteriosclerosis). In these states, SBP increases. If a concomitant rise in DBP is not present, then an elevated pulse pressure develops. Bradycardia can also cause an elevated pulse pressure. In this instance, lower DBP develops because of an extended diastole, which can lead to diastolic runoff. Low SV states (eg, hypovolemia) and high vascular compliance (eg, shock) will cause a decrease in SBP and, therefore, a decrease in pulse pressure (barring a proportional decrease in DBP). Tachycardia may cause a decreased pulse pressure by the reverse of the bradycardia mechanism.

The fast-flush feature previously discussed can also be used to test the accuracy of an arterial line or any transduced pressure. At times, it may appear to the CCTP that a monitoring system may not be accurately reproducing the pressures being measured inside the patient. The ability to reliably reproduce the actual pressures being measured is referred to as dynamic response. Two components make up the dynamic response: the frequency response (FR) and the damping coefficient. The FR is the speed of oscillation or the frequency with which the monitoring device samples the pressure being measured. Modern computers running hemodynamic monitoring software all but ensure sufficient FR. The damping coefficient refers to how quickly the system comes to rest or the shock-absorbing capability of the transducer. A system with too little shock-absorbing capability will not come to rest in between cardiac cycles, causing it to include part of the previous pressure waveform in the next one. This effect, which is called underdamping, often results in the display of falsely high systolic pressure values (ie, overshoot) and sometimes in the display of falsely low diastolic pressures. Often a “ringing” type of artifact is observed in the waveform tracings. In contrast, a system with too much shock-absorbing capability will not be sufficiently responsive so that it can accurately display the pressure waveforms. This effect, which is called overdamping, commonly results in poorly defined waveform tracings, slurred upstrokes, decreased systolic pressures, and increased diastolic pressures.

The fast-flush activator can be used to conduct a test of dynamic response, known as the square wave test or fast-flush test **FIGURE 15-30**. This test is performed by quickly activating and releasing the fast-flush activator, which produces a sharp upstroke on the waveform trace that peaks and flatlines at the maximal point on the monitor and then rapidly descends. The resultant waveform has the appearance of a square wave. Following its descent, the waveform should exhibit one or two oscillations (bounces) and then return to a normal waveform. If multiple oscillations or bounces (more than two) are present, then the system is underdamped. If only one or no oscillations appear following the fast flush, then the system is overdamped.



A



B

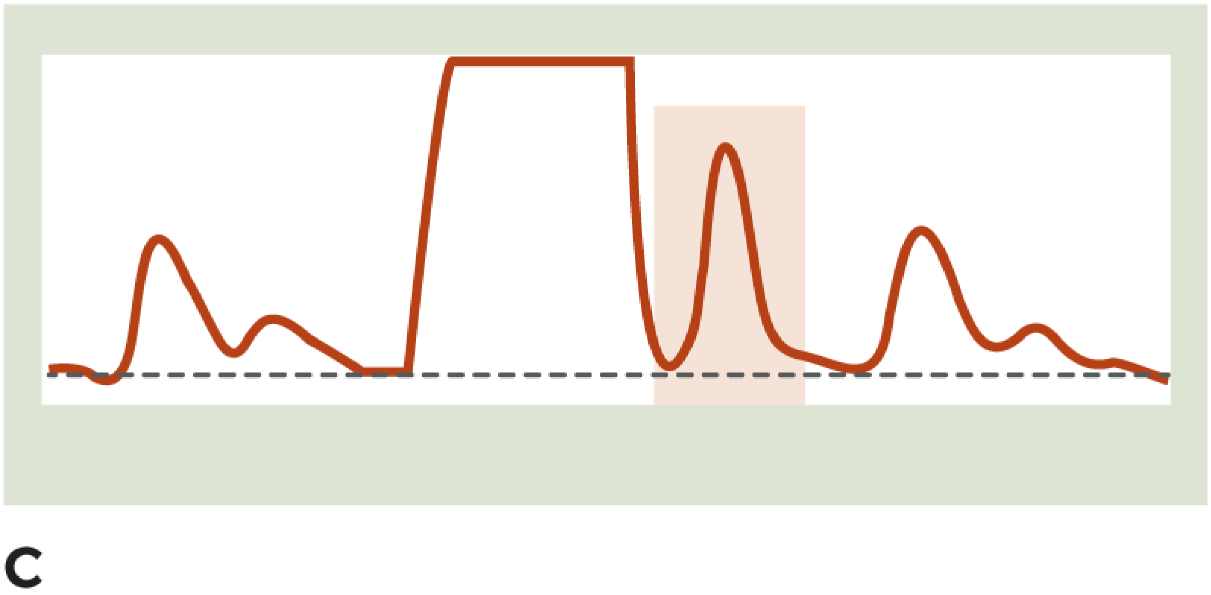


FIGURE 15-30 The square wave test. **A.** Normal test. **B.** Underdamped system. **C.** Overdamped system.

Reproduced from Tintinalli J, Stapczynski J, Ma OJ, Yealy D, Meckler G, Cline D. *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*. 8th ed. New York, NY: McGraw-Hill; 2015.

Troubleshooting an underdamped system may include carefully checking for so-called pinpoint air bubbles in the tubing, assuring the length of tubing between the transducer and catheter does not exceed 48 inches (122 cm), using a commercial damping device, or adjusting the frequency response through the monitor software. Often adjusting the frequency is the fastest and most efficient way to correct an underdamped system.

Overdamping is often caused by excessive length of tubing, clots or large bubbles in the tubing, use of nonrigid tubing instead of rigid pressure monitoring tubing, kinks in the tubing or catheter, or loose connections in the tubing. The most likely place for a kink to occur in an arterial catheter is the site where the catheter enters the skin. Discovering such a kink often requires removing the dressing from the arterial line site and redressing it in a fashion that prevents the catheter from kinking.

Measurements From a Central Venous Line

Central Venous Pressure

Central venous pressure (CVP) is a measure of the vena caval and RA pressures. Even though a CVP waveform tracing has systolic and diastolic values, only the mean value is used in clinical practice because the numbers are extremely low **FIGURE 15-31**. Three positive deflections are seen in the CVP tracing: the ***a*** wave, which represents atrial contraction; the ***c*** wave, which represents closure of the tricuspid valve; and the ***v*** wave, which represents passive atrial filling during diastole. Some textbooks suggest that the components of the CVP waveform can be identified by the corresponding location in an ECG tracing, but this technique is impractical given the varied lengths of tubing used and the differences in ECG monitor display timing between manufacturers.

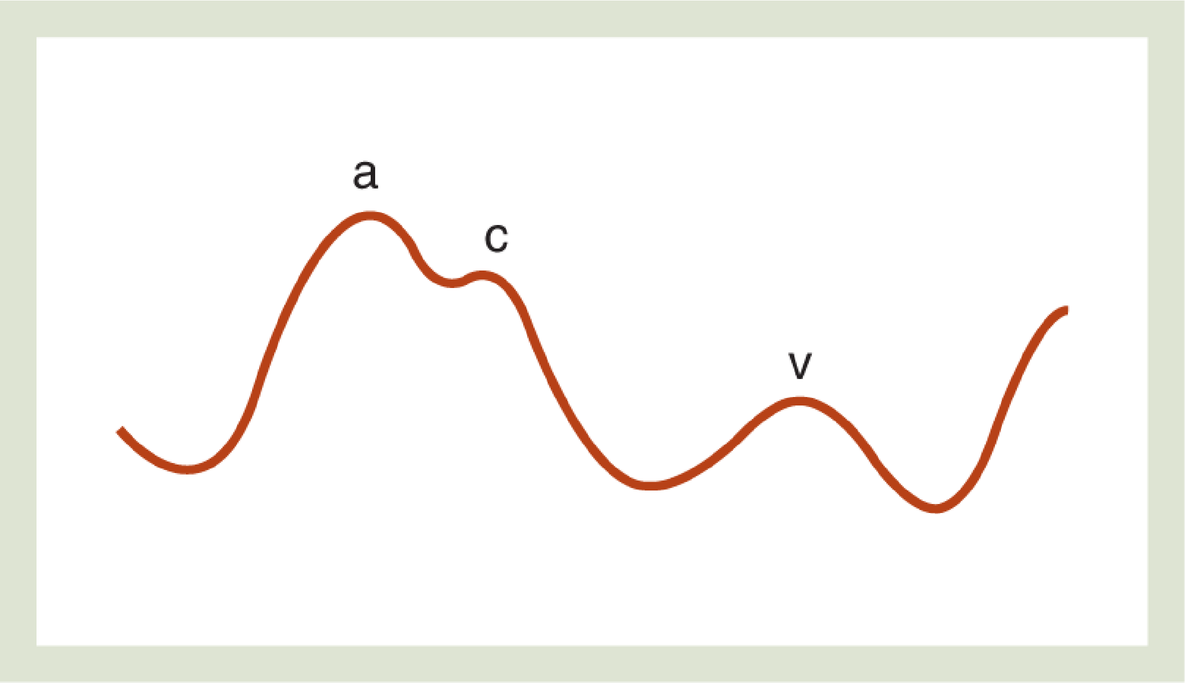

FIGURE 15-31 A central venous pressure waveform.

Modified courtesy of Henry Geiter, Jr., RN, CCRN from www.Nurse411.com. Copyright © 2009.

The absence of ***a*** waves in a CVP tracing suggests that atrial contractions are not occurring or, as in atrial fibrillation, they are so rapid that there is no meaningful output. In fact, when atrial fibrillation is suspected, a CVP tracing showing only ***v*** waves can be helpful in confirming the rhythm.

The normal range for CVP in a critically ill patient was previously listed as 2 to 6 mm Hg. Historically, CVP was considered a reflection of fluid volume status, with patients being given fluid boluses when their CVP fell below 5 to 8 mm Hg. Today, it is understood that as a static parameter, CVP must be interpreted in the context of other information when assessing fluid volume status. Elevated CVP may be suggestive of right-side heart failure, cardiac tamponade, massive pulmonary embolus, significant pulmonary vasoconstriction, or hypervolemia. Healthy patients typically have a CVP ranging from 0 to –2 mm Hg. This negative pressure facilitates a significant percentage of blood return to the heart.

Additional Measurements From a Pulmonary Artery Catheter

Right Ventricular Pressure

Although not routinely monitored or measured, the **right ventricular pressure** is important during insertion and use of a PAC. The right ventricular pressure has three components **FIGURE 15-32**:

- Systolic pressure, usually 20 to 30 mm Hg
- Diastolic pressure, usually 0 to 5 mm Hg
- Mean pressure, usually 10 to 20 mm Hg

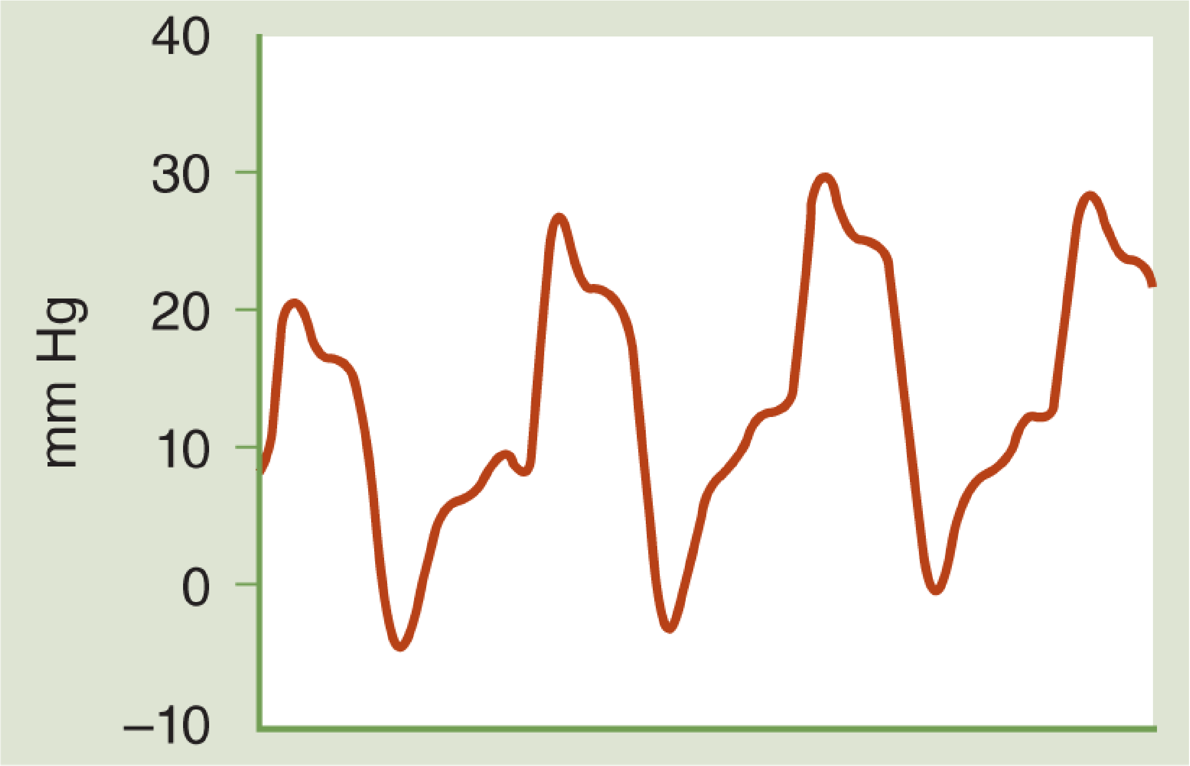

FIGURE 15-32 A right ventricular pressure waveform has a systolic pressure comparable to the pulmonary artery systolic pressure.

© Jones & Bartlett Learning.

Description

Ventricular ectopy is common when the tip of the PAC is in the right ventricle. For this reason, it is important for the CCTP to be able to recognize a right ventricular waveform and its characteristic low diastolic pressure, which distinguishes it from a pulmonary artery pressure waveform.

Pulmonary Artery Pressure

Like the arterial BP waveform, the **pulmonary artery pressure** has three components **FIGURE 15-33**:

- Systolic pressure, usually 15 to 30 mm Hg
- Diastolic pressure, usually 8 to 15 mm Hg
- Mean pulmonary artery pressure, usually 10 to 20 mm Hg

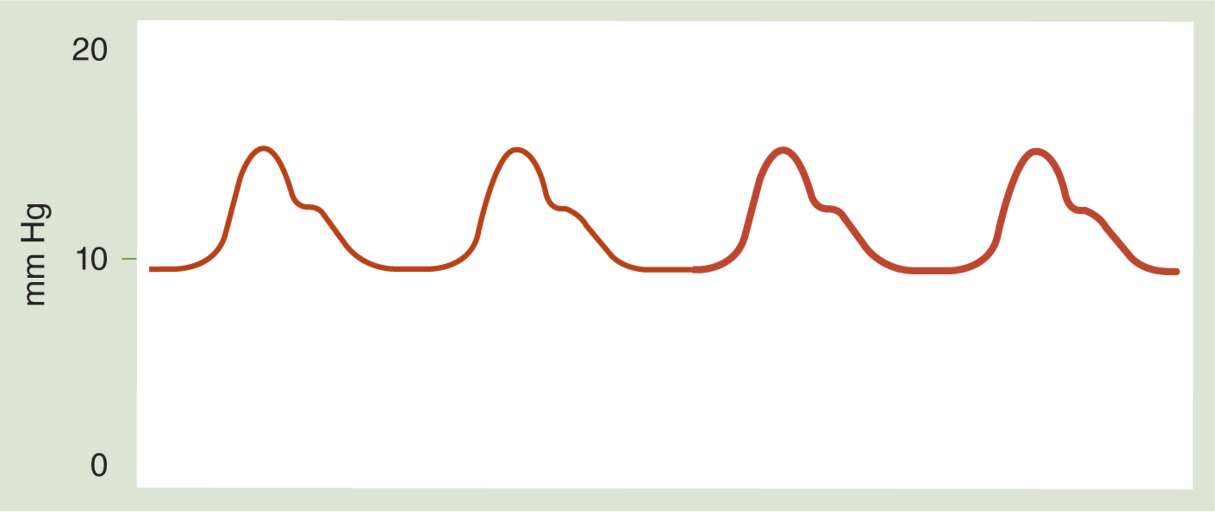

FIGURE 15-33 A pulmonary artery pressure waveform, which is similar to the arterial pressure waveform (ie, systolic, dicrotic notch, and diastolic components).

© Jones & Bartlett Learning.

Description

Pulmonary artery pressures are a function of right ventricular health and the vascular resistance of the pulmonary circuit. Although patients with significant heart failure or pulmonary obstructive disease can have chronically elevated pulmonary artery pressures or pulmonary hypertension, acute elevations in pulmonary artery pressures are unlikely to stem from causes other than hypoxemia or hypercarbia. An astute CCTP who observes a sudden and sustained increase in pulmonary artery pressures will immediately assess and correct any issues with oxygen saturation or ventilation (as reflected by end-tidal carbon dioxide readings or point-of-care blood gas testing).

Elevations in the pulmonary artery pressure can result from conditions that increase pulmonary blood flow, such as atrial and ventricular septal defects or hypervolemia. Elevations in the pulmonary artery diastolic pressure can result from tachycardia (usually greater than 120 beats/min in adults) or pulmonary emboli. Decreased pulmonary artery diastolic pressure can be seen with hypovolemia.

If pulmonary artery diastolic pressures suddenly drop, then the catheter position should be reevaluated to determine if the PAC has migrated into the right ventricle (see the earlier section “Right Ventricular Pressure”).

Pulmonary Capillary Wedge Pressure

Definition

The **pulmonary capillary wedge pressure (PCWP)** reflects LA pressure and was previously considered the gold standard for LV preload assessment. This measurement is also called pulmonary artery occlusion pressure and pulmonary artery wedge pressure. A function of a PAC, PCWP is an intermittent assessment performed by inflating a small balloon on the distal tip of the PAC, which causes the catheter to shift forward to wedge against the opening of the proximal branch of the pulmonary artery. This action occludes the pulmonary artery from any antegrade blood flow. With the tip inflated, the transducer reads a pressure that is equivalent to the left atrial pressure. The left atrial pressure is closely related to and often parallels the **left ventricular end-diastolic pressure**, which is indicative of LV health.

The normal range for PCWP is 4 to 12 mm Hg. A properly obtained PCWP will normally be slightly less than the pulmonary artery diastolic pressure (≤4 mm Hg). A PCWP of 10 to 12 mm Hg had previously been used to differentiate hypovolemia from euvolemia in clinical practice, but as a static measurement, it is no longer considered a valuable assessment of fluid volume status. More commonly, PCWP is followed in patients with heart failure. A PCWP of greater than 18 mm Hg is diagnostic for acute decompensated heart failure.

Interpretation

The CCTP needs to understand how to read the PCWP waveform **FIGURE 15-34**. Hemodynamic waveforms often show variations in the baseline as a result of respiratory-induced intrathoracic pressure fluctuations. Atmospheric and pleural pressures are most closely approximated at end expiration. To eliminate the effects of intrathoracic pressure on PCWP values, they must be measured at end expiration.

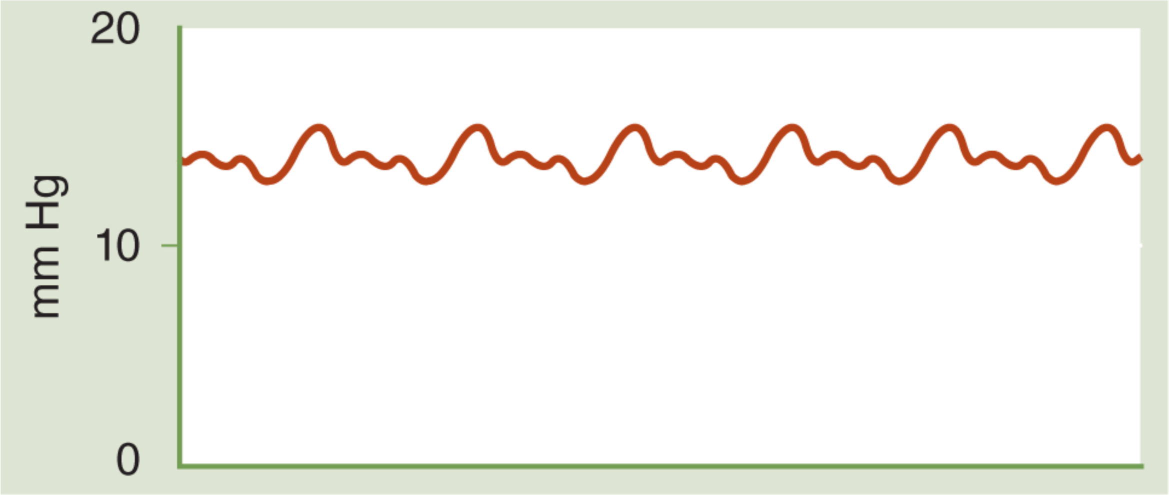

FIGURE 15-34 The waveform of a normal pulmonary capillary wedge pressure.

© Jones & Bartlett Learning.

Like the CVP waveform, a typical PCWP has three positive deflections: the ***a*** wave represents atrial contraction, the ***c*** wave represents closure of the mitral valve, and the ***v*** wave represents passive atrial filling during diastole. In practice, the ***c*** wave is rarely seen in a PCWP tracing, as the additional distance of the catheter often interferes with transmission of this part of the waveform.

One clinically significant condition that is readily seen in the PCWP waveform is mitral regurgitation. The greater the regurgitation, the greater the height of the ***v*** waves will be. The term "cannon ***v*** waves" refers to significant mitral regurgitation.

Depending on whether the patient is mechanically ventilated or spontaneously breathing, end expiration will be observed in different locations on the PCWP baseline. In mechanically ventilated patients, positive-pressure inspiration elevates intrathoracic pressure and results in a positive fluctuation in the PCWP tracing baseline. Expiration is passive; end expiration is found at the lowest point in the waveform baseline. In spontaneously breathing patients, inspiration is induced by negative pressure. Expiration in these patients produces an increase in the waveform baseline; end expiration can be found at the highest point.

When measuring PCWP, a helpful mnemonic to recall where to locate end expiration on the waveform baseline is "patient—peak; ventilator—valley." End expiration in spontaneously breathing patients is found at the peak of the waveform baseline. In contrast, in mechanically ventilated patients, end expiration is found in the valley of the waveform baseline.

After the proper position on the waveform is located, measurement of the PCWP waveform is done by locating two sequential positive deflections on the waveform immediately before the point where the baseline changes. In spontaneously breathing patients, this point would be immediately before the baseline begins to fall; in mechanically ventilated patients, it would be immediately before the baseline starts to rise. The two sequential deflections are averaged to determine the mean pressure **FIGURE 15-35**.

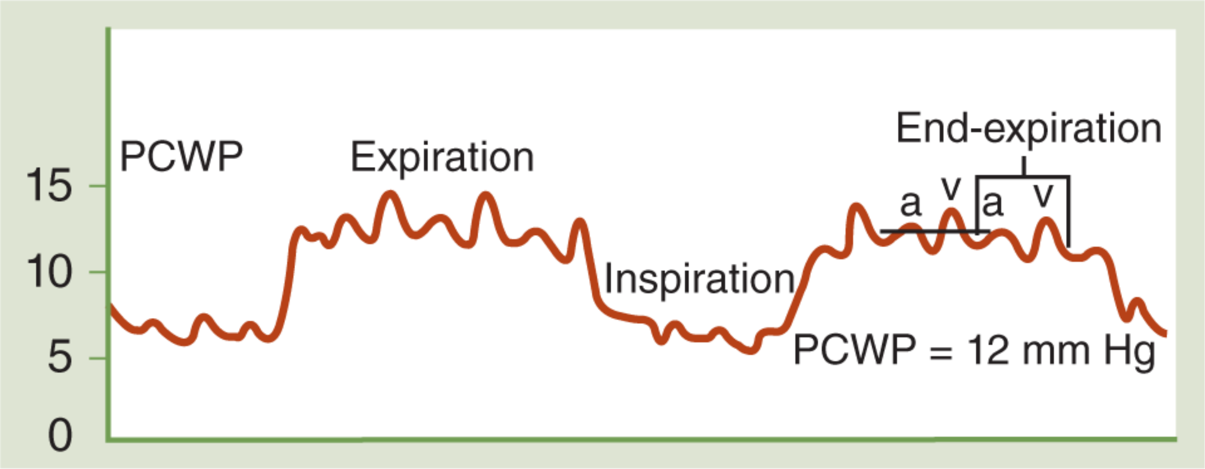

FIGURE 15-35 Respiratory-related variations in the pulmonary capillary wedge pressure (PCWP).

© Jones & Bartlett Learning.

Description

The PAC balloon typically holds up to 2 mL of air. Syringes included with the PAC normally allow the operator to inject only 1.5 mL of air to inflate the balloon. Regardless of the balloon's maximum capacity of 2 mL of air, it is recommended to inflate the balloon with only 1.5 mL, as overinflation may result in rupture of the pulmonary artery or damage to the balloon. This injection should be done slowly, over 2 to 3 seconds. It is common to feel some initial resistance during inflation (similar to the resistance one needs to overcome when blowing up a toy balloon by mouth). After a PCWP waveform is observed, the tracing can be "frozen" on the monitor screen, and the balloon should be allowed to passively deflate. Maximum inflation times should not exceed 10 to 15 seconds.

If less than 1 mL of air is needed to produce a PCWP tracing, then the PAC is likely inserted too far into the patient and is at risk for spontaneously wedging. Prolonged inflation or spontaneous wedging can result in pulmonary infarction. Manual flushing of a wedged catheter may cause pulmonary artery perforation.

Causes of elevated PCWP are numerous and difficult to resolve definitively. Often, elevated PCWP results from the LV not being able to clear the antegrade blood flow. If the LV cannot clear increased flow from the right side of the heart (as in heart failure), then an elevated PCWP will result. Left-side heart dysfunction (as in LV failure and mitral valve disease) will cause retrograde blood accumulation within the pulmonary vasculature, thereby creating an increased PCWP. A PCWP level greater than 18 mm Hg often suggests the potential for pulmonary edema, especially with a normal colloidal osmotic pressure (ie, normal serum albumin level).

High levels of PEEP used with mechanical ventilation can also cause an elevated PCWP. When PEEP levels greater than 10 cm H_2O are used, correction of the measured PCWP may be requested. This correction is done by subtracting 1.5 mm Hg from the measured PCWP for every 5 cm H_2O of PEEP. For example, if the PEEP is 15 cm H_2O and the measured PCWP is 22 mm Hg, the corrected PCWP would be 17.5 mm Hg. When correcting a measured PCWP for PEEP, both the measured PCWP and the corrected PCWP values should be recorded. This documentation eliminates potential confusion that might result if some clinicians correct their measured values and others do not.

In a patient with pulmonary edema, the CCTP may use the PCWP to differentiate between its possible causes. If pulmonary edema is the result of left-side heart failure (cardiogenic), the PCWP will be elevated. If the pulmonary edema results from increased pulmonary capillary permeability (as in pneumonia or ARDS), the PCWP may not be elevated. Care must be exercised with patients diagnosed as having ARDS because they often have elevated MAP levels and high levels of PEEP, so PCWP readings may be elevated as well. PCWP has increasingly been seen as a less reliable way to differentiate causes of pulmonary edema as the understanding of hydrostatic pulmonary pressures has evolved.

Between the transducer on the tip of the PAC and the LV lie three major anatomic components that may interfere with an accurate PCWP reading: the mitral valve, the LA, and the pulmonary venous vasculature. Furthermore, the PCWP is a pressure often used to reflect volume. Although this relationship sometimes holds, it fails if the distensibility of the LV has been affected (such as in a LV MI) or if the size of the tank changes as a result of vasoconstriction or vasodilation.

Like CVP, PCWP is a static measurement. While useful in guiding heart failure therapies, PCWP must be interpreted in the context of other data to accurately judge the patient’s fluid volume status.

Cardiac Output

Measurement of CO rounds out the basic assessments performed by a PAC. Like PCWP, CO is an intermittent assessment that involves some action by the CCTP. Normal CO ranges between 4 and 8 L/min. Investigation of low or higher than normal CO requires a stepwise approach considering each of the elements that compose the CO formula ($CO = HR \times SV$).

Typical CO assessment using a PAC is based on the thermodilution method. This method involves injecting 5% dextrose in water (D_5W) at a known temperature (iced or room temperature) into the proximal port (usually the CVP port) of the PAC. Note that D_5W is the solution with the precise osmolarity on which the PA catheter and monitor software are programmed to base the calculations. Other solutions should not be used, although the level of error introduced with these solutions is negligible (less than 1%).

As the injectate moves past the thermistor on the distal end of the catheter, the temperature is recorded by the monitoring system. A curve is plotted comparing the temperature change over time between the injectate sensor and the distal end of the catheter. The monitor then calculates the CO. This procedure is repeated several times (three to six times, depending on local protocol), and the mean of these results is used to interpret the patient's CO. Curves that suggest erroneous injection technique or faulty temperature measurement are not included in the averaging strategy.

Most transport monitors do not have the capability of performing thermodilution CO measurements during transport. Because thermodilution measurement of CO relies on the measured temperature change between blood and the injectate, rapid infusions of blood or medications into central catheters can potentially interfere with CO calculations.

Variations on CO Measurement

Various volumes of injectate can be used (3, 5, or 10 mL), different ports can be chosen, and either iced or room-temperature solutions can be used during CO measurements. Each requires a different computation constant to be entered into the monitor for performing the CO computations. The constants, which are specific to each manufacturer and each PAC, are available on the PAC package insert or on the manufacturer's website.

Continuous cardiac output (CCO) PACs continuously calculate and display CO by emitting a coded thermal energy signal from an element wrapped along the catheter. The CCO computer uses the thermodilution principle to calculate CO as often as every few minutes. Interference from infusions and other temperature variations is eliminated by downstream analysis of only the coded thermal signal. Although the greater accuracy and seeming simplicity of CCO catheters might appear attractive, troubleshooting the CCO technology requires considerably more experience and education than does the same task with thermodilution PACs.

Fick Principle

CO can also be calculated or estimated by using the **Fick principle**. First described by Adolph Fick in 1870, this method divides oxygen consumption based on the difference between the oxygen content of arterial versus venous blood. The formula uses assumed values for oxygen consumption derived from basal metabolic studies on healthy subjects, which may or may not be valid in critically ill patients. Nevertheless, the Fick principle is commonly used in cardiac catheterization laboratories and critical care units. The formula is as follows:

$$\text{CO} = \frac{\text{Oxygen Consumption}}{\text{Arteriovenous Oxygen Content Difference}}$$

The following data are needed to calculate CO with this equation:

- TBSA
- Hemoglobin level
- Arterial oxygen saturation (from a pulse oximeter or blood gas–measured oxygen saturation)
- Mixed venous oxygen saturation (from a blood gas sample drawn from the pulmonary artery port of a PAC or SvO_2 reading from a fiberoptic PAC)

TBSA is expressed in square meters, oxygen saturation is expressed as a decimal (eg, 98% would be expressed as 0.98), and hemoglobin is expressed in grams per deciliter (g/dL).

The estimated Fick CO is calculated as follows:

1. Calculate the oxygen consumption based on a presumed 125 mL of oxygen consumed per square meter of TBSA (ie, 125 × TBSA).
2. Calculate the arteriovenous oxygen content difference. Each gram of hemoglobin can carry 1.36 mL of oxygen. Hence, the difference is expressed as follows: 1.36 × Hemoglobin × (Arterial saturation – Venous saturation) × 10.
3. Divide the calculated oxygen consumption by the calculated arteriovenous oxygen content difference to produce the estimated CO in liters per minute.

Assuming the following values, here is an example of the calculation:

- TBSA = 1.33 m^2
- Hemoglobin (Hgb) = 12 g/dL
- Spo_2 (pulse oximeter) = 0.98 (98%)
- Svo_2 (saturation of blood gas sample drawn from pulmonary artery port) = 0.70 (70%)

$$\mathrm{CO} = \frac{125 \times \mathrm{BSA}\ 1.33}{\mathrm{Hgb}\ 12 \times 1.36 \times (0.98 - 0.70) \times 10}$$

$$\mathrm{CO} = \frac{166.25}{16.32 \times (0.28) \times 10}$$

$$\mathrm{CO} = \frac{166.25}{45.696} = 3.64\ \mathrm{L/min}$$

A simplified version of the formula can also be used. This version calculates the constants (here, 125 has already been divided by 1.36 and 10), so that fewer calculations are needed overall:

$$\mathrm{CO} = \frac{9.19 \times \mathrm{BSA}\ 1.33}{\mathrm{Hgb}\ 12 \times (0.98 - 0.70)}$$

Pulmonary Vascular Resistance

PVR is calculated with the following equation:

$$\mathrm{PVR} = \frac{(\text{Mean Pulmonary Artery Pressure} - \mathrm{PCWP})}{\mathrm{CO}} = 80$$

PVR represents the resistance of the pulmonary vascular circuit that opposes flow out of the right ventricle and pulmonary artery, commonly referred to as right-side heart afterload. The normal value is 100 to 250 dyne-sec/cm^{-5}. As mentioned previously, PVR is not commonly used when determining the treatment plan for critical care patients. The CCTP may see an elevated PVR in patients with pulmonary hypertension or mitral valve stenosis.

Systemic Vascular Resistance

If a patient's MAP, CVP, and CO are known, then the CO computer will calculate the SVR by using the following equation:

$$\mathrm{SVR} = \frac{(\mathrm{MAP} - \mathrm{CVP})}{\mathrm{CO}} \times 80$$

In a manner similar to PVR, a patient's SVR represents the total impedance to blood flow felt by the LV, commonly referred to as afterload. Calculation of SVR, which has a normal range of 800 to

1,200 dyne-sec/cm^{-5}, is extremely useful in helping to differentiate among the possible causes of shock. If SVR is elevated, the patient has vasoconstriction, suggesting hypovolemia or pump failure. If SVR is low, a distributive shock state such as neurogenic or septic shock is likely. Obviously, the effects of vasodilating or vasoconstricting agents can affect SVR values. Also, note that SVR is a calculated (not measured) value. As such, changes or errors in measuring any of the components included in the calculation could alter the results and lead to decisions based on inaccurate information.

The ideal SVR is thought to be slightly less than 1,000 dyne-sec/cm^{-5}. When a PAC is used to titrate vasodilator therapy (usually angiotensin-converting enzyme inhibitor agents) in patients with heart failure, the goal is to achieve an SVR of 900 to 1,000 dyne-sec/cm^{-5}.

Stroke Volume

The amount of blood ejected in each stroke of a ventricle is measured in milliliters and recorded as the SV. A normal SV is 60 to 100 mL/beat. The familiar equation that relates SV to CO and heart rate is as follows:

$$SV = \frac{CO}{\text{Heart Rate}}$$

As explained previously, ventricular performance is affected by the contractility (health) of the heart muscle and the preload and afterload for the respective ventricle. Any pathophysiologic factor that affects one of the performance determinants will either augment or depress the SV.

The stroke volume index is calculated by dividing SV by TBSA:

$$\text{Stroke Volume Index} = \frac{\text{SV}}{\text{TBSA}}$$

The normal stroke volume index is between 33 and 47 mL/beat/m^2.

An estimation of contractility can be made by calculating the left and right ventricular stroke work indexes.

Left ventricular stroke work index:

$$= \frac{\text{Stroke Volume}}{\text{Index (MAP} - \text{PCWP)} \times 0.0136}$$

Right ventricular stroke work index:

$$= \frac{\text{Stroke Volume Index}}{\text{(Mean Pulmonary Artery Pressure} - \text{CVP)} \times 0.0136}$$

The normal left ventricular stroke work index is 40 to 75 g-m/m^2/beat. (Note: g-m represents grams per meter.) The normal right ventricular stroke work index is 5 to 10 g-m/m^2/beat.

Mixed Venous Oxygen Saturation

If a fiberoptic oxygen saturation probe is attached to the distal end of the PAC, then a **mixed venous oxygen saturation (Svo_2)** measurement can be recorded. This measurement is constant and requires no action by the clinician after the catheter is placed. In PACs without fiberoptic oximetry capability, a blood gas specimen can be obtained from the distal (pulmonary artery) port of the catheter to determine the Svo_2 value.

In effect, the Svo_2 value reflects the global balance between oxygen delivery and consumption. The measurement is performed at the distal end of the PAC because the pulmonary artery is the most appropriate place to sample a mixture of all blood returning from the body. When obtaining a blood gas specimen from the pulmonary artery port of a PAC so as to determine the mixed venous oxygen saturation, the speed of withdrawal of the blood specimen does not affect the results. Historically, it was believed that rapid withdrawal from the very small lumen led to falsely elevated Svo_2 values.

When evaluating an Svo_2 value outside the normal range (0.60 to 0.80 [60% to 80%]), the CCTP should consider each of the four components that contribute to this parameter: total hemoglobin level, arterial oxygen saturation, CO, and oxygen consumption. Three of these factors pertain to oxygen delivery, with the other being related to oxygen consumption in the body. Oxygen delivery is affected by total hemoglobin levels, arterial oxygen saturation, and CO. Increases or decreases in any of these factors can affect the Svo_2 value. Changes in oxygen consumption (also called oxygen demand) can also affect the Svo_2 value. Oxygen consumption is increased with conditions that increase metabolic rate or muscle activity, such as fever, seizures, shivering, and increased work of breathing. Oxygen consumption may decrease when maldistribution of blood is present, which most commonly occurs in sepsis as a result of microcapillary obstruction that leads to arterial blood being shunted past the capillaries into the venous blood. Supranormal values can also be seen with exposure to certain poisons that impair tissue oxygen delivery, such as septic, carbon monoxide, and cyanide poisonings. Normally, when oxygen demand increases and threatens to exceed oxygen supply, the body compensates by increasing CO and/or oxygen extraction.

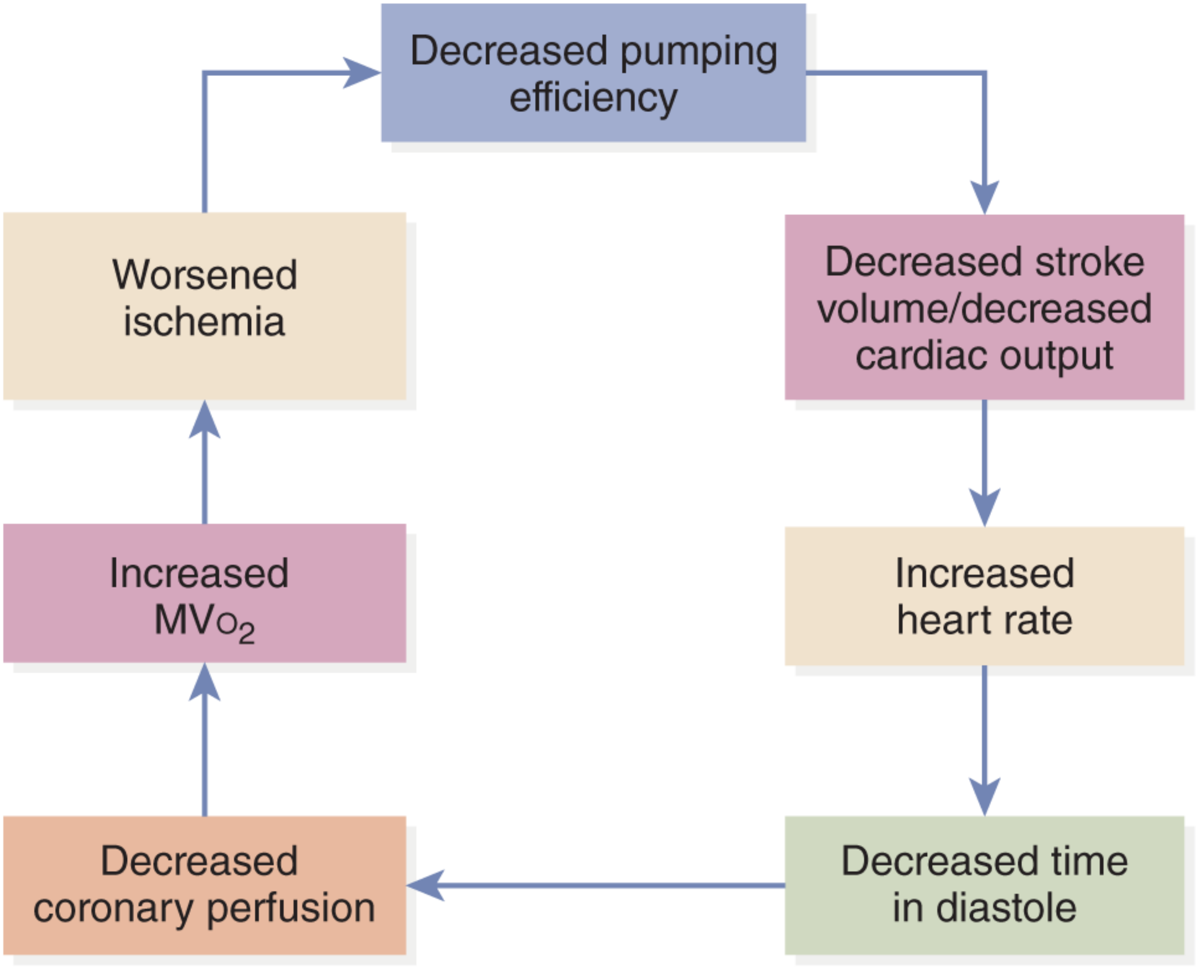
The **mixed central venous oxygen saturation ($Scvo_2$)** measurement is similar to mixed venous oxygen saturation. Like the Svo_2 value, the $Scvo_2$ value reflects the balance between oxygen supply and delivery. Measurements of $Scvo_2$ are obtained from a central venous catheter by drawing a blood gas specimen or using a fiberoptic oximetric tip connected to a specially designed monitor that displays the oxygen saturation. Because the location of the central venous line is more proximal than the pulmonary artery, blood sampled from a central venous line reflects extraction of oxygen by the brain and upper body rather than global extraction of oxygen from the blood; therefore, the $Scvo_2$ values are approximately 8% to 10% higher than the Svo_2 values. A normal $Scvo_2$ value is considered to be 0.70 to 0.90 (70% to 90%).

Heart Failure

Myocardial oxygen supply must balance myocardial oxygen demand (**myocardial oxygen consumption [MVo_2]**) to meet the myocardial metabolic requirements or ischemia will result. Factors that can affect myocardial oxygen supply include coronary artery pathology or pathoanatomy, diastolic pressure, diastolic time, and oxygen extraction. Because the majority of blood flow to the coronary arteries occurs during diastole, when the ventricle is at rest and the aortic valve is closed, diastolic pressure and time spent in diastole (diastolic time) profoundly affect the blood flow to the coronary arteries and, therefore, myocardial oxygen supply. Because the time required to complete systole is fixed, any increases in heart rate result in decreased diastolic time and, therefore, less time to perfuse the coronary arteries. The MVO_2 varies with heart rate, preload, afterload, and contractility; any increase in these factors increases oxygen demand.

Heart failure is a cyclic phenomenon. Injury to the myocardium, such as might occur with an acute myocardial infarction (AMI), results in a series of physiologic and hemodynamic changes that can affect the balance between oxygen supply and demand. The injury (from whatever cause) decreases pumping efficiency, CO, and arterial pressure. As discussed previously, CO depends on stroke volume (SV) and heart rate: CO = SV × Heart rate. In this equation, for CO to remain the same, a decrease in either SV or heart rate must be compensated for by an increase in the other component. Therefore, if the ability of the heart to pump effectively were to become impaired (such as might occur with an MI), causing a drop in the SV, then the heart rate must increase for CO to remain the same. Coronary perfusion occurs only during diastole, and any increase in heart rate results in less diastolic time and, in turn, less time for coronary perfusion. Because the heart rate is increased, the MVO_2 also increases, worsening the mismatch of oxygen supply and demand.

The decreased coronary perfusion, coupled with the increased MVO_2, leads to worsened ischemia. Ischemia causes the heart to pump less effectively, leading to a greater decrease in SV. The heart rate increases to maintain CO, and the cycle of heart failure continues **FIGURE 15-36**.



Decreased pumping efficiency
Decreased stroke volume/decreased cardiac output
Increased heart rate
Decreased time in diastole
Decreased coronary perfusion
Increased MVO_2
Worsened ischemia

FIGURE 15-36 The cycle of heart failure.

Description

The treatment of cardiac failure is aimed at restoring normal cardiac function and the balance between myocardial oxygen supply and oxygen demand. If the initial intervention fails to restore the balance among these factors, then the intra-aortic balloon pump (IABP) offers a mechanical means of rebalancing them.

Shock

Shock is a common cause of morbidity in the critical care setting. Because shock is characterized by reduced systemic tissue perfusion, the end result is decreased tissue perfusion. Prompt recognition and reversal of shock can help avoid the otherwise rapidly irreversible sequence of cell death, end-organ damage, and lactic acidosis resulting from anaerobic metabolism, multisystem organ failure, and death.

The three recognized shock states are hypovolemic, cardiogenic, and distributive. Each of these shock states is associated with classic hemodynamic findings that help differentiate among them. Specifically, two hemodynamic parameters distinguish the different types of shock: CO and SVR. Hemodynamic monitoring can help the CCTP to differentiate between the various types of shock and assess the effectiveness of treatment during transport.

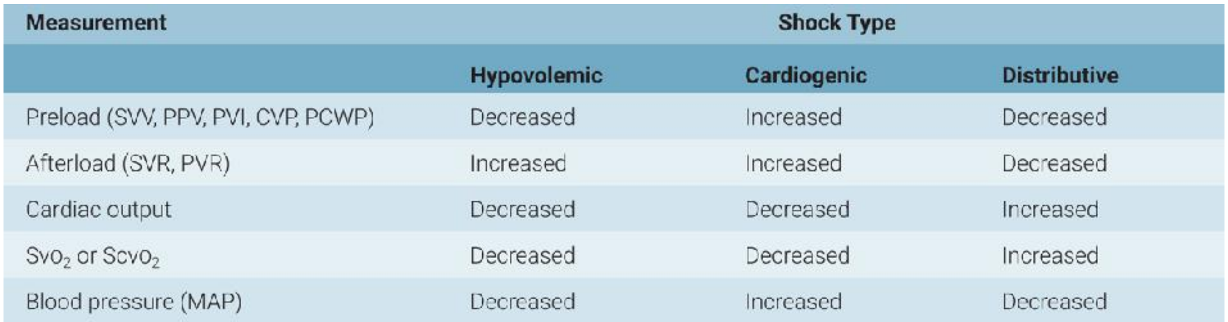
Hypovolemic shock includes volume loss from acute or chronic hemorrhage, excessive diuresis, third-space losses, and any other condition that depletes intravascular volume. In this type of shock, preload is decreased as a consequence of depleted intravascular volume. Decreased preload leads to a decline in SV, which results in decreased CO. To maintain end-organ perfusion, SVR increases to compensate for the declining CO.

Cardiogenic shock causes are diverse and include myocardial depression from ischemia and/or infarcts, cardiomyopathies, stunning following cardiac operations, arrhythmias that decrease flow, mechanical abnormalities leading to pump failure, and obstructive conditions such as massive pulmonary embolism, tension pneumothorax, pericardial tamponade, and aortic clots. This type of shock involves a complex cascade of events resulting from pump failure leading to decreased CO. The SVR typically increases in an effort to maintain CO, which further exacerbates pump failure and leads to increased preload and a relative total hypervolemic condition.

Distributive shock states include sepsis, systemic inflammatory response syndrome, toxic shock syndrome, anaphylaxis, poisonings, neurogenic conditions such as spinal cord injury, narcotic overdoses, and other vasodilatory etiologies. In this type of shock, vasodilation is often the primary culprit and is manifested as a significantly decreased SVR. When afterload declines dramatically, CO increases.

TABLE 15-4 summarizes the findings expected with each of the three shock states.

TABLE 15-4 Relationship Between Shock Type and Invasive Hemodynamic Measurements



Measurement	Shock Type		
	Hypovolemic	**Cardiogenic**	**Distributive**
Preload (SVV, PPV, PVI, CVP, PCWP)	Decreased	Increased	Decreased
Afterload (SVR, PVR)	Increased	Increased	Decreased
Cardiac output	Decreased	Decreased	Increased
Svo_2 or Scvo_2	Decreased	Decreased	Increased
Blood pressure (MAP)	Decreased	Increased	Decreased

Abbreviations: CVP, central venous pressure; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; PPV, pulse pressure variation; PVR, pulmonary vascular resistance; PVI, pleth variability index; Scvo_2, mixed central venous oxygen saturation; Svo_2, mixed venous oxygen saturation; SVR, systemic vascular resistance; SVV, stroke volume variation

Description

Flight Considerations

Effects of Altitude Changes on Hemodynamic Monitoring

Concerns pertaining to flight physiology include the hypoxic effects of altitude and gas expansion. Even in pressurized cabins, oxygen saturation in healthy people at normal cruising altitudes above 20,000 feet declines by a mean of 5.5%, and it often approaches 0.90 (90%). Patients with reduced oxygen saturation on the ground can be expected to experience further declines during flight. Close monitoring of oxygen saturation will enable the CCTP to respond to changes in the patient's condition and maintain sufficient levels of inspired oxygen to ensure adequate saturation.

Physiologic changes that may be evident in the patient in response to lowered oxygen levels at high altitude include a chemoreceptor-induced increase in tidal volume and, if respiratory compensation is inadequate, an increased CO achieved mainly through an increased heart rate. Hypoxia and increased sympathetic nervous system tone predispose patients to arrhythmias.

Gas expansion in flight occurs in accordance with Boyle's law, which states that the volume to which a given quantity of gas is compressed is inversely proportional to the surrounding atmospheric pressure. Pneumothoraces may become tension pneumothoraces with significant hemodynamic compromise. Air should be removed from IV bags before takeoff because it will expand at altitude, potentially increasing infusion rates. Pumps should be used for medication infusions. Zeroing of transducers is recommended when cruising altitude is reached, and once again following landing. The CCTP may see changes in transduced pressures with changes of altitude of 1,000 feet; if these variations appear clinically significant, then re-zeroing of the transducer is recommended prior to initiating treatment.

Summary

Hemodynamic monitoring provides CCTPs with multiple measures of the cardiovascular status of their patients. Proper use of these clues to guide patient care requires technical skill in the correct use of the equipment and an understanding of the meaning of the data it provides. Experienced CCTPs will use multiple methods (such as physical assessment findings and laboratory test results) to confirm that the hemodynamic measurements obtained accurately reflect perfusion. Hemodynamic monitoring provides one piece of the clinical picture needed to form an overall impression and diagnosis. The most important tool for hemodynamic monitoring will always be the CCTP's own knowledge and experience.

Perfusion deficits are the primary pathology that require critical care, both in hospital and during transport. Assessing perfusion should be the ultimate goal of hemodynamic monitoring and requires an understanding of oxygenation, circulation, preload, afterload, and cardiac performance. The plethora of monitoring devices, blood tests, and tools available to the CCTP all contribute to the ability to assess perfusion and correct deficits.

CASE STUDY

A 68-year-old man with pulmonary edema was brought to the emergency department of a community hospital by emergency medical services responders. Paramedics found the patient with acute shortness of breath and intubated him in the field when he failed to respond to high-dose nitroglycerin and continuous positive airway pressure. The patient is now in the ICU of the community hospital awaiting your arrival for ground transport to a heart failure program at a tertiary center located 2 hours away. The referring hospital personnel advise that an arterial line and PAC have been placed and that they are attempting to lower the patient's BP while they await your arrival. No evidence of an AMI is present. A chest radiograph revealed diffuse interstitial edema consistent with pulmonary edema. The results of all laboratory tests, including cardiac markers, electrolytes, and renal function tests, were normal.

On arrival, you confirm the information previously reported. You note the patient is ventilating well on a fraction of inspired oxygen of 0.4, a tidal volume of 7 mL/kg, a respiratory rate of 14 breaths/min in the synchronized intermittent mandatory ventilation mode, and a PEEP of 5 cm H_2O. Continuous infusions of propofol, fentanyl, and nitroglycerin are running. The nitroglycerin is infusing at 200 μg/min. The registered nurse reports that escalating doses of furosemide have not resulted in any increased urine output. The following hemodynamic readings were taken 5 minutes before your arrival at the bedside:

- Pulse rate: 100 beats/min
- BP (systolic/diastolic/mean): 220/110/135 mm Hg
- Pulmonary artery pressure (systolic/diastolic/mean): 57/34/40 mm Hg
- PCWP: 28 mm Hg
- CVP: 20 mm Hg
- CO: 3.9 L/min
- CI: 1.7 L/min/m^2
- SVR: 2,359 dyne-sec/cm^{-5}

1. What are the implications of these hemodynamic values?
2. Which interventions would help stabilize this patient's condition for transport?
3. Are other hemodynamic data available that would be helpful?

Analysis

Familiarity with the hemodynamic findings associated with various forms of shock would immediately point to cardiogenic shock in this patient. An initial decline in myocardial pumping efficiency from an as yet undetermined cause triggered a cascade of events beginning with vasoconstriction and progressing to hypervolemia, which ultimately resulted in pulmonary edema. Vasoconstriction is seen in the elevated afterload (SVR) and hypertension; hypervolemia is evidenced by elevated preload values (CVP and PCWP). The CO is likely low because the patient's heart is unable to pump against the incredibly high afterload. Urine output is likely compromised by renal retention of sodium and water in response to the low CO. The values seen in this case example are, in fact, classic values seen in patients with cardiogenic shock. As this patient's condition deteriorates, he will ultimately become hypotensive and acidotic and will die if untreated.

The first intervention suggested by the values obtained with the PAC is use of an agent to reduce the high afterload state. Staff reported attempting to lower the patient's BP with nitroglycerin, but the current dosing is generally considered maximal. Nitroglycerin is primarily a venodilating agent with minimal arterial-dilating properties except at extremely high doses. Given the patient's degree of hypertension, which persists even with the nitroglycerin infusion, achieving a significant reduction in afterload will require an agent with more potent arterial-vasodilating properties. The transport crew consulted with providers caring for the patient and decided to initiate an infusion of sodium nitroprusside. Nitroprusside has venous- and arterial-dilating properties and is a potent antihypertensive agent. Following initiation of a nitroprusside drip, gradually titrated up to 3 μg/kg/min, the patient's MAP declined to 95 mm Hg, CVP to 14 mm Hg, and PCWP to 24 mm Hg. The CO doubled to 7.8 L/min. The calculated SVR was then 831 dyne-sec/cm^{-5}. With the improved CO, the patient's urine output immediately increased.

Had CO remained low after afterload reduction was achieved, the transport crew would likely have sought to initiate an inotropic infusion. Dobutamine is the inotropic agent of choice for first-line treatment of low CO associated with heart failure.

Not all hemodynamic parameters discussed in this chapter were used in evaluating this patient. The patient's specific problems and the potential treatment options under consideration guide the hemodynamic measurements and calculations used. With the data used by the CCTPs receiving this patient, a clear picture of pump failure with low CO emerges. One question not apparent from these data is whether the perfusion needs of the patient are being met by the present CO. If the oxygen demand exceeds the oxygen supply, then the patient's condition will deteriorate, and most likely will continue to do so with the additional stress of transport.

Clearly, the patient's CO is low. The SvO_2 value would indicate whether the present CO is meeting the patient's perfusion needs. Some PACs have a fiberoptic oximetric tip that continuously displays the mixed venous oxygen saturation. Because this PAC did not, the transport crew requested that the hospital staff send a blood specimen from the pulmonary artery port of the PAC for blood gas analysis. The results showed an SvO_2 of 0.49 (49%), well below the normal range of 0.60 to 0.80 (60% to 80%). The result for a repeated specimen drawn after hemodynamics appeared more stable (ie, following initiation of the nitroprusside infusion) at 0.64 (64%), a dramatic improvement reflecting adequate tissue perfusion.

PREP KIT

Ready for Review

- Invasive hemodynamic monitoring is used to assess the heart, vascular network, and fluid volume status. It is used in conjunction with (not as a replacement for) physical assessment techniques such as capillary refill, skin color, skin turgor, body temperature, heart and lung sounds, and mental status.
- The atrioventricular (AV) valves (mitral and tricuspid) lie between the atria and the ventricles, and the semilunar valves (aortic and pulmonic) are the exits from the ventricles. The purpose of the cardiac valves is to prevent the backward flow of blood in the heart.
- The AV valves have chordae tendineae, which attach the edge of the valve to the papillary muscles attached to the endocardium; they hold the AV valves in place in the closed position and prevent them from prolapsing into the atria during systole or ventricular contraction. The semilunar valves do not have chordae tendineae; their opening and closing are related to the pressure changes in the heart, aorta, and pulmonary artery.
- Systole and diastole include five phases: atrial systole, isovolumetric contraction, ventricular ejection, isovolumetric relaxation, and ventricular filling.
- In atrial systole, the pressure in the ventricles increases. The atria contract, extra blood is ejected from the atria into the ventricles, the mitral and tricuspid valves are open, and the pulmonary and aortic valves are closed.
- Isovolumetric contraction occurs between the closure of the AV valves and the opening of the semilunar valves (in which no change in ventricular blood volume occurs) immediately before the blood is ejected through the semilunar valves. The pressure in the ventricles rises abruptly.

- During ventricular ejection, the pressure in the left ventricle exceeds the pressure in the aortic root, resulting in the aortic valve opening.
- During isovolumetric relaxation, the pressure in the ventricles is less than the arterial pressure. The ventricles are no longer contracting, the mitral and tricuspid valves are closed, and the pulmonary and aortic valves are closed.
- Ventricular filling occurs after the mitral and tricuspid valves open.
- Cardiac output (CO) is the product of stroke volume (SV) and heart rate: CO = SV × Heart rate. SV is determined by preload, afterload, and contractility of the heart. Because SV is determined by three components, heart rate contributes more to and has a more immediate effect on CO than any one component of SV. When confronted with a patient who has low CO, critical care transport professionals (CCTPs) should investigate the heart rate before evaluating the components of SV.
- Some hemodynamic values are indexed to account for differences in body size; for example, the cardiac index is the patient's CO divided by the total body surface area.
- Heart rate is a key sign of hemodynamic instability in the emergency or critical care patient. A heart rate obtained from a pulse oximeter is more reliable than manual assessment by the CCTP, particularly in the noisy environment of an intensive care unit or a CCTP vehicle.
- Preload is the degree of myocardial fiber stretch induced by volume in the ventricle at the end of diastole. Hypovolemia, venodilation, intrathoracic pressure changes, and intrapericardial pressure changes result in decreased preload. Hypervolemia and vasoconstriction result in increased preload.
- The Frank–Starling law states that a relationship exists between the distention of the ventricular myocardium and the force of the contraction. As the ventricular preload increases, the force of contraction of the myocardium also increases due to the increased stretch of the myocardial fibers. The Frank–Starling law

describes how administration of fluids can improve CO to a certain point, which varies among individual patients. Additional fluids given beyond that point worsen CO.

- Right ventricular preload is measured by central venous pressure. Left ventricular preload is measured by pulmonary capillary wedge pressure (PCWP) or pulmonary artery diastolic pressure.
- Afterload is the resistance the ventricles must overcome to eject blood. Four factors typically determine afterload: outflow obstructions, vascular tone, blood viscosity, and ventricular dilation. Outflow obstructions, vasoconstriction, and polycythemia increase afterload. Vasodilation reduces afterload. Lowered hemoglobin levels are often tolerated in critically ill patients because CO may be improved by decreasing afterload. Left ventricular afterload is measured by systemic vascular resistance, and right ventricular afterload is measured by pulmonary vascular resistance (PVR).
- Contractility is the inotropic state of the heart or the force with which the heart muscle contracts. Contractility is assessed with newer Doppler and ultrasonography devices. Six factors influence contractility: myocardial muscle health, autonomic nervous system, metabolic states, the ion environment, pharmacologic agents, and heart rate.
- BP is measured directly through the use of an arterial line or indirectly through the use of a device that senses pulsatile flow such as a sphygmomanometer, which measures systolic and diastolic pressures. Indirect measurements assess flow, and direct monitoring devices measure pressure. Pressure and flow are different parameters, so readings obtained using indirect and direct methods cannot be expected to correlate exactly.
- Direct pressure measurements are affected by changes in intrathoracic pressure. To obtain accurate measurements, readings should be taken at end expiration (the lower portions, or valleys, of the rise-and-fall pattern for mechanically ventilated

patients; and the peaks of the rise-and-fall pattern for spontaneously breathing patients).

- Systolic BP (SBP) is the measure of pressure on the arterial walls during systole; diastolic BP (DBP) is the measure of pressure on the walls of the arteries during diastole. The formula for BP is CO multiplied by systemic vascular resistance (SVR): BP = CO × SVR.
- To avoid errors when using indirect monitoring devices to measure BP, CCTPs should be careful to use the correct BP cuff size for the patient and to position the patient's extremity in which BP is measured at mid-heart level.
- Transport monitors often include noninvasive BP (NIBP) units, which automatically measure indirect BP at predetermined intervals. The NIBP units measure heart rate and mean arterial pressure (MAP) only. Computer software then calculates SBP and DBP.
- CCTPs should evaluate the heart rate obtained from the NIBP unit against the actual patient pulse, the heart rate displayed on a pulse oximeter, or an ECG heart rate display to determine the accuracy of the NIBP measurements. If the NIBP heart rate differs significantly from the actual patient heart rate, then the calculated SBP and DBP should be considered unreliable.
- Invasive hemodynamic measurements are obtained via a closed catheter system, which is typically placed in the patient by a physician. Catheter placement is usually outside the scope of practice for CCTPs. Measurements are read on a monitor that is connected to a transducer on the catheter.
- Direct BP measurement using an arterial line is indicated for patients who require constant BP measurement, particularly patients who are in shock and are not responding to therapy. In addition, arterial lines are used for patients receiving vasoactive or antihypertensive infusions. The arterial line also confirms the presence of pulsatile blood flow and enables access for arterial blood samples for arterial blood gas analysis.

- Contraindications to the use of an arterial line include ischemia of the extremity, infection at the puncture site, Raynaud disease, and a prior vascular operation in the area of the insertion site.
- CCTPs generally do not place arterial lines, but they may need to assist in the procedure; therefore, they should be familiar with the insertion procedure.
- The Allen test is used to assess extremity perfusion and test ulnar artery function.
- Before moving a patient with hemodynamic monitoring equipment in place, CCTPs should examine the equipment in use, note the values displayed, and trace the tubing from each transducer to the pressure-monitoring catheter. The catheter site should be examined to ensure that it is visibly clean, dry, and covered by an occlusive dressing and its condition documented. A CCTP who is unfamiliar with the operation of the stopcocks and catheters in use should ask the clinician at the bedside to explain their operation.
- The patient can be transferred to a stretcher before or after transducers are connected to the transport monitor. A deliberate, orderly manner is needed when moving connections from the hospital monitor to the transport monitor to avoid periods when the patient is not connected to any monitor. Agency or service policy should be followed for securing monitoring lines and catheters during transport. Monitoring alarms need to be set to protect against accidental dislodgement or dislocation of invasive monitoring catheters.
- The most common cause of error in obtaining direct hemodynamic pressure measurements is incorrect leveling of the transducer. To ensure accurate pressure readings, the transducer must be at mid-heart level. The transducer must be releveled with each position change of the patient. Because errors in leveling can significantly impact treatment decisions, all leveling should be performed using a carpenter’s level or a leveling tool specifically designed for the hemodynamic monitoring application.

- Pressure transducers must be “zeroed” to eliminate the effects of atmospheric pressure on the measurements obtained. Depending on flight patterns and altitudes, transducers may be zeroed at initial connection to the transport monitor, at cruising altitude, and at the destination.
- CCTPs should become familiar with transport monitors, cables, and transducers. Cables must be compatible with the equipment used at the referring and receiving hospitals.
- Asepsis is critical in the care of patients with central lines and hemodynamic monitoring equipment. Key practices that decrease the incidence of catheter-related bloodstream infections include hand hygiene, strict adherence to aseptic technique, maximal sterile barrier precautions, chlorhexidine skin antisepsis, optimal catheter site selection, and use of an appropriate dressing after the catheter has been inserted.
- Central venous lines provide access to the core vessels of the body. The right internal jugular vein is the easiest site to access. Other common insertion sites are the subclavian, brachial, and femoral veins. Subclavian sites have the lowest infection risk; femoral sites have the highest risk for infection, and their use is strongly discouraged in adults.
- Central venous pressure (CVP) monitoring is used to determine right ventricular preload and intravascular volume status and to assess right-side heart function. The normal range for the CVP is 2 to 6 mm Hg. To ensure accuracy, CVP measurement should be obtained during end expiration.
- Central venous lines often include outlet ports, which are used for rapid fluid replacement, medication administration, rapid access to central circulation, and invasive monitoring.
- Only a few contraindications to central venous access exist. They include significant coagulopathy, local trauma to the site of insertion, and infection at the site of insertion.
- The most common complication associated with the insertion of a central line is pneumothorax or hemothorax from an unsuccessful

attempt at subclavian line insertion. Other complications range from bleeding, to infection, to blood withdrawal problems.

- The triple-lumen catheter is the most commonly used central line. The lumens can be used for fluid and drug administration and for CVP monitoring. For some patients, one port may be reserved for total parenteral nutrition; that port should not be used during transport.
- Some central venous catheters have one or two access ports, and some are installed under the skin (tunneled). CCTPs should consult the receiving facility and local protocols for direction in using tunneled central lines.
- CCTPs should be familiar with the placement, use, and maintenance required for different types of catheters, including the Hickman catheter, the Groshong catheter, the Port-A-Cath, and the peripherally inserted central catheter. They should understand the possible complications and advantages and disadvantages of each catheter. All complications should be reported to the receiving facility as soon as possible.
- Although central venous lines are rarely placed by CCTPs, knowledge of how they are placed will help CCTPs care for patients who have a central venous line.
- The Seldinger technique is the technique most commonly used for line insertion. Specific procedures are used for femoral, internal jugular, and subclavian vein insertion.
- Common problems that occur when inserting a central venous line include sluggish infusion, inability to withdraw blood, and catheter damage.
- A pulmonary artery catheter (PAC), also known as a Swan–Ganz catheter or “swan,” is inserted into the patient’s venous system. Although CCTPs do not insert PACs, knowledge of the insertion procedure is useful in providing care.
- PACs have multiple lumens that terminate at different points along the catheter and correspond to different locations in the heart. PACs are marked at 10-cm intervals beginning at the distal tip of

the catheter. CCTPs should note the centimeter measurement of the PAC at the introducer when initially assessing a patient. This information will help to determine whether the catheter has moved into or out of the patient during transport.

- The PAC measures right atrial (RA) and pulmonary artery pressure. The RA pressures are displayed as mean pressures; pulmonary artery pressures are displayed as systolic, diastolic, and mean values. Inflation of the PAC balloon blocks blood flow from the right ventricle behind the balloon tip and results in the appearance of a PCWP waveform on the monitor. The PCWP waveform is measured as a mean value.
- Complications with PAC insertion are nearly the same as those with central line insertion. Probably the greatest potential complication of PAC use is misinterpretation of the data by clinicians, resulting in inappropriate therapy and potentially worsening outcomes.
- A thermistor is connected to the distal end of the PAC. The thermistor measures thermodilution CO and provides a continuous reading of the pulmonary artery temperature, which is considered the gold standard for core body temperature measurement.
- Indications for the use of PACs are based on clinician experience, not outcome studies. Clinicians are advised to consider the risks and benefits for critically ill patients on an individual basis.
- Contraindications to the use of a PAC include significant coagulopathy, local trauma to the site of insertion, infection at the site of insertion, and inability to float the PAC into the pulmonary artery.
- CCTPs should be familiar with normal hemodynamic ranges and values, as well as the lines from which these measurements are obtained.
- Continuous BP monitoring through an arterial line provides CCTPs with constantly updated SBP, DBP, and MAP values and an arterial waveform. Components of the arterial waveform include

the dicrotic notch, mean pressure, systole, diastole, systolic pulse pressure, and diastolic pulse pressure.

- The MAP is a function of the SBP and DBP. It is calculated by the transport monitor software or the CCTP. A MAP between 70 and 105 mm Hg is needed to satisfactorily perfuse the body's tissues; most medical orders require titration of drugs or administration of fluids to maintain a MAP of 70 mm Hg or greater.
- Regardless of whether direct monitoring with an arterial line or indirect monitoring with an NIBP is performed, the MAP is the value that should be used to make treatment decisions.
- Pulse pressure is another value calculated using SBP and DBP readings. It is the mathematical difference between these values. Normal values are 40 to 60 mm Hg.
- Central venous pressure (CVP) is a measure of the vena caval and right atrial pressures. It is measured from a central venous line or pulmonary artery catheter. A CVP waveform tracing has systolic and diastolic values, but only the mean is used in clinical practice because the numbers are extremely low.
- The normal range for CVP is 2 to 6 mm Hg. Fluids are often administered to patients with CVP values below 5 to 8 mm Hg to increase their preload.
- Pulmonary artery catheter measurements include right ventricular pressure, pulmonary artery pressure, PCWP, and CO. CCTPs should know the normal values for each of these measurements and how to evaluate each of the measurements.
- CCTPs should be able to recognize a right ventricular waveform and its characteristic low diastolic pressure, which distinguishes it from a pulmonary artery pressure waveform.
- A CCTP who observes a sudden elevation in pulmonary artery pressures should immediately assess and correct any issues with oxygen saturation or ventilation. If pulmonary artery diastolic pressures suddenly drop, then the catheter position should be reevaluated to determine if the PAC has migrated into the right ventricle.

- CCTPs should also know how to read a PCWP waveform. When a PCWP waveform is observed, the tracing can be frozen on the monitor screen, and the balloon should be allowed to passively deflate.
- The thermodilution method is typically used to assess CO with a pulmonary artery catheter. Most transport monitors are not capable of performing thermodilution CO measurements during transport.
- CO can be calculated or estimated by using the Fick principle. The formula used is as follows:

$$\text{CO} = \frac{\text{Oxygen Consumption}}{\text{Arteriovenous Oxygen Content Defference}}$$

- PVR is the resistance of the pulmonary vascular circuit that opposes flow out of the right ventricle and pulmonary artery. It is commonly referred to as right-side heart afterload. PVR may be elevated in patients with pulmonary hypertension or mitral valve stenosis.
- SVR is the total impedance to blood flow felt by the left ventricle, commonly referred to as afterload. Calculation of SVR is helpful in determining the cause of shock.
- The amount of blood ejected in each stroke of a ventricle is measured in milliliters and recorded as the SV. A normal SV is 60 to 100 mL/beat.
- Mixed venous oxygen saturation (Svo_2) reflects the global balance between oxygen delivery and consumption. It is measured at the distal end of the PAC because the pulmonary artery is the most appropriate place to sample a mixture of all the blood returning from the body. Four components contribute to Svo_2: total hemoglobin level, arterial oxygen saturation, CO, and oxygen consumption.

- Mixed central venous oxygen saturation ($\text{Scv}O_2$) reflects the balance between oxygen supply and delivery in the brain and upper body.
- Myocardial oxygen supply must balance myocardial oxygen demand to meet the body's myocardial metabolic requirements; otherwise, ischemia will occur.
- Prompt recognition and reversal of shock can help avoid a rapidly irreversible sequence of events that can result in the patient's death. Understanding the relationship between hemodynamic measurements and the different types of shock can help CCTPs recognize the type of shock and assess the effectiveness of treatment during transport.
- Oxygen saturation and gas expansion are concerns during flight. CCTPs should closely monitor the patient's oxygen saturation level so they can quickly respond to changes in the patient's condition and maintain sufficient levels of inspired oxygen. Gas expansion should be addressed by removing air from IV bags, using pumps for medication infusions, and zeroing transducers.

Vital Vocabulary

afterload The tension or stress that develops in the ventricles during systole; measured by pulmonary and systemic vascular resistance.

Allen test A technique in which the patient's hand is initially held above the head while the fist is clenched and the radial and ulnar arteries are compressed; the hand is then lowered and the fist is opened, ulnar pressure is released, and radial pressure is maintained. After the ulnar pressure is released, color should return to the hand within 6 seconds.

arterial lines Catheters inserted into the patient's arterial vascular system for the purpose of producing a waveform with pressure measurements; also called A-lines.

atrioventricular (AV) valves The valves (mitral and tricuspid) that separate the atria from the ventricles.

cardiac index (CI) A hemodynamic value that adjusts a patient's cardiac output to take into account the total body surface area.

cardiac output (CO) The amount of blood pumped out of the heart in 1 minute; the product of the stroke volume (average = 70 mL) and the heart rate (average = 60 to 100 beats/min).

caudal Pertaining to or in the direction of the feet.

central line–associated bloodstream infection (CLABSI) A primary bloodstream infection that develops in a patient who had a central line in place within the 48-hour period prior to the onset of the bloodstream infection.

central venous lines Intravenous access catheters that terminate in the central circulation, usually just proximal to the right atrium.

central venous pressure (CVP) The pressure in the superior vena cava (average = 2 to 6 cm H_2O), which reflects the pressure in the venous system when the blood is returned to the right atrium. It is indicative of a patient's fluid volume status and right-side heart performance.

cephalad Pertaining to or in the direction of the head or front.

chordae tendineae Tendons that connect the papillary muscles to the tricuspid and mitral valves.

dampened waveform A hemodynamic pressure waveform that appears to have lost crisp deflections.

diastole The relaxation phase of the heart cycle, in which the ventricles are dilated and filling with blood.

diastolic blood pressure (DBP) The trough or resting pressure in the arterial system that occurs during ventricular diastole.

dicrotic notch The brief increase in aortic pressure reflected in a notching of the wave; it is caused by the sudden closure and springing back of the aortic valve leaflets, and signals the start of diastole.

ejection fraction The average percentage of blood ejected from the left ventricle with each heartbeat.

Fick principle A method of indirectly determining cardiac output, in which the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood. The formula uses assumed values for oxygen consumption derived from basal metabolic studies on healthy subjects, which may or may not be valid in critically ill patients.

Frank–Starling law The principle that the force of the cardiac muscle contraction is proportional to the amount of stretch placed on the muscle fibers (meaning that the more the heart is stretched by the incoming blood, the more forcefully the ventricles contract and the more blood that is ejected); it demonstrates how changes in ventricular preload lead to changes in stroke volume. Also called the Starling curve.

invasive hemodynamic monitoring Methods for assessing the physiologic condition of the three principal components of the cardiovascular system: heart, vascular network, and fluid volume. It mainly assesses the capability of a patient's heart to pump the requisite amount of blood to the body, but also can assess compliance, tone, resistance of the vascular network, and fluid status; it includes a variety of pressure values and other measurements.

isovolumetric contraction The early stage of ventricular contraction during which ventricular blood volume is unchanging because all valves are closed (the semilunar valves have not yet opened).

isovolumetric relaxation The early stage of ventricular relaxation during which ventricular blood volume is unchanging because all valves are closed (the atrioventricular valves have not yet opened).

left ventricular end-diastolic pressure The pressure exerted on the left ventricle at the end of diastole; the normal value is 4 to 12 mm Hg and is measured by using a pulmonary artery catheter.

left ventricular stroke work index A calculation of the contractility of the left ventricle indexed to the patient's body surface area; equivalent to the stroke volume index.

leveling The process of ensuring that the hemodynamic pressure transducer is at the level of the atrium, which also corresponds to the level of the aortic root.

mean arterial pressure (MAP) The average (ie, constant) pressure in the arterial vasculature; a function of the systolic and diastolic blood pressures.

microcirculation Blood circulation provided to the tissues by the terminal end of vascular blood distribution: the capillaries, arterioles, postcapillary venules, and subunits.

mixed central venous oxygen saturation (ScvO$_2$) The percentage of oxygen bound to hemoglobin in blood returning to the right side of the heart from the head and upper body, which is representative of oxygen extraction from the blood by the head and upper extremities.

mixed venous oxygen saturation (SvO$_2$) The percentage of oxygen bound to hemoglobin in blood returning to the right side of the heart, which is representative of global oxygen extraction from the blood.

myocardial oxygen consumption (MVO$_2$) The volume of oxygen that the heart muscle consumes; an expression of the level of oxygen demand in the heart.

papillary muscles A type of muscle in the ventricle from which the chordae tendineae extend and attach to the cusps of the atrioventricular valves.

perfusion The circulation of oxygen and nutrients at the cellular level and removal of waste products of metabolism for elimination.

phlebostatic axis An imaginary point located at the fourth intercostal space, mid-chest level, which serves as an external landmark for the right atrium.

preload The end-diastolic stretch of the muscle fibers of the ventricle; measured by right atrial pressure or central venous pressure and wedge pressure.

Poiseuille's law The relationship that flow varies directly with any increase in pressure.

pulmonary artery catheter (PAC) A catheter with a balloon near its tip that is passed through a vein into the right side of the heart, through the right ventricle, and into the pulmonary artery; it records the pressure transmitted back from the left atrium. Also called a Swan–Ganz catheter.

pulmonary artery pressure The pressure measured in the pulmonary artery, usually displayed with a pressure waveform and digital systolic, diastolic, and mean values.

pulmonary capillary wedge pressure (PCWP) The mean pressure measured while occluding the pulmonary artery with a balloon-tipped catheter proximal to the site of measurement; it reflects left atrial pressure. Also called pulmonary artery wedge pressure or pulmonary artery occlusion pressure.

pulmonary vascular resistance (PVR) The resistance or impedance to ejection of the right ventricle of the heart.

pulse pressure The difference between the systolic and diastolic blood pressures.

pulsus paradoxus A decrease of more than 10 mm Hg in systolic blood pressure during inspiration.

right ventricular pressure The pressure in the right ventricle, which consists of the systolic, diastolic, and mean pressures; it is important during insertion and use of a pulmonary artery catheter.

right ventricular stroke work index A calculation of the contractility of the right ventricle indexed to the patient's body surface area.

Seldinger technique The technique most commonly used for inserting a central venous line. It involves inserting a needle with a syringe, then inserting a guide wire into the needle. After the guide wire is in place, the needle is removed, an incision is made, and a catheter is inserted over the guide wire; the guide wire is then removed.

semilunar valves The valves (aortic and pulmonic) that are the exits from the left and right ventricles into the aorta and the pulmonary artery, respectively.

stroke volume (SV) The amount of blood ejected by the ventricles during each contraction; it varies between 60 and 100 mL/beat, with the average being 70 mL.

stroke volume index A calculation of the contractility of the left ventricle indexed to the patient's body surface area; equivalent to the left ventricular stroke work index.

systemic vascular resistance (SVR) The resistance or impedance to ejection of the left ventricle of the heart.

systole The contraction phase of the heart cycle in which the ventricles pump blood out of the heart through the aorta and the pulmonary artery into the systemic and pulmonary circulatory systems.

systolic blood pressure (SBP) Peak pressure in the arterial system, which occurs during ventricular ejection or systole.

thermistor The apparatus used for quickly determining very small changes in pulmonary artery temperature.

triple-lumen catheter A type of catheter consisting of three distinct continuous tubes that allow for pressure monitoring, blood sampling, and fluid and drug administration.

zeroing The process of calibrating a pressure transducer to eliminate extraneous atmospheric and hydrostatic pressures from the data being measured.

CHAPTER 16

Mechanical Circulatory Support

W. David Sadler, MS, BSN, CCRN, CFRN, NRP
Johnnie Peoples, BSN, CCRN, CFRN, NREMT-P
William Hallinan, MSBA, RN

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the technical considerations in transporting a patient receiving mechanical circulatory support (MCS) (pp 841–842).
2. Explain how MCS systems interact with native circulation (p 841).
3. Discuss the considerations a provider should address when caring for a patient receiving MCS (pp 841–842).
4. Discuss how a team should approach and organize a transport involving MCS (p 842).
5. Discuss the principles of and indications for intra-aortic balloon pump therapy (p 842).
6. Discuss the principles of and indications for extracorporeal membrane oxygenation (p 860).
7. Discuss the principles of and indications for a microaxial catheter pump system (pp 866–868).
8. Discuss the principles of and indications for implantable left ventricular assist devices (pp 869–886).

Introduction

Mechanically assisted circulation, mechanical circulatory systems, and ventricular assist devices all describe means of augmenting or replacing the native cardiac output (CO) from the heart. The general term used for these interventions in this chapter is **mechanical circulatory support (MCS)**. MCS may be used to treat both acute and chronic conditions and may apply either a univentricular or biventricular approach, where the circulatory system's pumping mechanism may be external to the body (ie, extracorporeal) or internal to the body (*intracorporeal*). MCS may be complemented by gas exchange, temperature control, or renal replacement therapy.

MCS may occur in the prehospital, community hospital, or specialty hospital setting. As patient volume grows, the critical care transport provider (CCTP) will, in turn, be called upon to transport these patients with increasing frequency. Given the advanced medical technology and rapidly progressing nature of this field, CCTPs will need to stay current and competent on the procedures and equipment used to support and care for patients receiving MCS.

Safe transport should focus on detailed assessment and patient monitoring, balanced with high-quality patient care and technical proficiency with the pump system. Critical care transport (CCT) teams should include members who have been adequately trained and have demonstrated competency working in this transport environment. Team members should have a strong understanding of the interdependence of the pump system and the patient, including how the patient interacts with the pump.

This chapter addresses the commonly seen pump platforms: the intra-aortic balloon pump (IABP), the microaxial percutaneous pump, extracorporeal membrane oxygenation, and left ventricular (LV) assist systems.

Intra-aortic Balloon Pump

The earliest and perhaps best-known cardiac-assist device is the IABP. **Intra-aortic balloon pump (IABP) therapy** involves use of a balloon connected to a pump via a catheter that has been inserted into the aorta to provide temporary assistance to a failing heart. IABP counterpulsation is a therapy used worldwide to assist patients with LV failure.

IABP units have benefited from miniaturization, such that some IABP models will fit easily into a helicopter for transport. The intra-aortic balloon (IAB) catheters have also become smaller, with multiple-lumen designs allowing for arterial pressure monitoring, IAB inflation and deflation, and, in current models, fiberoptic sensors.

Important responsibilities of the CCTP include securing the patient to prevent movement of the balloon (which can create significant problems or injuries) and ensuring that all equipment has the necessary power supply to continue operating during transport **FIGURE 16-1**. Although the transport of a patient during IABP therapy can be a daunting task for even IABP-trained transport professionals, CCTPs can obtain the knowledge and skills necessary to comfortably assist in this situation, and in some programs may actually transport patients receiving IABP therapy themselves. IABP therapy is an advanced skill. This section discusses maintaining IABP therapy, recognizing and correcting problems, and performing emergency procedures during IABP failure. It is not intended to be an all-inclusive guide to IABP therapy.

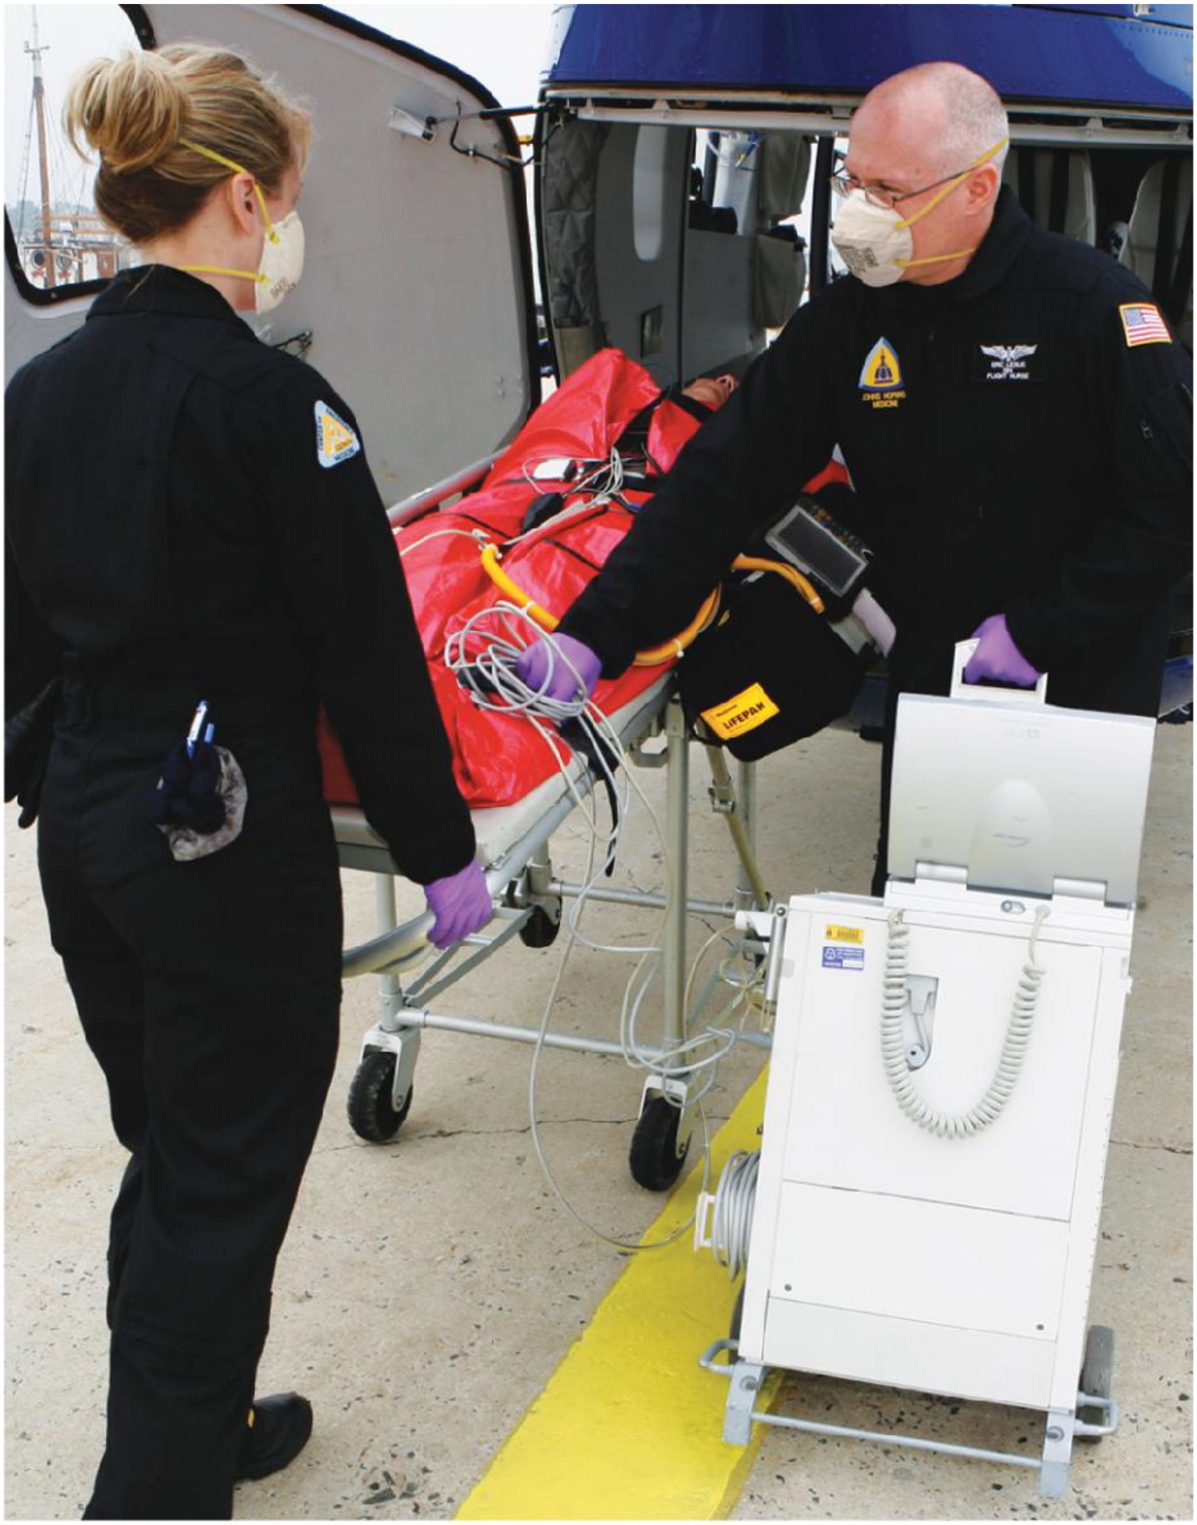

FIGURE 16-1 An important CCTP responsibility when transporting a patient with an intra-aortic balloon is to secure the patient to prevent balloon movement.

© Jones & Bartlett Learning.

Most CCT programs require that a CCTP be accompanied by a certified perfusionist or critical care registered nurse knowledgeable about the IABP. Thus, CCTPs will be working with a colleague with additional training in this area on calls that involve a patient receiving IABP therapy.

Mechanics of IABP Function

IABP therapy begins with the insertion (by a trained and credentialed provider, physician, or surgeon) of a balloon, typically via the femoral artery, into the descending thoracic aorta. The tip of the balloon catheter is located just distal (approximately 0.75 inch [2 cm] below) the takeoff of the left subclavian artery. After it is in place, the balloon is connected to a console to shuttle helium gas; the balloon is inflated with this gas at the onset of diastole and then deflated just before systole (ventricular ejection). Inflation and deflation are timed to the cardiac cycle, resulting in significant augmentation of flow to the coronary and renal arteries during diastole (increased supply) and substantially reduced afterload during systole (decreased demand).

Balloon Structure and Position

The IAB catheter consists of a long, narrow balloon mounted on a thin catheter. Older catheters had two lumens: a central lumen and a gas lumen. Newer catheters have a third, fiberoptic lumen.

- The **central lumen** is used to guide catheter insertion into the femoral artery and through the arterial system, positioning the IAB tip in the descending thoracic aorta just below the origin of the left subclavian artery **FIGURE 16-2**. After the catheter is in place, the central lumen also allows monitoring of aortic blood pressure (BP) through a setup much like a standard arterial line.
- The **gas lumen** carries helium gas from the pump console to the IAB to control balloon inflation.
- The fiberoptic lumen contains fiberoptic strands used to measure aortic pressure and (in some models) aortic oximetry.

Description

Typically, the IABP catheter is threaded into the descending aorta through the femoral artery. Alternative placement strategies for these catheters include access through the axillary artery and, rarely, transthoracic placement, which is typically reserved for critically ill patients unable to be weaned from cardiopulmonary bypass following cardiac operations in whom femoral access is not possible or is contraindicated.

Insertion can be accomplished through a sheath (a large-diameter catheter placed into a vessel to allow smaller catheters or devices to be inserted through the catheter lumen into the vessel) or by using a catheter designed for sheathless insertion. When access to the femoral artery has already been obtained using a sheath (such as in a cardiac catheterization laboratory), a practitioner inserting an IABP catheter may decide to insert the device through the existing sheath rather than making a separate puncture. When IABP placement is elective or planned, or when significant concerns about leg ischemia exist, sheathless insertion offers the advantage of an overall smaller-diameter device in the access vessel. Sheathless insertion, then, may reduce complications of limb ischemia by reducing the size of the obstruction in the femoral artery.

Counterpulsation Sequence

Following placement of the catheter, it is connected to the IABP console. The IABP console pump inflates and deflates the balloon with helium in conjunction with the mechanical cardiac cycle. Helium is used because of its low molecular weight, which allows it to be pumped rapidly without much turbulence from the flow of the gas. Helium also enhances the safety of this therapy because it is less likely to cause an air embolus if the balloon ruptures. Correct IABP timing inflates the balloon during diastole when the LV is relaxed and the coronary arteries are filling with oxygenated blood **FIGURE 16-3**.

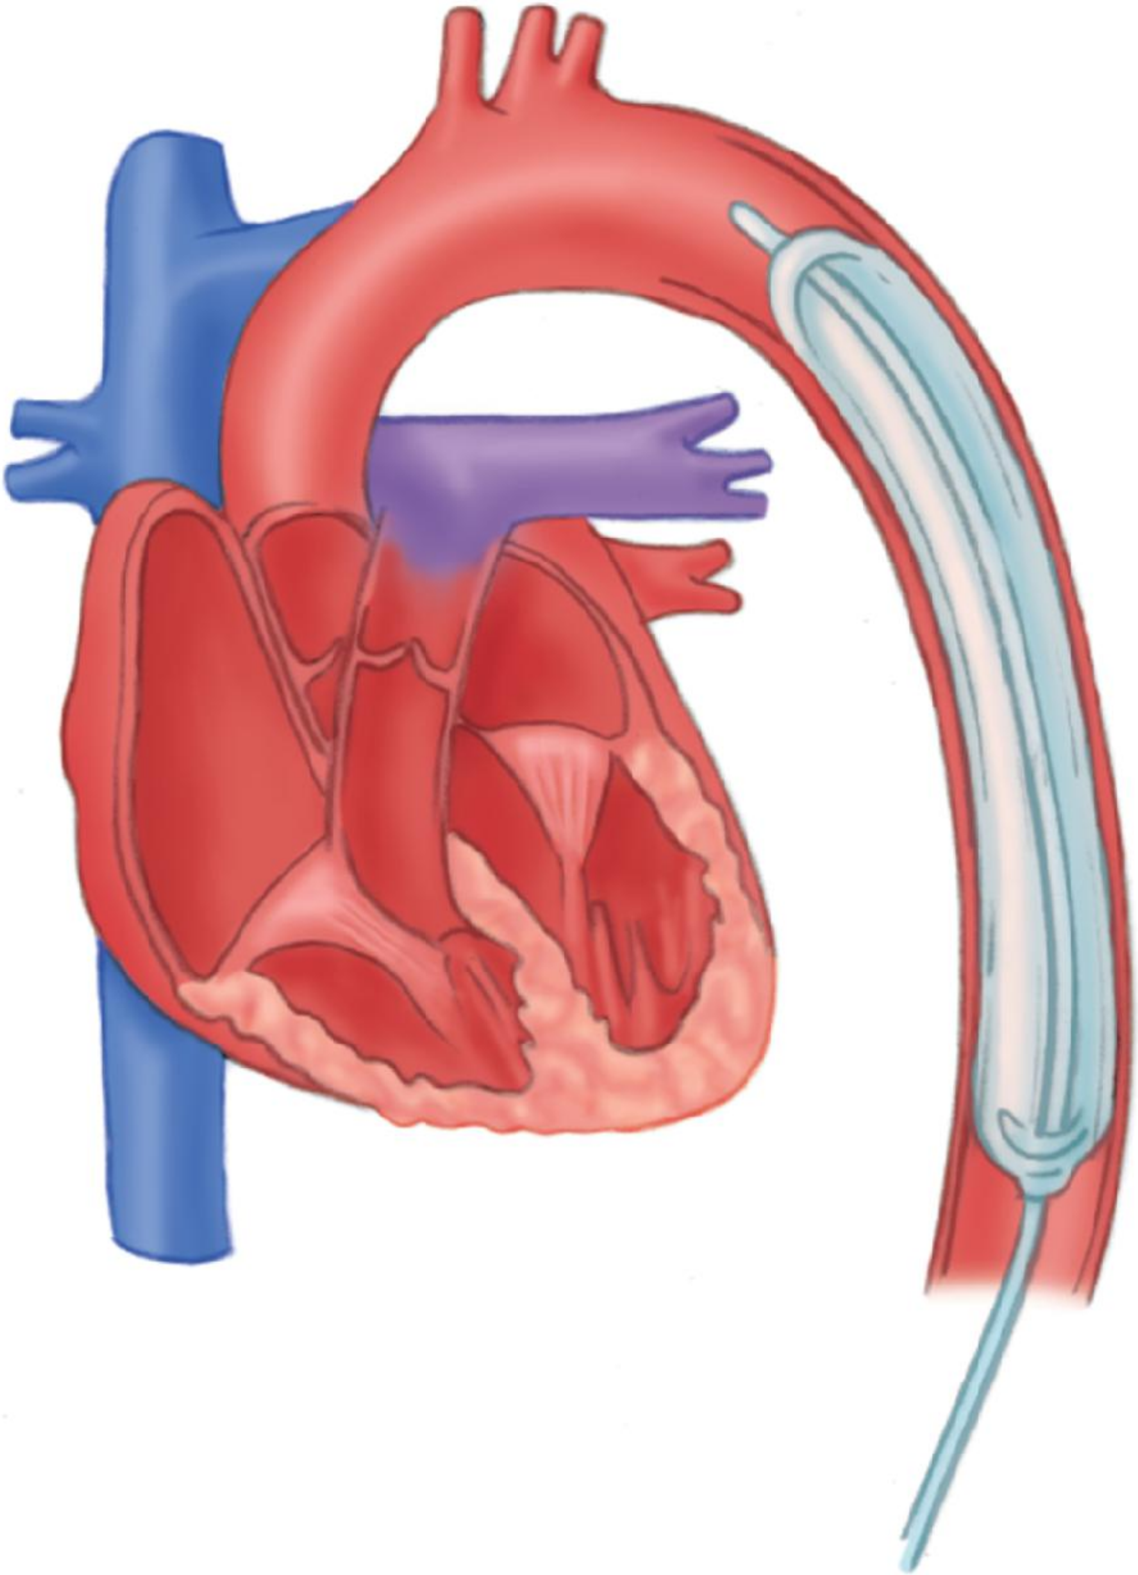

FIGURE 16-3 Intra-aortic balloon inflation.

Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

During IABP therapy, the balloon deflates during systole and inflates during diastole. An electrocardiography (ECG) machine determines when the balloon should be inflated and deflated. If a ECG signal is unavailable, then timing can be triggered based on an arterial pressure waveform or at a fixed rate.

Physiologic Effects of IABP Therapy

For patients in cardiogenic shock, IABP therapy lowers systolic blood pressure (SBP) as the balloon deflates at the onset of systole and raises diastolic pressure when the balloon inflates during diastole. Mean arterial pressure (MAP) will also rise as a result of the **diastolic augmentation**. Diastolic augmentation may be best thought of as a "second systole" because it occurs during diastole, but the rapid inflation of the balloon augments the diastolic pressure and effectively creates a second pressure wave to perfuse the heart and tissues. This sudden increase in pressure improves the flow to the coronary arteries and systemic circulation.

The balloon deflates at the end of diastole, just before the next ventricular ejection **FIGURE 16-4**. The sudden deflation of the balloon causes a drop in aortic pressure because the space that was occupied by the balloon is suddenly gone. This dramatic drop in pressure reduces the resistance against which the ventricle has to work to open the aortic valve and eject blood. Because the majority of the myocardial oxygen demand is expended in overcoming this pressure, the result is a dramatic decrease in myocardial oxygen consumption (MVo_2). In addition, the stroke volume (SV) is maximized. The increase in SV allows the heart rate to decrease while still maintaining CO. A decrease in heart rate leads to increased diastolic time and, therefore, longer coronary perfusion time. The improvement in CO, in conjunction with a lower MVo_2, is intended to interrupt the cycle of heart failure, allowing the heart to "rest" and recover from the insult that started the cycle. The increased CO results in increased renal and peripheral perfusion, which may also improve metabolic derangements that may have developed as a result of the shock state during the period of decreased CO.

Balloon Volume or Augmentation

The IABP console allows the operator to control the volume of gas shuttled back and forth to the balloon with each counterpulsation cycle. This control is referred to as either augmentation or balloon volume. Typically, when IABP therapy is initiated immediately after the IABP catheter is inserted, software in the console begins shuttling gas at the lowest volume possible, gradually increasing the volume over several inflation–deflation cycles to allow the balloon to unfurl from the compressed condition in which it is packaged.

During routine use or during transport, little reason exists to adjust the balloon volume or augmentation to less than maximal or full volume. This control is used with nonstandard balloon catheters, such as might be inserted in pediatric patients or, in some settings, to wean the patient from IABP therapy before removing the balloon. Given that a fully inflated balloon rarely occupies more than one-half the total diameter of the average aorta, weaning is more efficiently accomplished by reducing the assist ratio or frequency (discussed later in this chapter) rather than the inflation volume.

Waveform Changes and Triggers

The **timing** of the balloon's inflation and deflation is crucial; if inflation and deflation do not occur at the proper time in the cardiac cycle, then the device will not only fail to yield the desired results, but also could harm the patient. In earlier-model IABP consoles, it was necessary to ensure that timing occurred at the proper points in the cardiac cycle. Modern consoles use complex computerized algorithms to continually monitor the patient's ECG and pressure waveforms, optimizing timing with a level of accuracy that exceeds the capabilities of human operators. Although it is possible for the CCTP to modify IABP timing, this modification is almost never necessary except in emergency situations. However, because improper timing can be detrimental to the patient, it is important for clinicians to be able to recognize incorrect timing and understand the implications for the patient. Not only does poor timing fail to maximize

IABP therapy, but errors in timing, such as late deflation of the balloon, can actually worsen heart failure and early inflation can damage the aortic valve.

The console constantly monitors the arterial pressure waveform, the patient’s ECG, and the balloon gas pressure waveform during pumping to evaluate and adjust the timing and effectiveness of the therapy. The arterial pressure waveform that the IABP console monitors may come from the central lumen of the IAB catheter, from the fiberoptic catheter, or from a peripheral arterial catheter **FIGURE 16-5** and **FIGURE 16-6**. IAB inflation and deflation can be set to respond to the ECG, a pressure waveform, a pacemaker, an internally preprogrammed rate, or combinations of these factors. The most reliable triggering mechanism, however, is based on the ECG. Triggering the IABP from the ECG provides the optimal timing for inflation and deflation while still permitting the IAB to immediately deflate if the console senses an increase in pressure indicating ventricular ejection (such as with a premature ventricular or atrial contraction), a paced beat, or another signal that systole has begun. Most modern IABP console computers are able to track irregular arrhythmias and tachyarrhythmias (eg, atrial fibrillation) and adjust the timing as needed to protect the patient. The provider caring for the patient chooses the trigger best suited to the patient’s condition.

Description

Trigger Selection

Trigger signals available to initiate balloon inflation and deflation vary by manufacturer, although all IABP consoles usually default to using the QRS complex from the ECG to locate each cardiac cycle **FIGURE 16-7**. Current-generation IABP consoles have sophisticated computer software capable of not only recognizing changes in heart rate, balloon pressure, patient BP, tubing dead space, and console pneumatic rate of response, but also instantly making changes in timing to inflate and maintain balloon inflation throughout diastole. So-called real timing using sophisticated computer software offers greater afterload reduction and improved MAP by extending the inflation period into the early isovolumetric contraction period.

Description

ECG Triggering

The safest trigger on most IABP consoles is the ECG, which allows the pump to trigger from the R wave on the patient's ECG for deflation. Using this trigger for deflation is effective for preventing early deflation. It allows for sudden deflation of the IAB, resulting in the end-diastolic dip that decreases the workload of the ventricles to overcome the aortic pressure and eject blood from the ventricles. Pacer spikes are ignored in most consoles when using the ECG as the trigger source. Some manufacturers offer more than one ECG trigger mode, depending on heart rate and morphologic features of the ECG complexes. During ECG triggering, deflation will also occur if the IABP console senses an increase in SBP indicative of the onset of systole, regardless of whether an R wave appears on the ECG.

Pressure Triggering

Pressure can also be selected as a trigger source. In this case, the systolic upstroke of the patient's arterial pressure waveform is used as the trigger source. Using pressure as a trigger source is not as desirable as using the ECG because pressure delays deflation until systolic ejection has already begun, reducing the beneficial effects of deflation simultaneously with ventricular ejection. With pressure selected as the trigger, most IABP consoles ignore the ECG signal. Pressure is the preferred trigger mode during cardiopulmonary resuscitation (CPR) because it works synchronously with compressions to improve diastolic perfusion. This mode can be useful when the ECG signal is unavailable, excessive artifact exists, or ECG voltage is too low to produce a recognizable R wave. Excessive movement of ECG wires, very active patients, and procedures such as operations that involve considerable staff contact with ECG lead areas or electrocautery interference with ECG signals may make pressure a desirable trigger mode.

Pacemaker Triggering

Most IABP consoles also offer a pacemaker trigger, which may be set based on either atrial-paced or ventricular-paced rhythms. The only time that pacemaker triggers are useful is when the patient rhythm is 100% paced and the QRS complex has such poor morphologic features that the IABP console cannot use it when operating in the ECG trigger mode. For patients with an AV-paced rhythm, the ventricular-paced trigger should be selected if pacer triggering is required. Most IABP consoles also offer an internal trigger mode that works completely asynchronously with the patient's ECG and arterial pressure. This internal trigger mode should never be used in any patient with a cardiac output, including patients undergoing CPR. Situations when internal triggering may be used are generally limited to cardiac surgical procedures where no ECG and external circulatory support is available. Internal triggering can prevent thrombus formation on the IABP catheter in such cases.

Evaluation of an IABP Waveform

The IABP device has the option to pump in several modes called **assist ratios** or IABP frequency. These modes are as follows:

- 1:1 assist ratio, in which the pump inflates with each heartbeat
- 1:2 assist ratio, in which the pump inflates with every other heartbeat
- 1:3 assist ratio, in which the pump inflates with every third heartbeat
- 1:4 assist ratio, in which the pump inflates with every fourth heartbeat
- 1:8 assist ratio, in which the pump inflates with every eighth heartbeat

The CCTP should assess several parameters of the waveform. The evaluation of the IABP waveform is most easily accomplished by placing the IABP into the 1:2 assist ratio, which allows comparison of pressure waves of the unassisted cycle with the assisted one. In this mode, every other contraction is augmented by the IABP. In a strip of 1:2 augmentation waveforms, the peaks created by the inflation of the IAB are easily identified because they should be the highest pressure peaks **FIGURE 16-8**. Because the IAB inflates during diastole, these pressure waveforms are referred to as the diastolic augmentation waveforms. The pressure waveform that follows the diastolic augmentation peak (IAB inflation) is referred to as the **assisted systole** waveform because the deflation of the IAB assists the ventricle in ejecting blood, thereby reducing the ventricular afterload (the resistance that must be overcome to eject the blood from the ventricles). The third pressure waveform is referred to as **unassisted systole** because the balloon pump is not moving and the waveform reflects what would normally occur without IABP intervention.

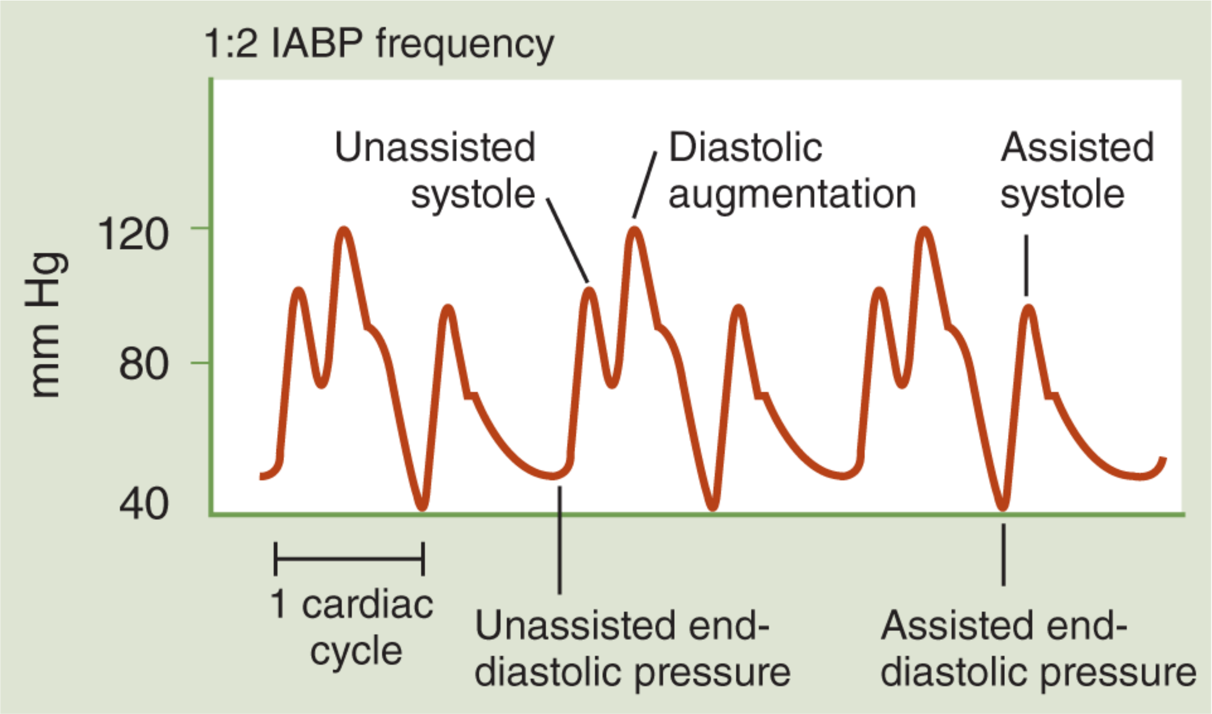

FIGURE 16-8 Pressure waveform augmented with a 1:2 assist ratio.

Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Description

To evaluate for correct IABP timing, the pressure peaks, slopes, and inflation and deflation points of each of these pressure waveforms must be evaluated in a systematic manner. The parameters of the IABP waveform that should be evaluated are as follows:

- **Systole and diastole of each pressure waveform.** Although it may seem confusing at first, it is critical to identify systole and diastole in the pressure waveforms. The balloon inflation gives an appearance of systole as the pressure peaks are high; however, it is important to remember that the heart is in diastole. It may help to think of balloon inflation as a second systole that occurs in diastole.
- **Diastolic augmentation, assisted systole, and unassisted systole.** When looking at a 1:2 augmentation strip, this step can

be done easily by identifying the balloon inflation. This pressure waveform will be the diastolic augmentation. Immediately before this waveform is the unassisted systole. The pressure waveform that occurs immediately after the diastolic augmentation is the assisted systole.

- **The point of inflation.** Inflation should occur at the dicrotic notch, which signals the closure of the aortic valve **FIGURE 16-9A**. In the rare case in which the operator might need to adjust the timing, the dicrotic notch can be visualized by manually moving the IAB inflation point to a later time in the cardiac cycle. After the dicrotic notch is located, the inflation should be adjusted to an earlier time until the notch created by the inflation of the balloon on the dicrotic notch forms a crisp *V* **FIGURE 16-9B**. The balloon inflation point should be reflected on the pressure waveform as a sudden increase in pressure during diastole. A crisp *V* with no evidence of the dicrotic notch reflects inflation of the balloon immediately at the onset of diastole. If the dicrotic notch is visible, then inflation is likely occurring too late. If inflation occurs too early, then the *V* will open slightly as the slope of the diastolic augmentation decreases slightly (less steep slope).
- **End-diastolic dip in pressure created by balloon deflation.** The end-diastolic dip should dip below the baseline end-diastolic pressure (EDP) occurring with unassisted systole. This dip should be followed by a straight-line slope to the next systolic peak. If a diastolic dip is created, followed by a plateau and then the beginning of the systolic peak, then deflation is occurring too early. If no end-diastolic dip is present, but rather an EDP that is above the baseline of the unassisted systole and a straight slope up to the next systolic peak, then deflation is occurring late. Ideally, the IABP software will optimize deflation by adjusting it (earlier or later) to obtain the lowest possible assisted EDP while not reducing diastolic augmentation. CCTPs will find it helpful to be familiar with the expected waveforms; however, it is important to remember that deflation is best optimized to achieve the most favorable pressures indicative of reduction in afterload (assisted

EDP) without impinging on ventricular ejection (reduced diastolic augmentation).

- **Slope of diastolic augmentation pressure and slope of assisted systole.** The slopes of the diastolic augmentation peak (balloon inflation) and the slope from the end-diastolic dip to the assisted systolic peak should be straight lines and nearly parallel **FIGURE 16-10**.
- **Diastolic augmentation peak pressure.** With effective IABP therapy, the diastolic augmentation peak pressure will be higher than (or at least equal to) the systolic pressures.
- **Comparison of the peak pressure of assisted systole with the peak pressure of unassisted systole.** With effective IABP therapy, the peak pressure of assisted systole will be lower than the systolic peak of unassisted systole **FIGURE 16-11**. This reflects that the IABP is reducing the peak pressures and, therefore, decreasing the workload of the heart and reducing the MV_{O_2}.

Description

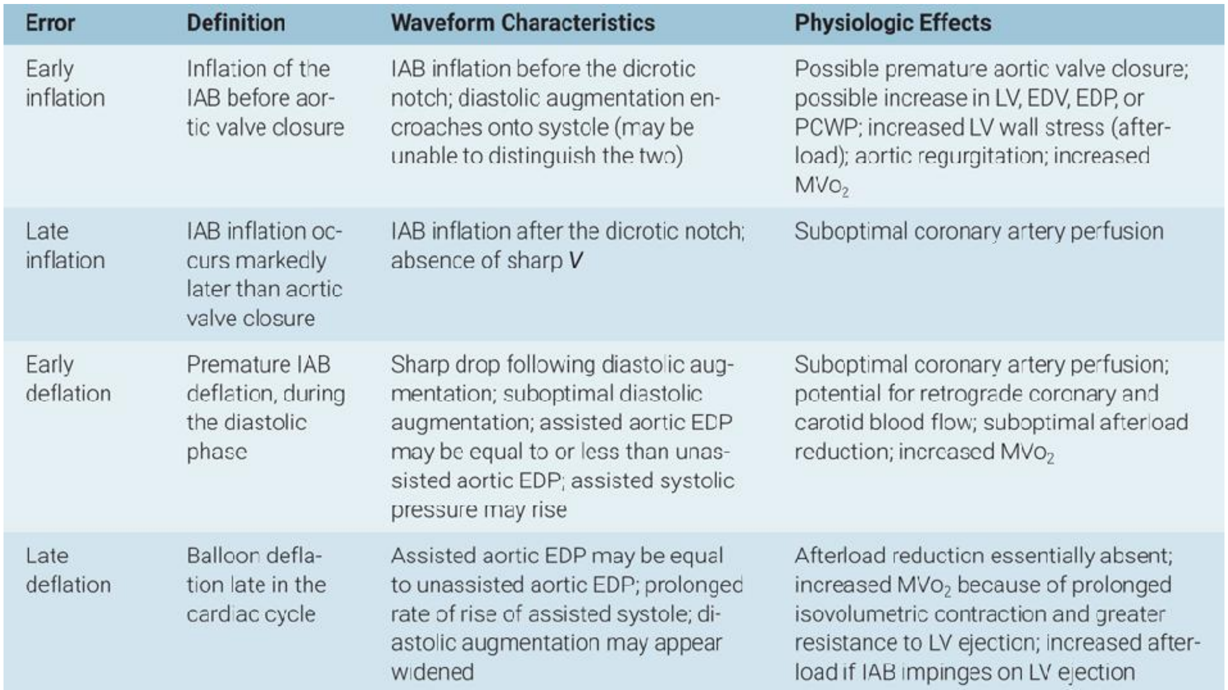
Evaluation of IABP Timing

Software algorithms work effectively and efficiently to monitor and adjust IABP timing in virtually any situation. Nonetheless, although this knowledge is far less important today than with earlier IABP technology, the CCTP should be familiar with potential timing errors, waveform characteristics, and physiologic effects associated with this therapy **TABLE 16-1**. Today, most timing errors result from operators overriding the IABP software.

TABLE 16-1 **IABP Timing Errors**



Error	Definition	Waveform Characteristics	Physiologic Effects
Early inflation	Inflation of the IAB before aortic valve closure	IAB inflation before the dicrotic notch; diastolic augmentation encroaches onto systole (may be unable to distinguish the two)	Possible premature aortic valve closure; possible increase in LV, EDV, EDP, or PCWP; increased LV wall stress (afterload); aortic regurgitation; increased MVo_2
Late inflation	IAB inflation occurs markedly later than aortic valve closure	IAB inflation after the dicrotic notch; absence of sharp ***V***	Suboptimal coronary artery perfusion
Early deflation	Premature IAB deflation, during the diastolic phase	Sharp drop following diastolic augmentation; suboptimal diastolic augmentation; assisted aortic EDP may be equal to or less than unassisted aortic EDP; assisted systolic pressure may rise	Suboptimal coronary artery perfusion; potential for retrograde coronary and carotid blood flow; suboptimal afterload reduction; increased MVo_2
Late deflation	Balloon deflation late in the cardiac cycle	Assisted aortic EDP may be equal to unassisted aortic EDP; prolonged rate of rise of assisted systole; diastolic augmentation may appear widened	Afterload reduction essentially absent; increased MVo_2 because of prolonged isovolumetric contraction and greater resistance to LV ejection; increased afterload if IAB impinges on LV ejection

Abbreviations: EDP, end-diastolic pressure; EDV, end-diastolic volume; IAB, intra-aortic balloon; LV, left ventricular; MVo_2, myocardial oxygen consumption; PCWP, pulmonary capillary wedge pressure

Description

Early Inflation

The IAB should inflate at the dicrotic notch, which signals the closure of the aortic valves. Inflation that occurs too early is reflected on the waveform by a shortened normal pressure decrease that follows diastole. Because the aortic valves have not closed, this error in timing can be detrimental to the patient by decreasing pumping efficacy. On the pressure waveform, this is reflected as an “opened *V*” and with a lessened slope on the diastolic augmentation waveform. The pathophysiologic effect of early inflation is that the ejection of blood from the LV is impaired by the sudden increase in aortic pressure while the aortic valve is open, forcing premature closure of the aortic valves and decreasing the SV **FIGURE 16-12**. It is also possible for early inflation to result in damage to the aortic valve.

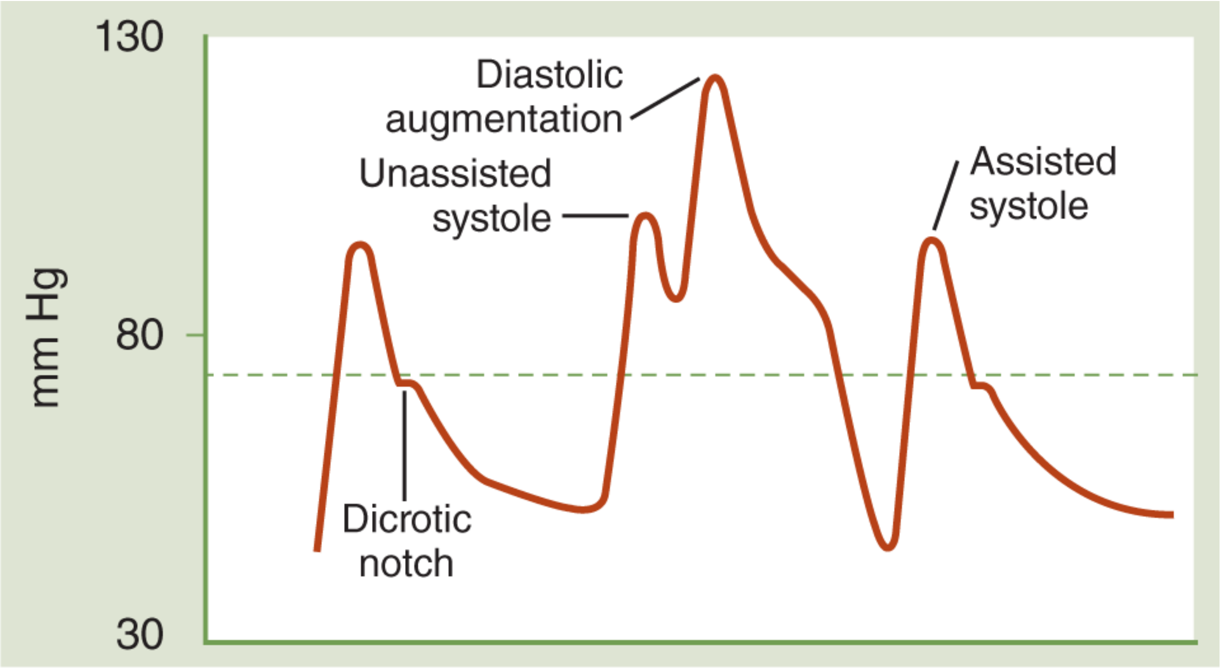

FIGURE 16-12 Early inflation.

Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Description

Late Inflation

If the dicrotic notch is visible on the pressure waveform, then inflation of the IAB is late. The late inflation of the IAB, although causing little harm to the patient, does not maximize the benefits of IABP therapy because the pressure in the aorta has decreased before the IAB inflates. Therefore, the profound increase in diastolic pressure that maximizes coronary and systemic circulation is not realized **FIGURE 16-13**.

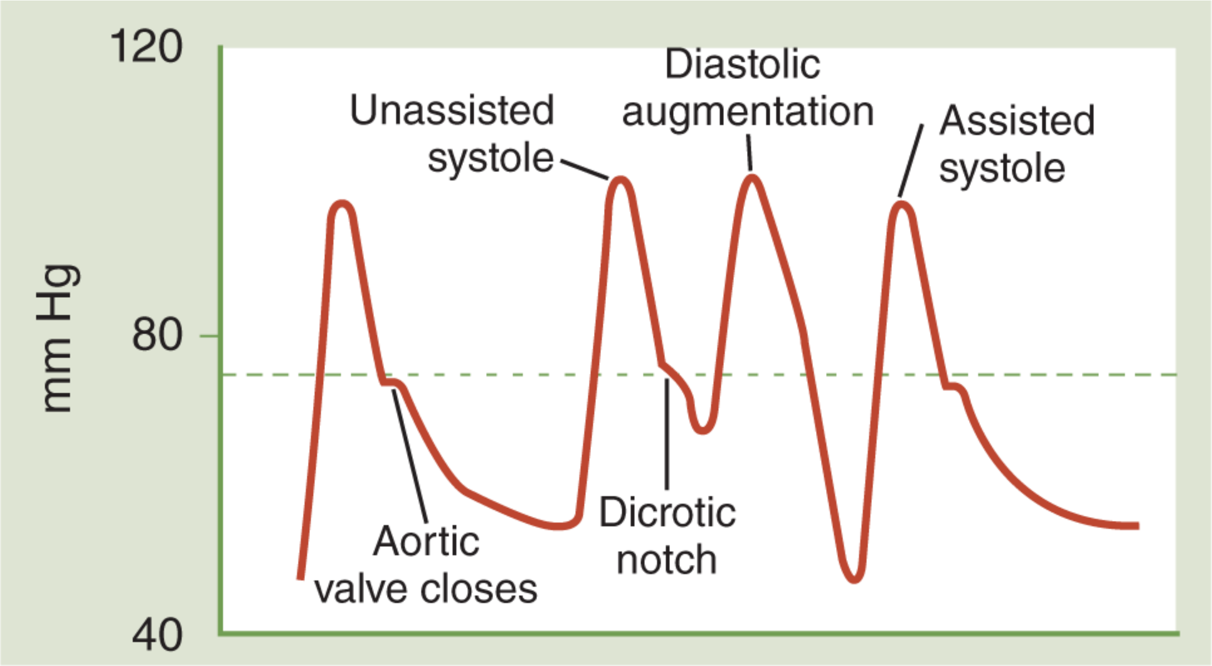

FIGURE 16-13 Late inflation.

Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Description

Early Deflation

If deflation occurs too early, then the pressure in the aorta will equalize and rise slightly to plateau before systole, meaning that a higher EDP must be overcome for the ventricles to eject blood. The waveform will exhibit a sharp drop from diastolic augmentation with a characteristic prolongation of the assisted aortic end-diastolic period. This lack of inflation through to the end of diastole means not only that the benefits of IABP therapy are not realized by assisting the next systole, but also that the duration of increased pressure during diastole (which benefits the coronary arteries and systemic circulation) is decreased **FIGURE 16-14**.

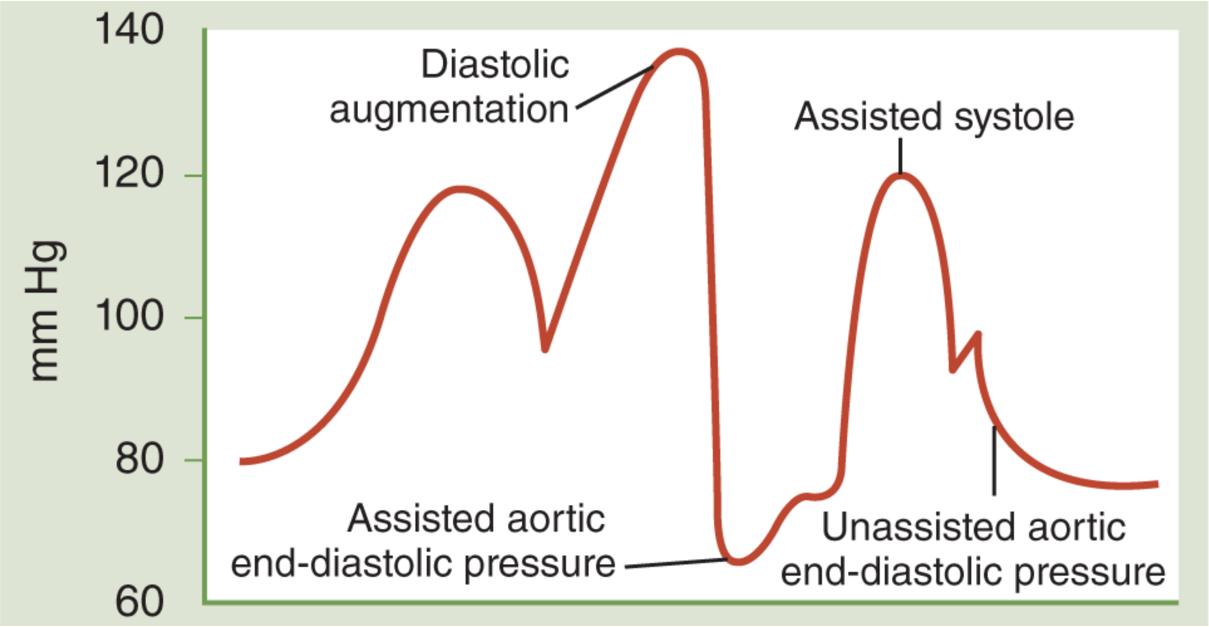

FIGURE 16-14 Early deflation.

Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Description

Late Deflation

Late deflation of the IAB can be extremely detrimental to the patient. Late deflation is characterized by a widened appearance of the diastolic augmentation waveform base and a prolonged rate of rise in the assisted systolic waveform **FIGURE 16-15**. Because the balloon is still inflated while the heart is trying to eject blood from the LV, the pressure in the aorta never drops to the baseline or dips below it. This increased pressure at which the aortic valves can open and eject blood from the ventricles increases the afterload and significantly increases the MVO_2 of the LV because the majority of MVO_2 is used to overcome the pressure in the aorta to eject the blood. Thus, late deflation of the balloon worsens myocardial ischemia and needs to be avoided.

Description

IAB Insertion

Indications

IABP therapy can be used effectively to treat a variety of conditions resulting in heart failure. Conditions or situations that benefit from IABP therapy are listed in **TABLE 16-2**. Whatever the indication for its use, the IABP fulfills basic roles: reducing the workload of the myocardium, improving coronary and systemic flow, and restoring the balance between the metabolic demands of the heart and body and the supply of oxygen available. **TABLE 16-3** summarizes the potential benefits of IABP therapy.

TABLE 16-2	**Conditions or Situations That Benefit From IABP Therapy**
Chest pain from unstable angina	

Severe arrhythmias
Cardiogenic shock
Heart failure
Myocardial ischemia from unstable angina
Myocardial infarction
Ventricular irritability
Ventricular septal defect (before surgical intervention)
Papillary muscle dysfunction (before surgical intervention)
Papillary muscle rupture (before surgical intervention)
Impaired cardiac function (before surgical intervention)
Support during diagnostic and interventional procedures (eg, coronary angiography and angioplasty)
Weaning from cardiopulmonary bypass
Failed angioplasty (until the patient undergoes surgical intervention)
Unsuccessful valvuloplasty (until the patient undergoes surgical intervention)
During cardiopulmonary bypass
Cardiac support during noncardiac operations
Prophylactic support while awaiting cardiac operations
Myocardial contusion
Mechanical bridge to other assist devices or heart transplantation

Indications for IABP therapy include the following:

- Refractory ventricular failure
- Cardiogenic shock
- Unstable refractory angina
- Impending infarction
- Mechanical complications caused by acute myocardial infarction (AMI), ventricular septal defect (a hole in the wall between the ventricles), mitral regurgitation, or papillary muscle rupture
- Ischemia-related intractable ventricular arrhythmias
- Cardiac support during high-risk general surgical or coronary angiography or angioplasty procedures
- Weaning from cardiopulmonary bypass
- Intraoperative pulsatile flow generation
- Support for failed angioplasty and valvuloplasty

In patients with myocardial ischemia and chest pain associated with unstable angina, impending infarction, and intractable ventricular arrhythmias related to ischemia, the IAB can be beneficial in maintaining adequate coronary artery perfusion, relieving myocardial ischemia, and decreasing myocardial oxygen demand. If cardiac catheterization and further interventions are necessary, then the patient can undergo these procedures while in a more hemodynamically stable condition. The IAB can also be used in conjunction with cardiopulmonary bypass pumps to provide pulsatile flow.

Patients who experience severe chest pain accompanied by ECG changes or arrhythmias and who do not obtain relief from drug therapy are at great risk of developing a myocardial infarction (MI). Improving coronary blood flow and reducing LV work will minimize chest pain and the ECG changes associated with the MI. IABP therapy is often considered when symptoms persist despite maximal medical therapy. If cardiac catheterization and further interventions are indicated, then the IABP can improve the patient's hemodynamic status before these procedures are performed.

Depending on the area of an AMI, mechanical complications can occur from the heart damage. Although these complications arise in only a small percentage of MIs, the resulting hemodynamic compromise can have lethal consequences, especially if not treated immediately. Ventricular septal defects, papillary muscle dysfunction, and papillary muscle rupture usually require surgical interventions, often on an emergency basis. If the patient undergoes cardiac catheterization or surgical intervention in a hemodynamically compromised state, then the potential for mortality and morbidity increases significantly. The IABP provides temporary support to achieve hemodynamic stability before undertaking definitive treatment measures.

Ventricular irritability, a frequent complication of an AMI, can lead to severe arrhythmias and further hemodynamic compromise. In most patients, conventional drug therapy and supportive measures are sufficient to reverse the irritability and arrhythmias. However, those patients who do not respond to conventional medical therapy are at high risk for further myocardial damage and death. IABP therapy has proved effective in stabilizing the hemodynamic condition of patients with ventricular irritability or arrhythmias by increasing coronary artery perfusion, reducing ischemia, and maintaining adequate peripheral perfusion.

In the already compromised heart, a decrease in arterial pressure can reduce the myocardial oxygen supply and cause a loss of functional myocardial tissue. To prevent worsening of their heart failure and cardiogenic shock, these patients require prompt treatment of any signs of hemodynamic instability. Treatment aims at relieving LV workload and restoring the balance between myocardial oxygen supply and demand, allowing the myocardium time to heal and recover its maximal function. IABP therapy assists in this effort by decreasing LV workload and increasing coronary artery perfusion.

LV failure following an AMI may progress to cardiogenic shock. As with LV failure, the objectives of cardiogenic shock treatment are decreased cardiac work, increased myocardial oxygen supply, and a lowered MVO_2. The combined effects of IABP therapy (ie, increased oxygen supply, decreased afterload, and improved systemic perfusion) allow the heart to rest and help halt the subsequent vicious cycle that often occurs in an AMI.

Patients with impaired cardiac function are considered high-risk candidates for general surgical procedures. Anesthetic agents and the procedure itself can place increased oxygen demands on the weakened heart. IABP therapy provides hemodynamic stability by helping balance myocardial oxygen supply and demand preoperatively, intraoperatively, and during the critical postoperative period when demands on the heart are particularly high.

The IABP works in conjunction with coronary angiography and angioplasty to support and stabilize the condition of high-risk patients undergoing these procedures. Overall, IABP therapy can provide increased coronary artery perfusion and a reduction in cardiac work, thereby lowering the risk of hemodynamic compromise caused by reduced coronary flow during IAB inflation or acute coronary occlusion.

Weaning a patient from cardiopulmonary bypass may be difficult when support of the heart and lungs on the cardiopulmonary bypass machine is prolonged, surgical revascularization (placement of bypass grafts around blocked coronary arteries) is only partially achieved, or the patient has preexisting myocardial dysfunction. Termination of cardiopulmonary bypass may result in hypotension and a low CO, despite administration of inotropic and vasoactive drugs. IABP therapy in this setting decreases LV resistance, improves CO, and increases coronary artery and systemic perfusion pressures, facilitating the patient's removal from the cardiopulmonary bypass machine.

IABP therapy can support and stabilize patients with severe LV failure resulting from failed angioplasty (ie, an attempt to open an occluded coronary artery in an interventional cardiac catheterization laboratory). In this setting, it can provide increased coronary artery perfusion and decreased cardiac work, thereby reducing the risk of hemodynamic compromise because of reduced coronary flow or acute coronary occlusion. When valvuloplasty (a procedure in which a balloon-tipped catheter is used to dilate a stenotic heart valve) is unsuccessful, however, it may produce cardiac dysfunction. The IABP helps support cardiac function until the patient can undergo definitive valve repair or replacement.

Contraindications

Although CCTPs do not insert the IAB, they may arrive before or during consideration of IAB insertion. It is useful to understand the contraindications to IABP therapy, which include the following:

- Severe aortic valvular insufficiency
- Abdominal or aortic aneurysm
- Severe calcific aortic or iliac arterial disease or severe peripheral vascular disease

These contraindications are discussed individually in the following sections.

Severe Aortic Insufficiency

IABP therapy is contraindicated in patients with severe aortic valve insufficiency. For the benefits of IABP therapy to be realized, the aortic valve must be competent. Balloon inflation in the setting of aortic valve insufficiency would force blood from the aorta across the valve into the ventricle. This **aortic regurgitation**, in turn, would increase cardiac work by overloading the ventricle with additional blood volume. In essence, the ventricle would have to pump the same blood back and forth, paradoxically increasing the workload. An incompetent aortic valve is also more likely to sustain damage from an improperly inserted IAB or poorly timed inflation and deflation of the IAB.

Aortic Aneurysm or Dissection

Use of the IABP is contraindicated if the patient has an abdominal or thoracic aortic aneurysm or aortic dissection. During insertion, the IAB catheter could become misdirected into the aneurysm itself or tear the weakened wall of the aorta. The increased pressure generated with counterpulsation could worsen the aneurysm or dissection.

Aortoiliac or Severe Peripheral Vascular Disease

Severe, calcific arterial or peripheral vascular disease is also a contraindication to IABP therapy, although some sources view it as a **relative contraindication**. The physician must decide whether the benefits of IABP therapy outweigh the risk of further compromise of the arterial blood flow. Peripheral vascular disease may limit the ability to advance the catheter through the atherosclerotic vessel. In addition, the presence of the catheter could cause plaque rupture or vessel occlusion, resulting in leg ischemia. This information is important to the IABP operator (usually a CCTP) because blood flow to the extremity distal to insertion must be monitored for evidence of circulation compromise.

Insertion Site Factors

Using a catheter without a sheath (ie, sheathless insertion) is not recommended if the patient has any of the following conditions:

- A large amount of fatty tissue at the insertion site over the common femoral artery, because the excessive distance between the skin and the femoral artery is likely to trap the catheter in the subcutaneous tissue
- Extensive scarring or fibrosis at the insertion site
- Other contraindications to percutaneous insertion

Side Effects and Complications

Side effects and complications of IABP therapy include the following:

- Limb ischemia (compartment syndrome may develop after the IAB is removed)
- Excessive bleeding from the insertion site
- Thrombocytopenia (owing to platelet destruction)
- Immobility of the balloon catheter
- Balloon leak
- Infection
- Aortic dissection
- Thrombosis

Note that anticoagulation is no longer routinely prescribed specifically to prevent IABP-associated clotting or thrombus, although some patients who receive IABP therapy may be anticoagulated for reasons unrelated to the IABP. Management of specific complications is discussed later in this chapter.

Equipment

The following equipment should be gathered before working with an IABP during transport:

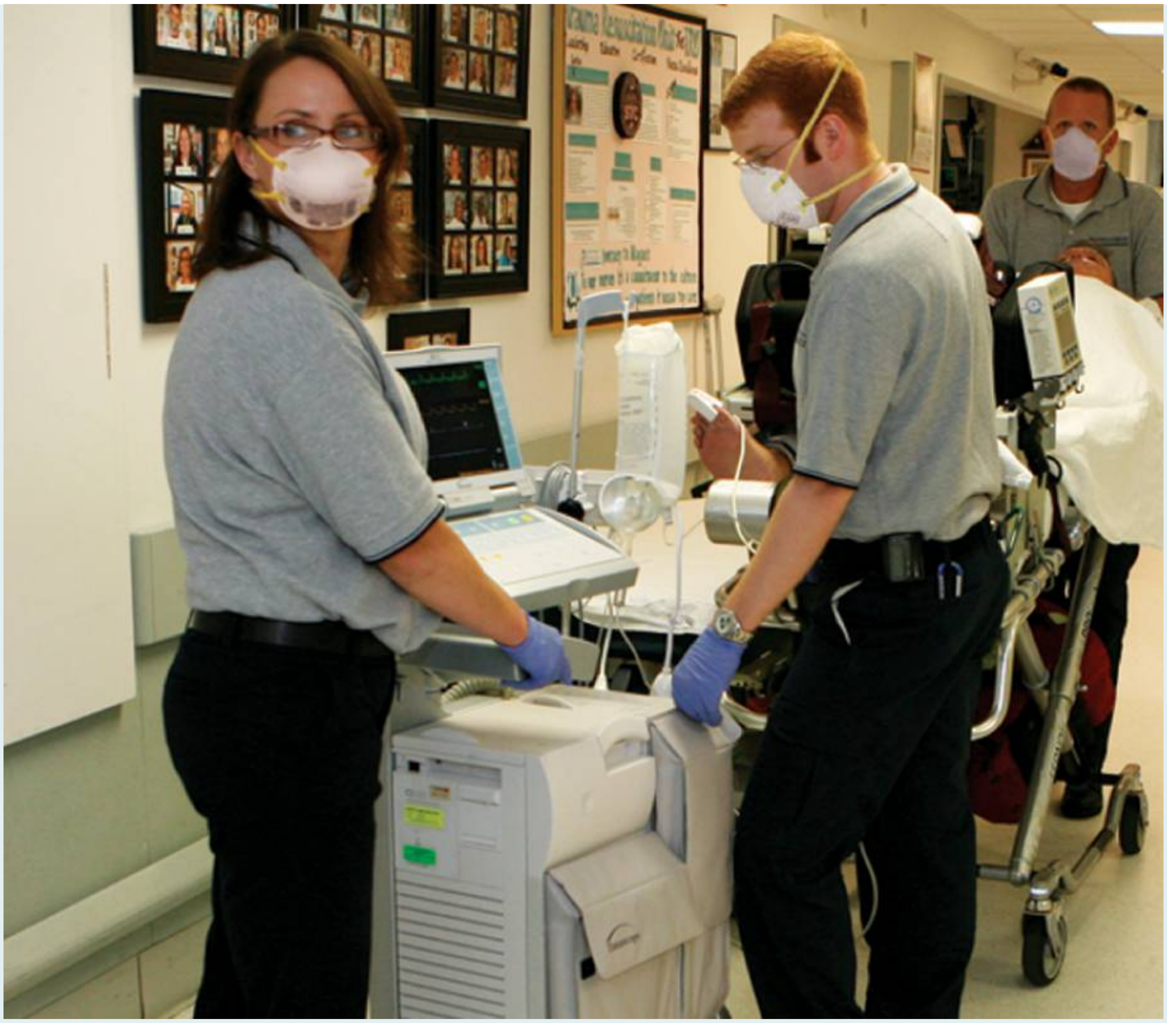
- IABP with transport module
- Appropriate-size balloon catheters with insertion kit
- Spare helium tank (200 psi)
- Operator’s manual

- Stopcocks
- 60-mL syringe (Luer tip)
- Skin electrodes
- IABP extension tubing
- Doppler ultrasonography device (to assess distal pulses)
- Extra ECG cables
- 2-inch (5-cm) cloth tape to secure the IABP ECG electrodes and catheter to the patient
- Arterial pressure monitoring transducer and setup
- Pressure transducer cables
- Arterial flush solution (normal saline)
- Adapters to fit other brands of balloon catheters to the IABP console
- Knee splint
- Soft restraints

Steps for Using the IABP

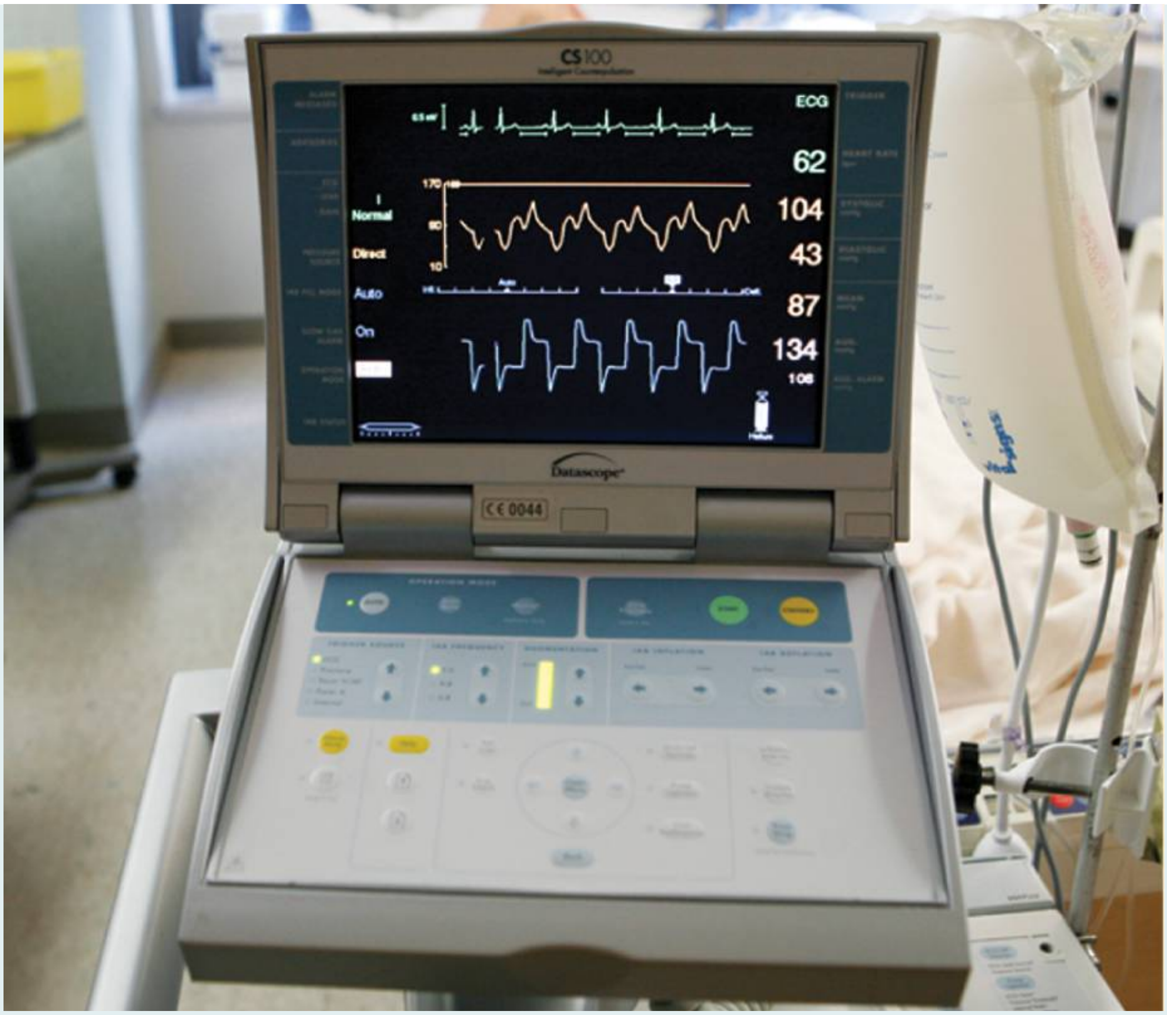
Skill Drill 16-1 describes the steps when beginning a call involving a patient receiving IABP therapy. These steps are summarized here:

SKILL DRILL 16-1 Operating the IABP During Transport



Step 1
Visually assess the surroundings to ensure that hallways, elevators, and routes of travel will accommodate the necessary equipment and personnel.

Step 2
Obtain the patient report.



CS100
ECG

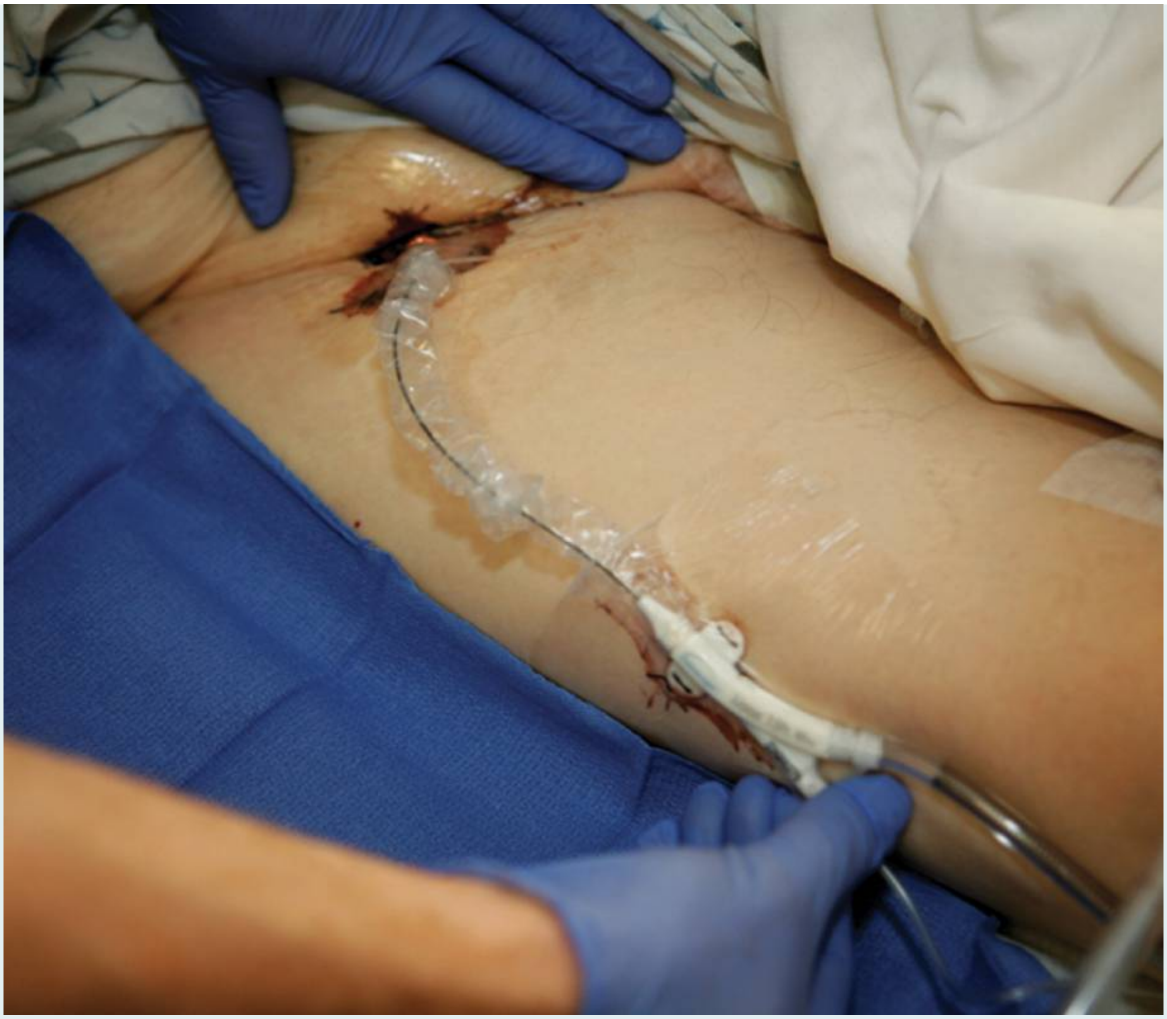
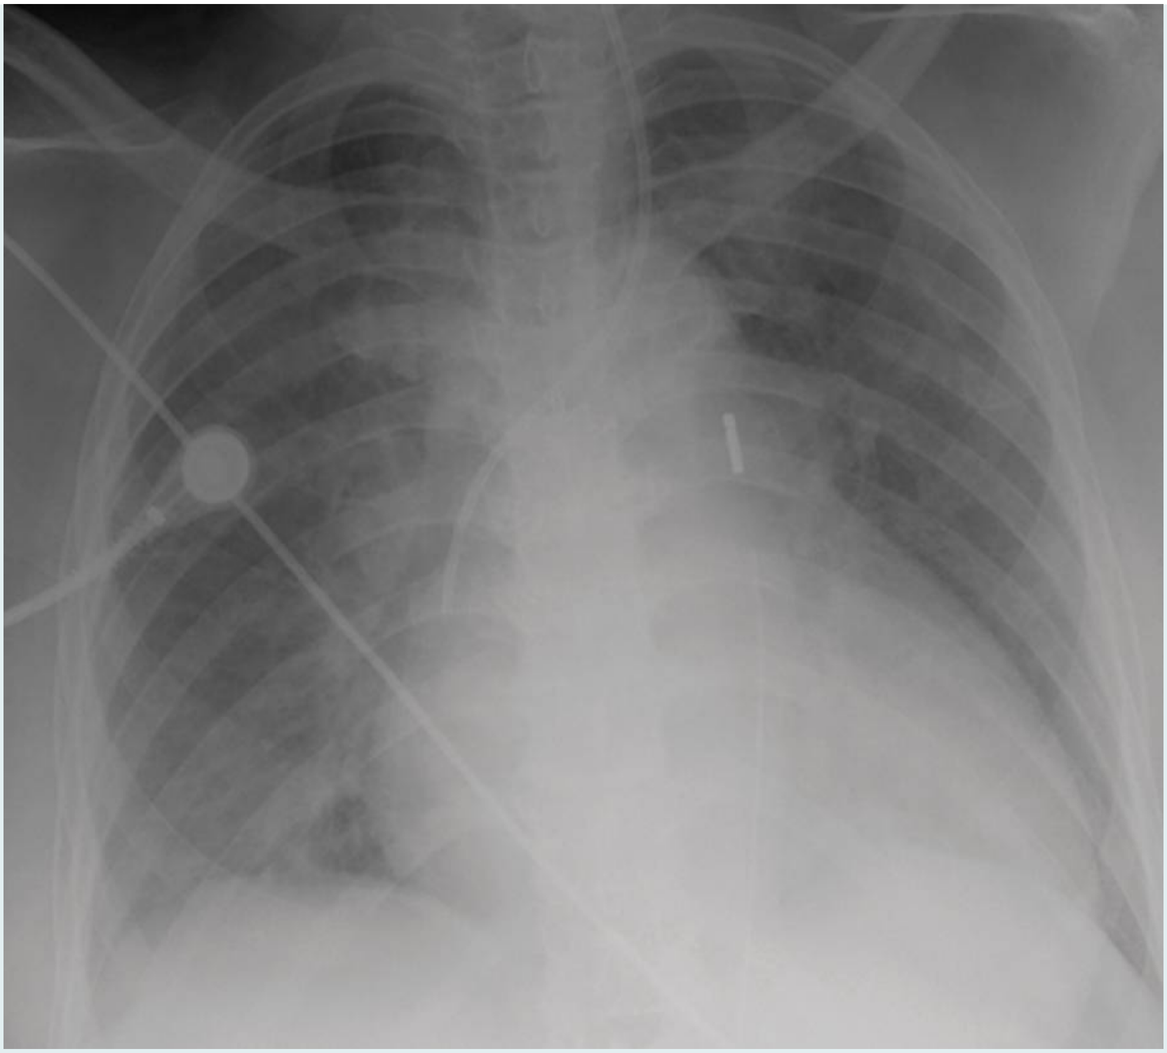
134
108
Datascope
CE 0044

Step 3
Determine the current battery status (it should be fully charged and connected to a power outlet). Ascertain the current IABP settings and note typical pressures.

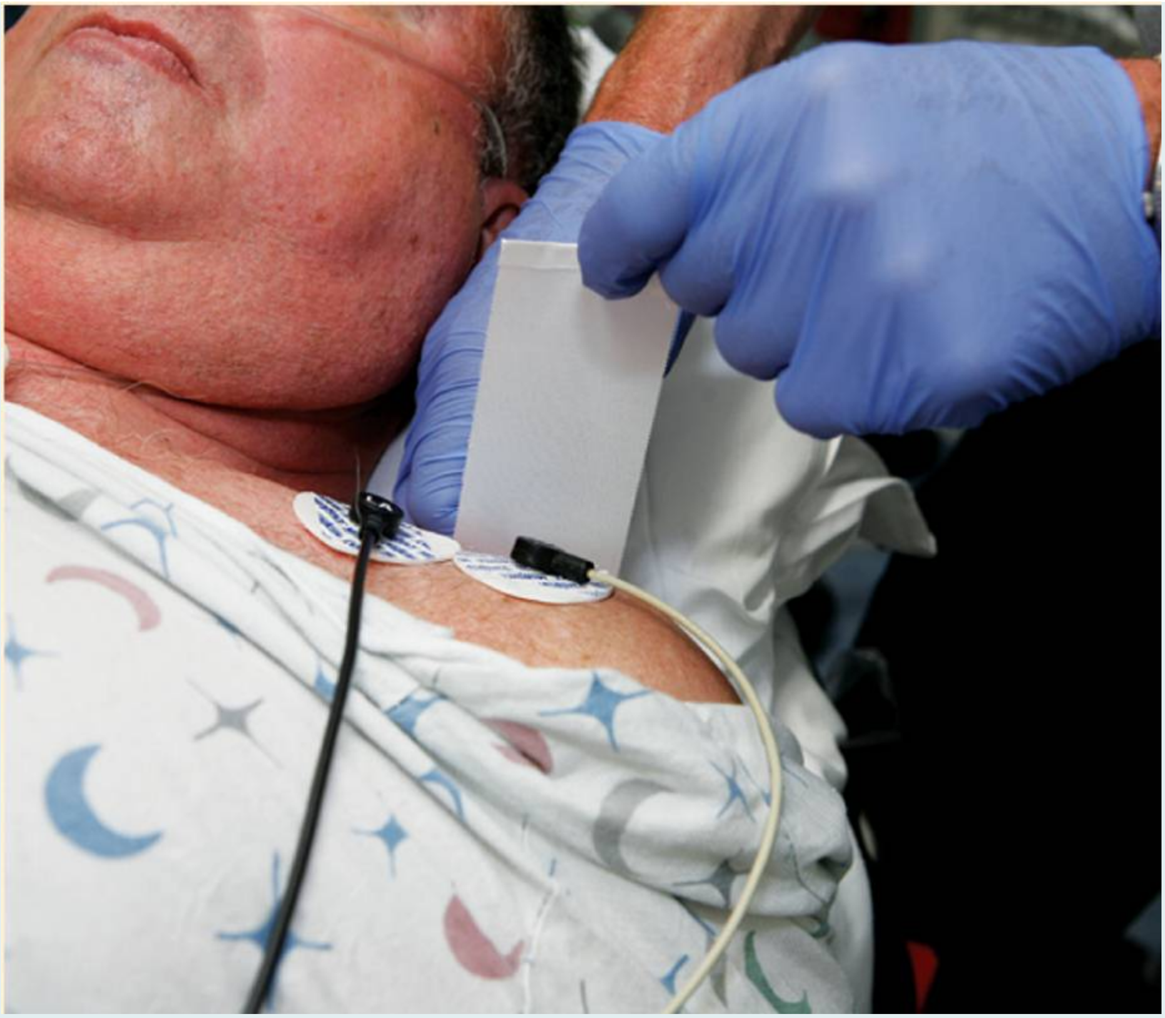


Step 4
Determine the IAB catheter model, size, and insertion depth.

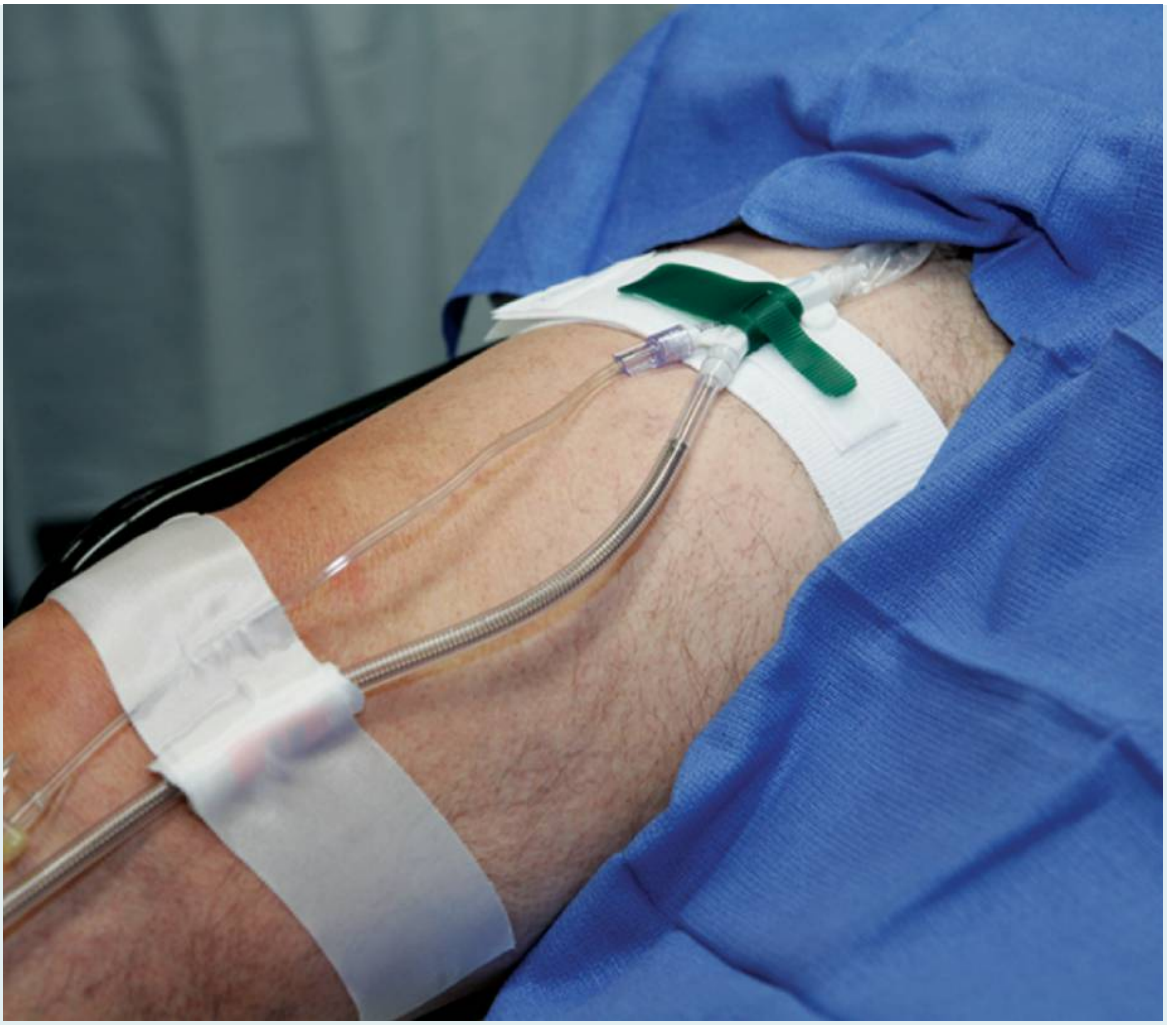


Step 5
Ascertain that the balloon tip’s location has been verified by chest radiograph.

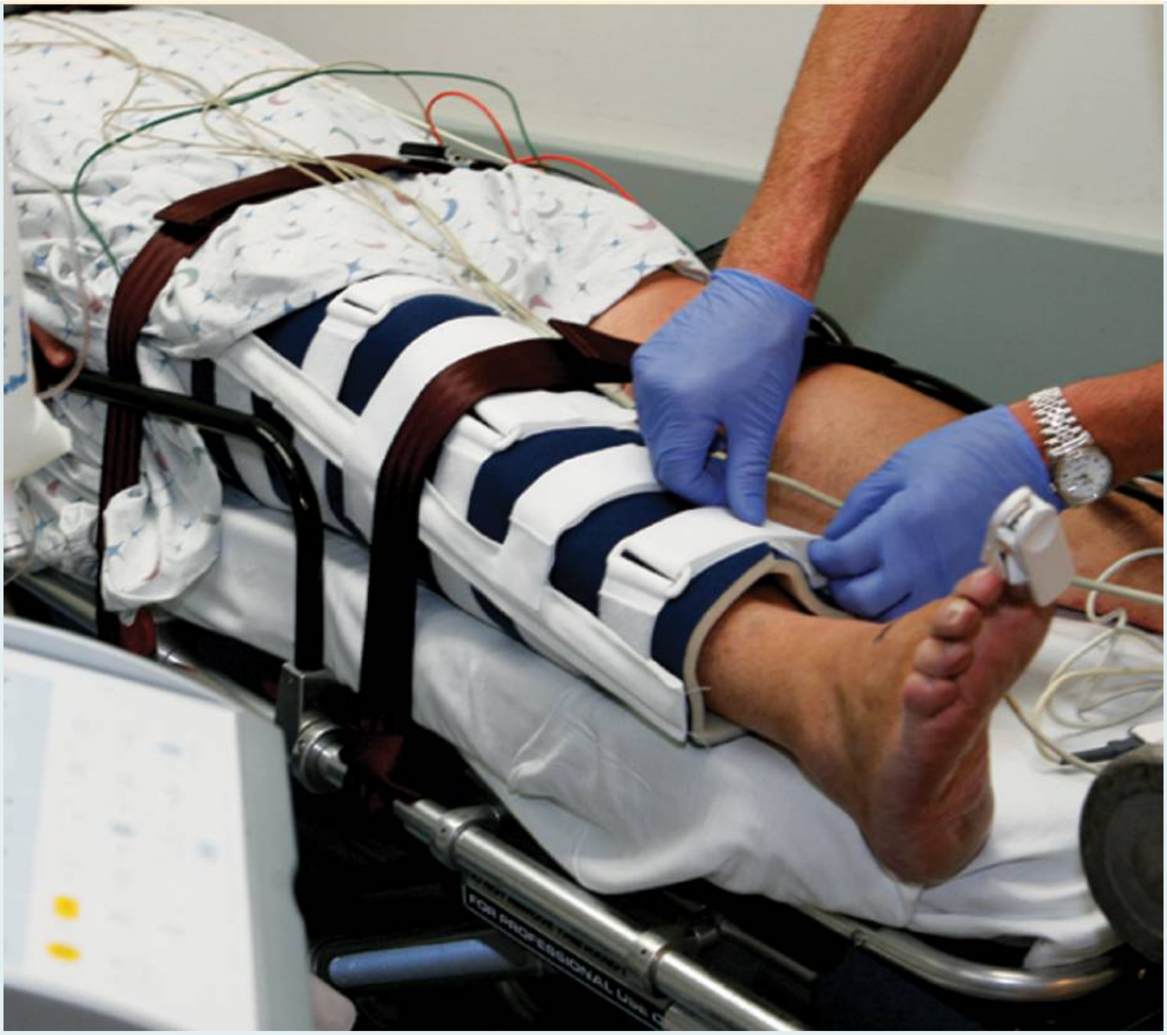
Step 6
Conduct an assessment.



Step 7
Attach new ECG leads and secure each lead over the electrode with 2-inch (5-cm) cloth tape.

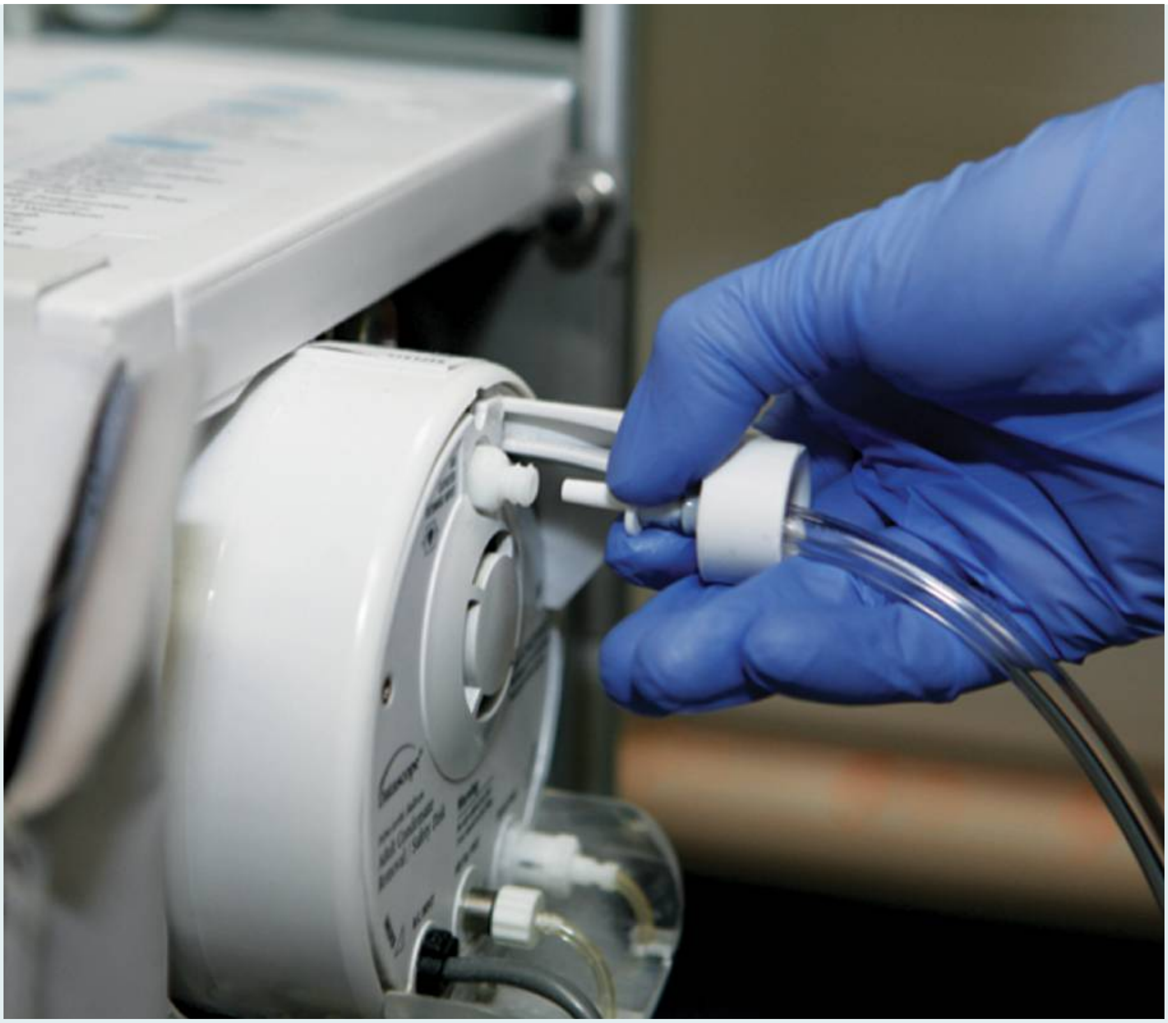


Step 8
Ensure that the IAB catheter is taped securely to the patient’s leg.

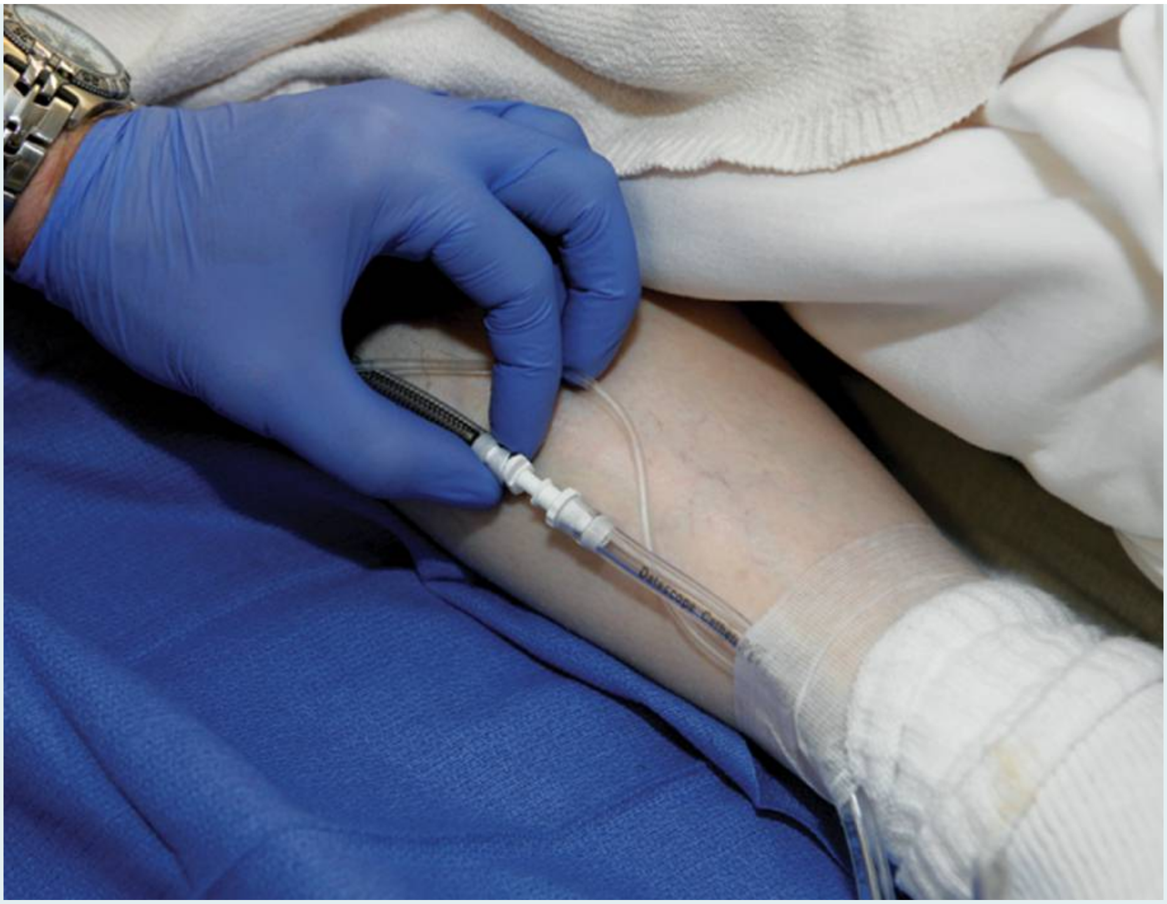


Step 9
Apply a knee immobilization splint to the leg in which the IAB was inserted to prevent leg flexion during transport. Ensure that the appropriate connectors to attach the IABP to the transport console are available. Take any adapters that will be necessary at the receiving facility.

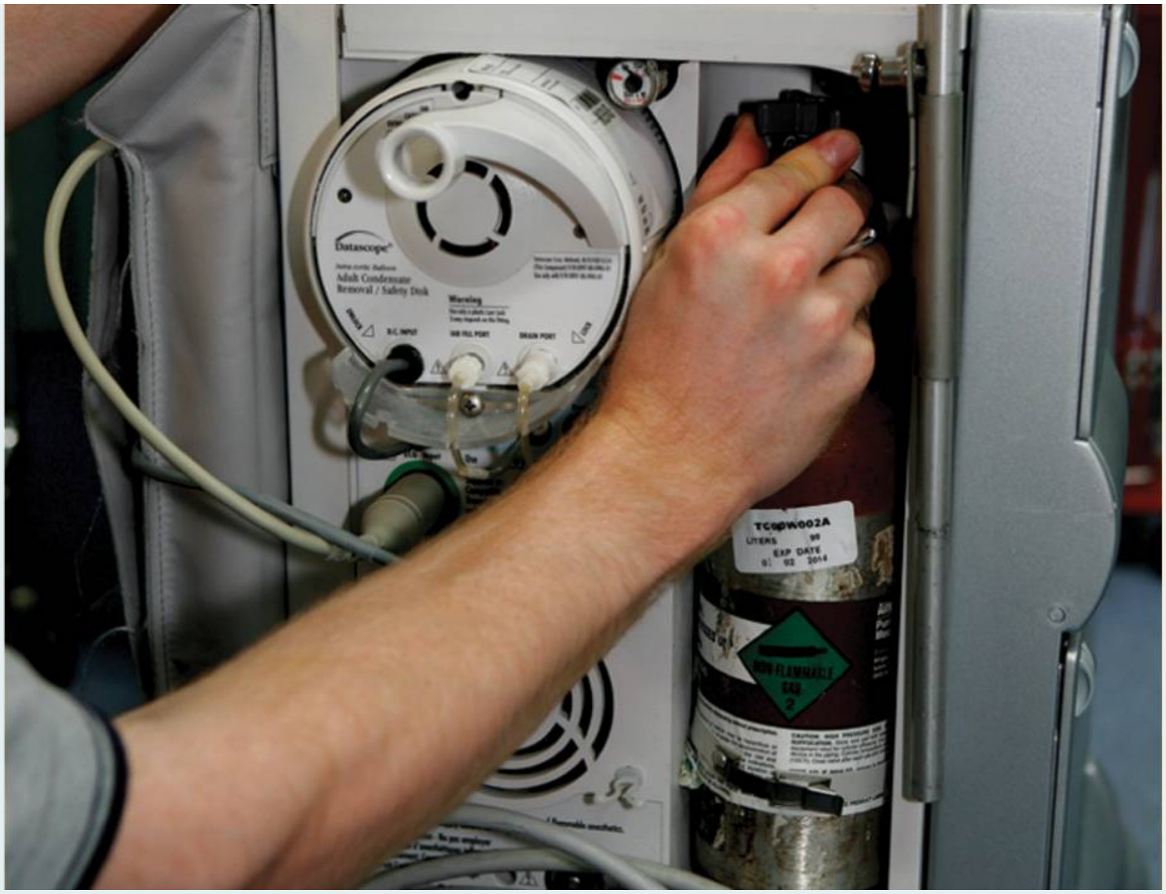
Step 10
Move the patient to the transport stretcher. Connect and secure all pumps, monitors, ventilators, and other equipment.



Step 11
Transfer the IABP to the transport console at the bedside or in the transport vehicle (if the IABP console is mounted in the vehicle).



Step 12
Ensure that all connections between the patient and the console are tight and correct.



Step 13
Open the helium tank and verify its pressure.

Step 14
Follow the IABP console instructions for start-up (on the console help screens or in the manufacturer-provided user manual):

- Establish the ECG and pressure waveforms from the patient.
- Confirm the initial pump settings.
- Ascertain the appropriate timing.
- Initiate IAB pumping.
- Set the console alarms.
- Confirm all pump settings.

Steps 1-4, 6-14: © Jones & Bartlett Learning; **Step 5:** Courtesy of Andrew N. Pollak, MD, FAAOS.

1. When entering the facility to transport a patient receiving IABP therapy, visually assess the surroundings to ensure that hallways, elevators, and routes of travel will accommodate the necessary equipment and personnel **STEP 1**.

2. Obtain the patient care report **STEP 2**.
3. Determine the current battery status of the IABP console (it should be fully charged and connected to a power outlet). Ascertain the current IABP settings and note typical pressures (console systolic, diastolic, augmentation, and mean arterial pressures) **STEP 3**.
4. Determine IABP catheter model, size, and insertion depth (measured at the insertion site) **STEP 4**.
5. Ascertain that the balloon tip's location has been verified by chest radiograph **STEP 5**.
6. Conduct an assessment **STEP 6**. The focus of assessment for a patient attached to an IABP includes inspection of the insertion site for active bleeding, peripheral pulses in both lower extremities (may require Doppler ultrasonographic confirmation), and a radial pulse in the left upper extremity (to ensure subclavian blood flow).
7. Attach new ECG leads and secure each lead over the electrode with 2-inch (5-cm) cloth tape **STEP 7**. This step will prevent lead disconnection and potential loss of trigger during transport.
8. Ensure that the IAB catheter is taped securely to the patient's leg **STEP 8**.
9. Apply a knee immobilization splint to the leg in which the IAB was inserted to prevent leg flexion during transport **STEP 9**.
10. Ensure that the appropriate connectors to attach the IABP to the transport console are available. Determine the console that will be used at the receiving facility, and be certain to take any necessary adapters or connectors (usually included in the IAB insertion kit).
11. Move the patient to the transport stretcher **STEP 10**. Connect and secure all pumps, monitors, ventilators, and other equipment.
12. Transfer the IABP to the transport console at the bedside or in the transport vehicle (if the IABP console is mounted in the vehicle) **STEP 11**.
13. Establish power to the transport IABP console. Ensure that the console screen indicates that the battery is charging **STEP 12**.
14. Open the helium tank, and verify its pressure **STEP 13**.

15. Follow the IABP console instructions for start-up (on the console help screens or in the manufacturer-provided user manual) **STEP 14**:
    - Establish the ECG and pressure waveforms from the patient.
    - Confirm the initial pump settings.
    - Ascertain the appropriate timing.
    - Initiate IAB pumping.
    - Set the console alarms.
    - Confirm all pump settings.

Special Populations

Always immobilize the knee of the patient’s leg to which the IABP is attached prior to transport. This step helps avert sudden leg movement, which may lead to bleeding or dislodgement of the IABP catheter. This step is especially relevant with geriatric patients, whose tissues are less elastic and therefore more susceptible to damage from sudden movement.

Patient Assessment

Among all patients who are admitted to a community hospital with an AMI, cardiogenic shock develops in 7% to 10%. Because the IABP can be an effective means of support for patients in LV failure and cardiogenic shock, personnel in these facilities may initiate IABP therapy. Unfortunately, such hospitals may not be equipped with cardiac surgery or cardiac catheterization laboratories or have the ability to perform interventional cardiology procedures. When the choice is made to transfer a patient with such a condition to a tertiary facility for further evaluation and treatment, early insertion of an IAB may make transport safer by promoting hemodynamic stability. Some IABP-related considerations need attention before transport.

Assessment of a patient receiving IABP therapy revolves around two questions:

- Is the therapy effective for the patient?

- Are there any complications as a result of the therapy?

Special Populations

Be certain to evaluate the patient’s mental status and level of orientation prior to transport. IABP therapy may lead to confusion, necessitating use of physical or chemical restraints during transport. With geriatric patients, it is important to determine whether this confusion is normal behavior for the patient (such as with dementia) or the result of altered cerebral blood flow secondary to IABP counterpulsation.

Patient assessment parameters that are useful for evaluating the effectiveness of IABP therapy include vital signs, oxygenation, urine output, peripheral perfusion, the central nervous system (mentation), and overall general condition. A patient receiving correctly administered IABP therapy would be expected to experience an improvement in each of these parameters (except in the most severe cases). Improvement of the vital signs, oxygenation, urine output, peripheral perfusion, and mentation, and overall condition of the patient can be expected because of the increase in CO. Some patients develop confusion or agitation during IABP therapy, which may be attributed to alterations in cerebral circulation induced by IAB counterpulsation. In the transport environment, the CCTP should be prepared to restrain or sedate an agitated patient receiving IABP therapy to ensure the safety of both the patient and the crew. The CCTP should assess and document these parameters at least every 15 minutes or whenever a change occurs in the patient’s condition.

Complications that may result from IABP therapy are most often related to the device’s insertion site or impairment of circulation by the balloon or in the extremity where it is inserted. When in the proper position, the IAB lies in the thoracic aorta just distal to the takeoff of the left subclavian artery. The depth of insertion of the IAB should be monitored and documented. If the IABP were to migrate toward the patient’s head (cephalad) during transport, then the distal portion of the IAB could occlude the takeoff to the left subclavian artery, which may be evidenced as a dampening or absence of the pulse in the left arm. Therefore, the CCTP should palpate or, if necessary, use a handheld Doppler ultrasonography device to assess the left radial pulse and compare it with the right radial pulse when performing vital signs or patient assessments. Placing a pulse oximeter probe on a finger of the patient’s left hand would also provide an early warning of compromised circulation to the left subclavian artery. Alternatively, the IAB may potentially migrate toward the patient’s feet (caudal), causing an impairment in renal function. A sudden decrease in urine output may signal this impairment in renal blood flow; therefore, urine output should be noted and documented.

As mentioned earlier, the majority of IABs are inserted using a percutaneous technique in the femoral artery. This site should be inspected for evidence of bleeding, externally or internally. Any hematomas that have developed should be noted and marked on the skin to allow the CCTP or other health care providers to assess progression of the hematoma. Care should be taken to inspect the patient’s buttocks and posterior hip area, because bleeding in this area may be difficult to detect.

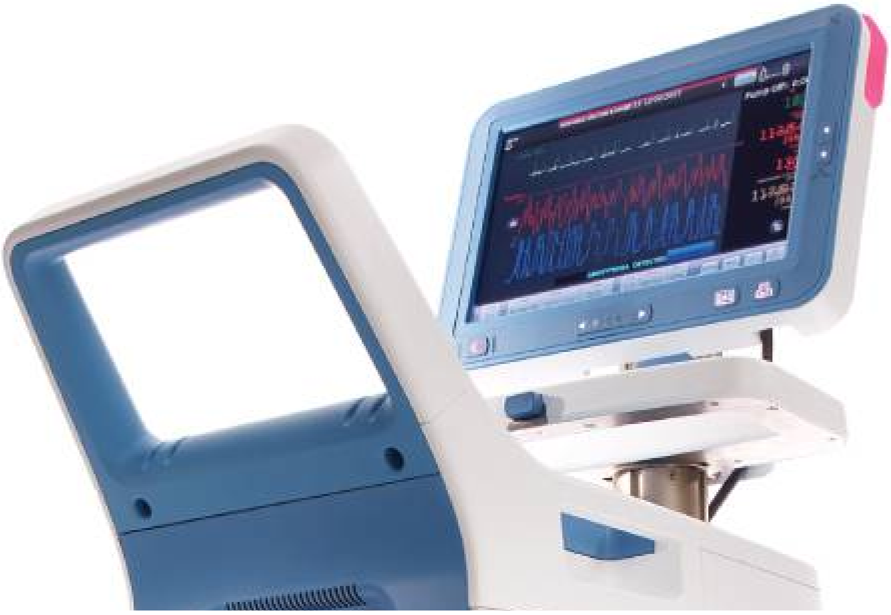
If the femoral artery is used as the insertion site, then the CCTP should assess and document the presence of the distal pulses and capillary refill time (CRT) in the extremity used and compare it with the distal pulses and CRT in the other leg. The CCTP should splint the knee of the leg in which the IAB was inserted to prevent excessive movement that might lead to bleeding at the site or impairment of distal circulation.

A sudden loss of pulses or decrease in CRT could signal that the IAB is occluding the femoral artery and causing ischemia in the limb. If this complication occurs, medical control should be notified immediately and consideration given to removal of the device in a facility as soon as feasible. In addition, because circulation in the extremity may be impaired, the potential for compartment syndrome is high both while the catheter is in place and after it has been removed. Compartment syndrome is heralded by the five Ps: Pain (out of proportion to what is expected), Pallor, Paralysis, Pulselessness, and Paresthesia. Also, the extremity might feel cold to the touch.

Transport Considerations

Patients receiving IABP therapy are candidates for transport in ground ambulances or in fixed- or rotary-wing aircraft. Some issues to consider when using these vehicles for transport of IABP-treated patients include battery life and vehicle power supply, space and weight constraints, and loading, unloading, and securing the pump in the vehicle. Addressing these issues when developing an IABP transport program will resolve most potential problems before the first transport occurs. Careful attention to transport-related physical and logistic considerations, well in advance of an actual transport, ensures that CCTPs will be able to focus on patient-specific needs during transport.

Transport vehicles often have an inverter capable of converting the direct current (DC) voltage generated by the engine to alternating current (AC) voltage suitable for powering the IABP. In addition to AC power, some aircraft produce 24 V of DC power. Many IABPs are capable of operating on 110 V to 120 V of AC power or 24 V of DC power, although the latter may require an adapter cable. Most IABP systems also incorporate batteries that allow for limited periods of portable operation **FIGURE 16-16**.



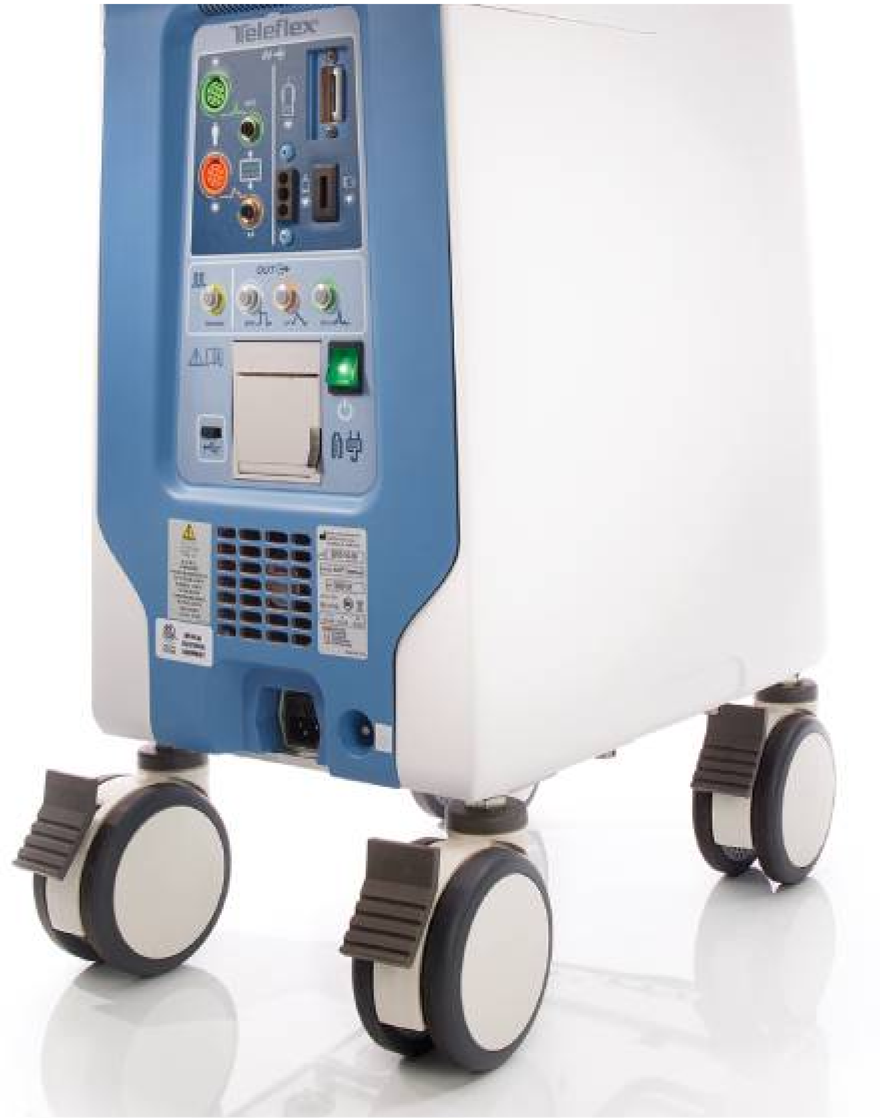


FIGURE 16-16 A portable intra-aortic balloon pump.

Ensuring a match between the IABP power requirements and the available power supply in the transport vehicle is a crucial planning step when establishing an IABP transport program. Given the electrical demands of all the medical equipment likely to accompany an IABP-treated patient, it is recommended that the crew have access to the inverter circuit breaker from inside the transport vehicle. This access allows the crew to monitor the status of the inverter and reset the circuit breaker without having to stop the transport and disembark from the vehicle.

It is also necessary to evaluate the space and weight constraints of the transport vehicle before transport and the logistics of loading and unloading the IABP and the patient. Ground ambulances generally have minimal restrictions on weight, and the system will usually fit easily into the vehicle. In a transport aircraft, space limitations may require reconfiguration of the pump and monitor module. The additional weight of the system may also be an issue in air operations—another important planning point during transport program development.

After the IABP is placed in the transport vehicle, it is critical to secure the pump so that it remains stable for safe operation throughout transport. It may be necessary to work with the IABP manufacturer, Federal Aviation Administration representatives, and the aircraft mechanic to ensure that an adequate system is in place to secure the IABP against air turbulence.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO), also referred to as extracorporeal life support (ECLS), is a temporizing mechanism of extracorporeal gas exchange with or without hemodynamic support **FIGURE 16-17**. Artificial extracorporeal oxygenation has held an allure for scientists and physicians throughout modern medicine. In 1869, Ludwig and Schmidt documented the first successful attempts at extracorporeal oxygenation by shaking blood inside a balloon. Research and advancements continued with surgeon John Gibbon completing the first successful extracorporeal bypass on a human in 1953. Born from the cardiopulmonary bypass machine found in the operating room, the original application of ECMO was primarily for support of severe respiratory failure where native cardiopulmonary function is pathologically decoupled. In contrast to cardiopulmonary bypass, ECMO allows for longer-term support in the intensive care unit (ICU), makes use of the patient’s intravascular volume as the fluid reservoir, and ostensibly captures 80% of circulating blood volume. ECMO is not curative; rather, it is a supportive therapy for presumed reversible respiratory and/or cardiac failure and is a keystone to one of the following strategies: bridge to recovery, bridge to transplantation, destination therapy, or bridge to decision. ECMO is currently the only available therapy to functionally replace the heart and lungs, albeit imperfectly.

Calculating Uncaptured CO in the ECMO Circuit

The following equation is used to estimate the percentage of CO that is not captured by the ECMO circuit:

$$(Q \times SaO_2) + (x \times SvO_2) = SpO_2(Q + x)$$

where *Q* is ECMO flow, SaO_2 is arterial oxygen saturation, SvO_2 is venous oxygen saturation, and SpO_2 is oxygen saturation as measured by pulse oximetry. For example, if *Q* is 3.5 L/min, ECMO SaO_2 is 100%, ECMO SvO_2 is 60%, and the patient's SpO_2 is 85%, the equation would be written as follows:

$$(3.5\ \text{L/min} \times 100\%) + (x \times 60\%) = 85\%(3.5 + x)$$

$$3.5 + 0.6x = 3 + 0.85x$$

$$3.5 = 3 + 0.25x$$

$$0.5 = 0.25x$$

$$2 = x$$

Thus, $x = 2$ L/min, meaning 2 L/min of CO is not being captured by the ECMO circuit. The uncaptured or deoxygenated blood would continue through the native pulmonary circulation. (Note: This calculation assumes that the lungs do not contribute to oxygen saturation.)

ECMO Support Types and Configurations

Cannulation sites and circuit configurations vary depending on the patient and intended type of support. A common nomenclature describes the ECMO circuit configuration and support type by a combination of the letters *V* and *A*, where the letters before the *A* are referred to as the inflow/drainage cannula(s), and the *A* and all subsequent letters refer to the outflow/return cannula(s) **FIGURE 16-18**. The exception to this nomenclature is VV-ECMO. It is imperative that all members of the care team understand the locations and the vessels accessed for the *inflow* and *outflow* cannulas.

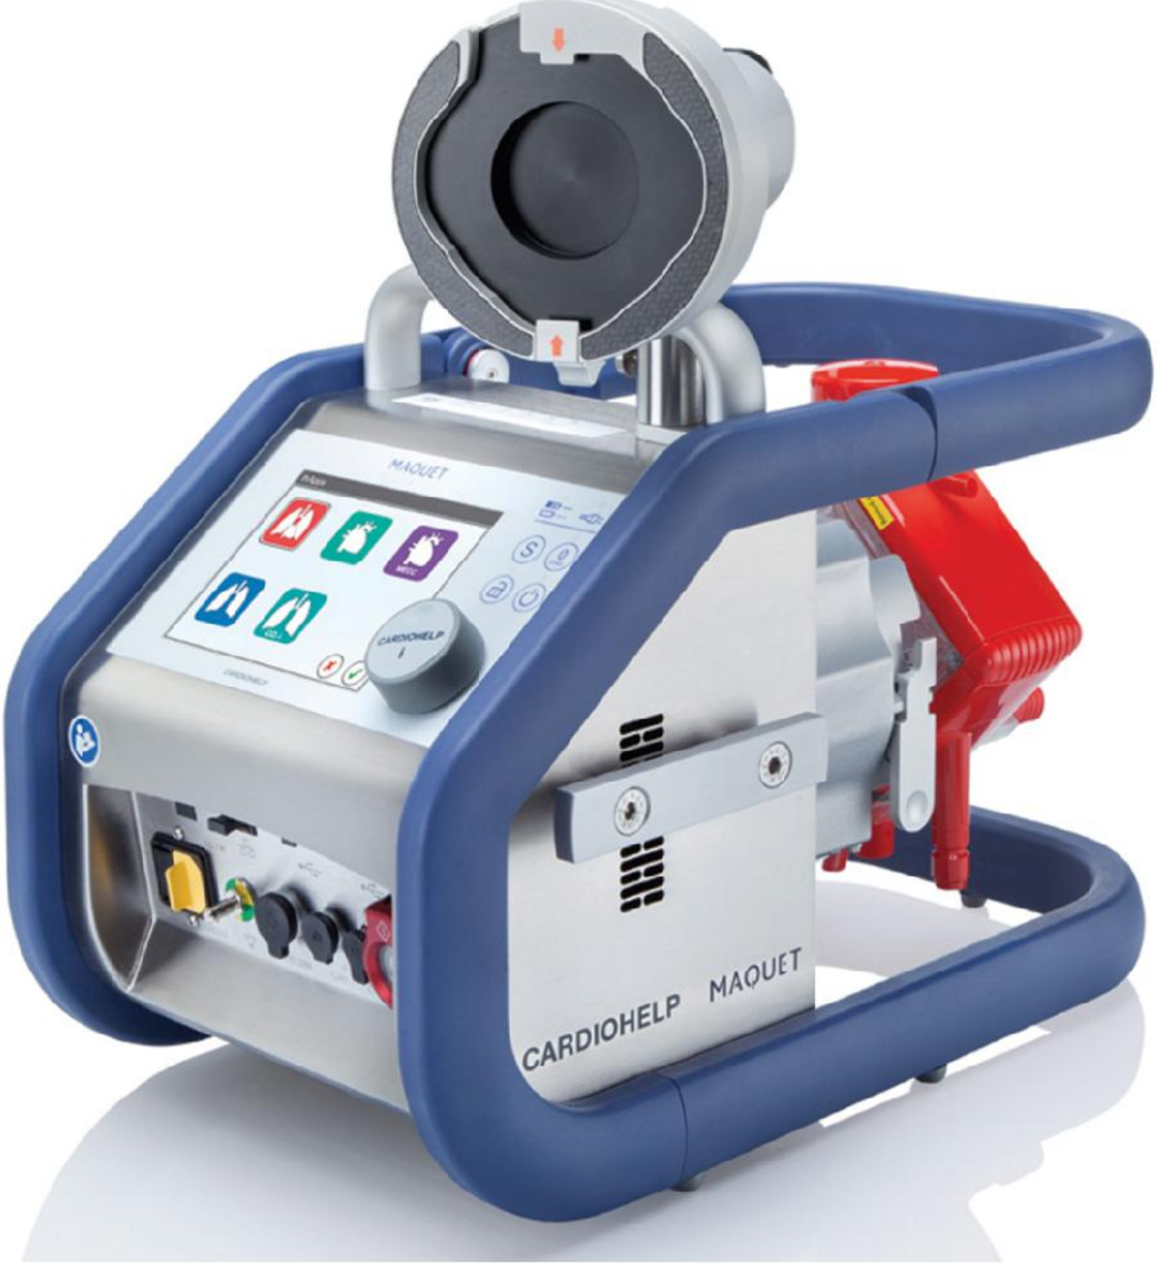

FIGURE 16-18 The circulatory function of extracorporeal membrane oxygenation systems is provided with a centrifugal pump; the pulmonary function relies on the use of an artificial lung, known as an oxygenator, to exchange gases.

Reproduced from Maquet Cardiopulmonary GmbH, with permission.

- **Venovenous-ECMO (VV-ECMO).** Blood is drained from the venous circulation, passes through the circuit where gas exchange occurs, and is returned as oxygenated and decarboxylated blood to the venous system. VV-ECMO functions in series, with the native lungs providing gas exchange without circulatory support.

- **Venoarterial-ECMO (VA-ECMO).** Blood is drained from the venous circulation, passes through the circuit where gas exchange occurs, and is returned as oxygenated and decarboxylated blood to the arterial system. VA-ECMO functions in parallel to the native heart and lungs, providing gas exchange with a degree of circulatory support.
- **Veno-veno-arterial-ECMO (VVA-ECMO) or veno-arterio-venous-ECMO (VAV-ECMO).** These configurations are colloquially referred to as *triple-cannulation*. Both support respiratory and cardiac function without the differential hypoxemia that may occur during VA-ECMO, albeit at the expense of added circuit complexity.

Circuit Components and Concepts

A basic ECMO circuit is composed of the vascular cannulas, circuit tubing, pump, heater–cooler, and oxygenator. ECMO circuits vary in configuration and may include pressure and blood flow monitors, bubble detectors, continuous arterial and venous oxyhemoglobin saturation monitors, circuit access sites, and an emergency arterial–venous bridge:

- **Vascular cannulas.** The cannula is the interface between the patient and the ECMO equipment. Cannulas can have a single or double lumen, be designed for percutaneous or central access (ie, open chest), and come in a range of diameters and lengths. Selection of cannula style, size, and cannulation site is individualized to the patient and support required. In adults, VV-ECMO cannulation typically occurs in the right internal jugular vein and femoral vein, with the cannulas’ openings positioned more than 4 inches (10 cm) apart to reduce the propensity for *recirculation*. The size of the femoral vein in pediatric patients who weigh less than 33 pounds (15 kg) can limit this location's usability for cannulation. In those situations where femoral cannulation is not possible or preferred, a double-lumen catheter placed in the right internal jugular vein can serve as an alternative strategy. VA-ECMO arterial cannulation typically occurs in the right common carotid artery or femoral artery. Venous cannulation is accomplished by using the same sites listed for VV-ECMO. Central cannulation (ie, open chest) is an additional option in VA-ECMO, where the venous cannula is placed into the right atrial appendage and the arterial cannula into the aorta.

- **Tubing.** The circuit tubing is a polyvinyl chloride compound. Modern circuit tubing and components include both biocompatible coatings and materials to pacify the body's innate inflammatory and coagulative responses to the nonbiologic material of the circuit.
- **Pump.** The pump creates forward blood flow through the circuit by generating negative pressure within the inflow/drainage limb and positive pressure after the pump in the outflow/return limb. The negative pressure pulls venous blood to the pump inlet and the spinning rotor then drives the blood forward. Modern pumps are centrifugal and nonocclusive, relying on magnetic communication between a drive motor and pump head. Due to the nonocclusive design, care must be taken to ensure that the revolutions per minute are sufficient to maintain forward flow to avoid retrograde flow.
- **Oxygenator.** Located distal to the pump, the primary function of the oxygenator is to reproduce the alveolocapillary function of the lungs. The blood passes through a mesh of hollow semipermeable membrane oxygenator fibers, exchanging oxygen and carbon dioxide through diffusion with the sweep gas. A secondary function of the oxygenator is to warm the blood, serving as a heat exchanger, in conjunction with a heater–cooler device.

- **Sweep gas.** The sweep gas is 100% oxygen, although some centers make use of blenders. The 1.0 F_{IO_2} (fraction of inspired oxygen) creates a pressure gradient between the sweep gas and blood, allowing for the diffusion of oxygen into the blood and carbon dioxide into the sweep gas. The sweep gas is titrated (L/min) to achieve a specified parameter, either pH or partial pressure of carbon dioxide (P_{CO_2}), based off the arterial blood gas. Conceptually, the *sweep* is analogous to the minute ventilation of a ventilator.
- **Heater–cooler.** This thermoregulatory device sends temperature-controlled water to the oxygenator, which acts as an external heat exchanger to warm or cool the blood to achieve a specified patient temperature. The large surface area of the ECMO circuit results in significant heat loss via convective, conductive, and radiant mechanisms.
- **Revolutions per minute (rpm).** The rpm reflects the speed of the pump rotor. This setting is directly controlled by the ECMO specialist or perfusionist to achieve a desired flow.
- **Flow (L/min).** Flow is the rate of blood movement through the circuit. It is variable at a set rpm and is a function of the rpm and conditions affecting the inflow and outflow limbs of the circuit (eg, cannula diameter, length, and position; patient fluid status, native CO). The flow delivers oxygenated blood, functioning analogously to CO during VA-ECMO, and is the main contributor to oxygen delivery (D_{O_2}) in VV-ECMO. In general, target flow rates are as follows:
    - Neonates: 100 to 160 mL/kg/min
    - Children: 80 to 90 mL/kg/min
    - Adults: 50 to 70 mL/kg/min

Note, however, that the flow rate should be goal directed and individualized to the patient.

Circuit and Patient Management

ECMO is a complicated therapy that requires constant, intensive, and careful oversight. Monitoring of a patient receiving ECMO begins with the same assessment provided to any patient in the ICU. Particular focus must be paid to the ECMO device, circuit, tubing, connectors, alarms, and overall integrity of the entire circuit. Specific considerations include the following:

- **Anticoagulation.** During ECMO, patients receive systemic anticoagulative therapy to both protect the major organs from thromboembolism and maintain the patency of the ECMO circuit. Contemporary ECMO circuits generally include biocoatings to resist thrombus formation. Owing to its importance and dynamic nature, anticoagulation status is monitored at set time intervals ranging from every hour to every 6 hours, depending on the specific coagulation study. Additionally, the significant risk for uncontrolled bleeding must be acknowledged in the planning of any patient procedure.
- **Circuit assessment.** The ECMO circuit and cannulas require continual assessment to monitor their integrity and patency. A thorough, methodical approach for assessment of all components, connections, and securing points will aid in the early identification of potential issues. Throughout therapy, providers must remain vigilant, preventing or removing kinks in the cannulas and circuit tubing. Cannula sutures must be inspected for continued integrity and tautness. A flashlight should be used to inspect the inlet and outlet of the oxygenator, as well as the entirety of the circuit and cannulas for clot and fibrin accretion. Common sites for fibrin deposition and thrombus formation are those that cause a disruption to laminar blood flow leading to turbulence and stagnation of blood; such sites include connectors, pigtails, and stopcocks. A truism of ECMO is that with the increasing complexity of a circuit comes increasing turbulence and stagnation of blood, and with it a heightened risk of clot formation.

- **Monitoring of support.** Venous oxygen saturation (Sv_{O_2}) and serum lactate levels provide insight into the adequacy of systemic perfusion; generally, Sv_{O_2} greater than 70% and serum lactate less than 2.2 mmol/L imply a balance between D_{O_2} and oxygen consumption (V_{O_2}). Pressure monitoring can help providers detect early or acute dysfunction in the ECMO circuit and also suggest clinical changes in the patient. However, pressure monitoring is not essential, and target pressures vary with the characteristics of the ECMO circuit, cannulas, and patient status. While additional pressures can be obtained, the four typical pressures monitored are P_{vein} (venous pressure), P_{art} (arterial pressure), P_{int} (oxygenator inlet pressure), and Δp (differential pressure of P_{int} and P_{art}).
    - **P_{vein}.** A pressure measurement taken prior to the pump (which is therefore a negative pressure). Monitoring of P_{vein} provides insight into the environment of the drainage/inflow cannula (IFC). Changes in P_{vein} reflect changes in the preload of the pump. As such, a more negative P_{vein} indicates a reduction in preload, which can result from patient hypovolemia, kinked tubing/cannula, or thrombus formation restricting blood flow, among other factors.
    - **P_{art}.** A positive-pressure measurement taken after the oxygenator and pump (which is therefore a positive pressure). Monitoring of P_{art} provides insight into the environment of the reinfusion/outflow cannula. Changes in P_{art} reflect changes in the afterload of the pump. As such, a more positive P_{art} indicates an increase in afterload, which can be a result of increased native CO and/or systemic vascular resistance (SVR) in VA-ECMO. An increased P_{art} can also result from kinked tubing/cannula or thrombus formation and is not specific to VA-ECMO.
    - **P_{int}.** A positive-pressure measurement taken after the pump at the inlet of the oxygenator. An increase in P_{int} is

  nonspecific when viewed in isolation. When used to calculate Δp and trended over time, P_{int} can be useful in assessing the patency of the oxygenator.
  - **Δp**. This differential pressure of P_{int} and P_{art}, which is viewed as the transmembrane pressure or pressure drop across the oxygenator. A rise of greater than 20 mm Hg in the Δp can be damaging to red blood cells and is also concerning for thrombus formation within the oxygenator.
- **Routine documentation.** Documentation will vary by institution, but should at a minimum include hourly notation of flow, rpm, monitored circuit pressures, trending of the preferred coagulation study, anticoagulation dose, as well as circuit and cannulation site assessments.
- **BP and pulsatility.** When in VA-ECMO, the nonpulsatile/continuous blood flow of the pump bolsters native CO, augmenting perfusion and in the process potentially weakening or obliterating native pulsatility. In this scenario, arterial lines may display only MAP. Generally, flows are titrated to maintain a pulse pressure of at least 10 mm Hg, attempting to mitigate the increased afterload on the LV.

Complications and Troubleshooting

There are inherent risks and complications specific to each mode and configuration of ECMO support. Individualized and thorough assessment of both the ECMO circuit and the patient will give practitioners the best opportunity to identify issues before clinically meaningful events occur.

Patient Hypoxemia

- **Hemolysis.** Every component of the ECMO circuit is a potential cause of hemolysis (eg, kinking of tubing/cannulas, excessive pump rpm, thrombosis formation at any point in the system). Hemolysis is monitored through routine chemistries (eg, hematocrit, serum hemoglobin, lactate dehydrogenase [LDH]) and patient assessment (eg, voiding of dark red urine) to prevent organ damage and anemia caused by massive intravascular hemolysis; serum hemoglobin of 50 mg/dL or greater is cause for source identification.

- **Pulmonary edema and LV distention.** Prolonged LV distention from the increased afterload in VA-ECMO can lead to pulmonary edema. Initial treatment of high MAPs through preload/afterload reduction and administration of inotropes can help mitigate pulmonary edema; however, LV decompression is commonly necessary. In the setting of systemic anticoagulation, if pulmonary congestion is not addressed, it can progress to fatal pulmonary hemorrhage.
- **Limb ischemia.** Distal limb perfusion should be frequently assessed. The presence of hypoperfusion may require the insertion of a reperfusion catheter to restore blood flow to distal tissue.
- **Insufficient flow.** The pump is said to be preload dependent and afterload sensitive; flow is a product of the relationship among pump preload, rpm, and afterload. Insufficient flow must be differentiated from all potential causes: cannula malpositioning, inadequate circulating volume, sepsis, increased afterload (eg, inadequate sedation, increased native CO), pulmonary congestion, kinking of circuit tubing, or accumulation of thrombi within the circuit, cannulas, or oxygenator. *Chugging*, or *chatter* (ie, visible and often rhythmic movement or vibration within the venous line), is a sign of impaired venous drainage. Highly negative pressure around the inflow/drainage access point will lead to vessel collapse and possibly cavitation. As pressures become less negative, the vessel releases and chugging is observed. Chugging results in decreased flow, cavitation, and hemolysis. To resolve chugging, the practitioner can decrease the rpm to stabilize the flow and/or replace intravascular volume.
- **Recirculation.** This condition occurs in VV-ECMO when the oxygenated outflow is recaptured by the IFC and unable to follow

the native circulation. The oxygenated blood then recirculates through the ECMO circuit instead of passing through the systemic circulation to the end organs. Multiple factors can influence the severity of recirculation, including flow, rpm, and cannula type, size, or position. Classic signs of recirculation are a low Sa_{O_2} in the presence of elevated and/or rising Sv_{O_2}. Initial reaction to a low Sa_{O_2} or Sp_{O_2} may be to increase flow to increase D_{O_2}; however, increasing flow in the presence of recirculation will only exacerbate the recirculation and reduce the D_{O_2}. A more effective approach to reducing the degree of recirculation would be to increase the distance between the cannulas' openings, ensure additional drainage cannula, or insert a dual-lumen cannula with reinfusion directed toward the tricuspid valve.

- **North–south (Harlequin) syndrome.** During VA-ECMO in patients with both cardiac and respiratory failure, perfusate from the LV (ie, deoxygenated blood) mixes in the aorta with highly oxygenated blood from ECMO; the mixing blood is referred to as a mixing cloud or watershed. With either low ECMO flows or the recovery of native CO, especially with a femoral return cannula, CO can push the mixing cloud distal, past the aortic arch, preventing delivery of oxygenated blood to the cerebral and myocardial capillary beds. Clinically, the patient will present with a sharp midline demarcation owing to the differential oxygenation of the upper and lower body.

ECMO Emergencies and Circuit Disruptions

The critical nature and instability inherent in patients requiring ECMO therapy leaves them vulnerable to interruptions in support, with decompensation assured if support is not restored. Vigilance is the most valuable tool in caring for ECMO-treated patients and must be employed by all members of the team for optimal management and safety. While all components of the ECMO circuit can fail or malfunction, routine thorough inspections in conjunction with a proactive approach can detect and remedy most problems before clinically meaningful events transpire. A coordinated and well-rehearsed approach by the entire care team is required to successfully manage the complexities of emergent situations during ECMO support.

- **Oxygenator dysfunction.** Oxygenator failure can be insidious and manifest as an increasing Δ*p* and consumption of platelets. Oxygenator failures typically result from thrombus formation within the oxygenator, resulting in decreasing efficiency and DO_2. An acute change in oxygenation and ventilation of the patient may be due to a disconnection/depletion of the sweep gas line or source, although oxygenator failure due to thrombus or embolus formation should also be investigated.
- **Air entrainment.** Introduction of air into the circuit can range from a single microbubble to massive entrainment that causes a complete cessation of blood flow. While a microbubble may not be immediately detrimental to either the circuit or the patient (if it were to reach the patient), air within the circuit causes turbulence in blood flow, increasing the likelihood of thrombus formation. The presence of air within the circuit, which is caused by a communication with the external environment, threatens the continuity of ECMO support. Any access point or connection along the negative-pressure inflow limb (ie, from the tip of the IFC to the pump head) and oxygenator is a potential site of entrainment. Additionally, central lines and their placement, inadvertent injection of air into the circuit during medication administration, and cavitation of the right atrium during low-volume states can all serve as sources of air entrainment. Any air embolus must be removed, though the choice of a removal approach depends on the embolus's severity/volume and location within the circuit.
- **Circuit rupture.** A loss of integrity to the circuit can be a result of component failure or disconnection. In either case, the patient should be isolated from the circuit by clamping the circuit tubing to stop blood draining from and flowing to the patient. In the

absence of an expeditious response to isolate the patient, circuit rupture will involve rapid blood loss from both the patient's circulating volume and the circuit. Both medical and mechanical ventilatory adjuncts (eg, volume replacement, titration of vasopressors, and/or an increase in ventilator settings) will be necessary to stabilize the patient in the absence of ECMO support. Circumstances will dictate whether the circuit can be repaired in the moment or if a new circuit must be implemented.

- **Pump failure.** A pump failure is described as the inability of the pump to create adequate flow in the setting of a patent circuit with no additional confounding factors. Potential causes of pump failure include pump head disengagement, pump motor failure, electrical power supply failure (battery or AC), and pump head failure. Obviously, with a pump failure, regardless of its cause, there will be a loss of ECMO support and possible retrograde flow through the circuit. Isolating the patient from the circuit is necessary to prevent retrograde blood flow and to allow for repair of the circuit.
- **Inadvertent decannulation.** In any scenario involving the accidental removal, either partial or complete, of an ECMO cannula, the patient must be isolated from the circuit. Furthermore, the patient will require medical and mechanical ventilatory support and intravascular volume resuscitation in the setting of blood loss. If the cannula was completely removed, providers must apply direct pressure to the cannulation site. The main cause of inadvertent decannulation is excessive tension placed on the circuit tubing or cannulas. Anchoring the circuit tubing and maintaining visualization of the cannulas and tubing at all times can help prevent inadvertent decannulation.

Transport Considerations

The Extracorporeal Life Support Organization (ELSO) distinguishes between two types of ECMO-related interfacility transport:

- **Primary transport.** The transport team cannulates and initiates ECMO support at the referring facility, transporting the patient to an ECMO center.
- **Secondary transport.** A patient who is already supported by ECMO is transported from the referring center to another facility.

The two components of ECMO transport are (1) transport of the ECMO team to the referring facility and (2) transport of the patient to an ECMO center. In the case of primary transport, expeditious arrival of the ECMO team is a priority. The time needed to stabilize a patient supported by ECMO prior to transport can be lengthy and may require additional equipment and supplies. The transport vehicle must be able to carry the ECMO team, plus all necessary supplies and equipment. An ECMO team usually includes a physician or surgeon, an ECMO specialist/perfusionist, and an ECMO-trained registered nurse. Checklists can help to ensure that all the necessary equipment and supplies are carried in the transport unit.

Microaxial Catheter Pump Systems

A **microaxial continuous-flow pump** is a means of temporary circulatory support that consists of an axial-flow pump mounted on a catheter connected to a bedside console. Generally, while under fluoroscopy or ultrasonography, the catheter tip is maneuvered in a retrograde fashion up the aorta, across the aortic valve, and into the LV. Alternatively, placement can be done surgically through a graft attached directly into the aorta or via the axillary artery. When positioned properly, the pump pulls blood into the IFC located in the LV and propels it through an outflow port into the ascending aorta, functioning like a jet pump on a jet ski.

CCT teams working within referral networks for cardiogenic shock should be prepared to conduct interfacility patient transports involving a microaxial continuous-flow pump system. Specifically, CCTPs should be familiar with Impella ventricular assist catheters **FIGURE 16-19**. The Impella is a catheter-based ventricular assist system containing a microaxial pump that is designed to provide temporary partial hemodynamic support. Like most cardiac-assist devices, the Impella device aims to reduce ventricular work and provide the circulatory support necessary to allow cardiac tissue recovery and early assessment of residual myocardial function. Impella devices have been applied in settings of cardiogenic shock, low output syndrome, ST-segment elevation MI (STEMI), ventricular support during high-risk percutaneous coronary interventions, VA-ECMO to unload the LV, and cardiac decompensation while on VV-ECMO support.

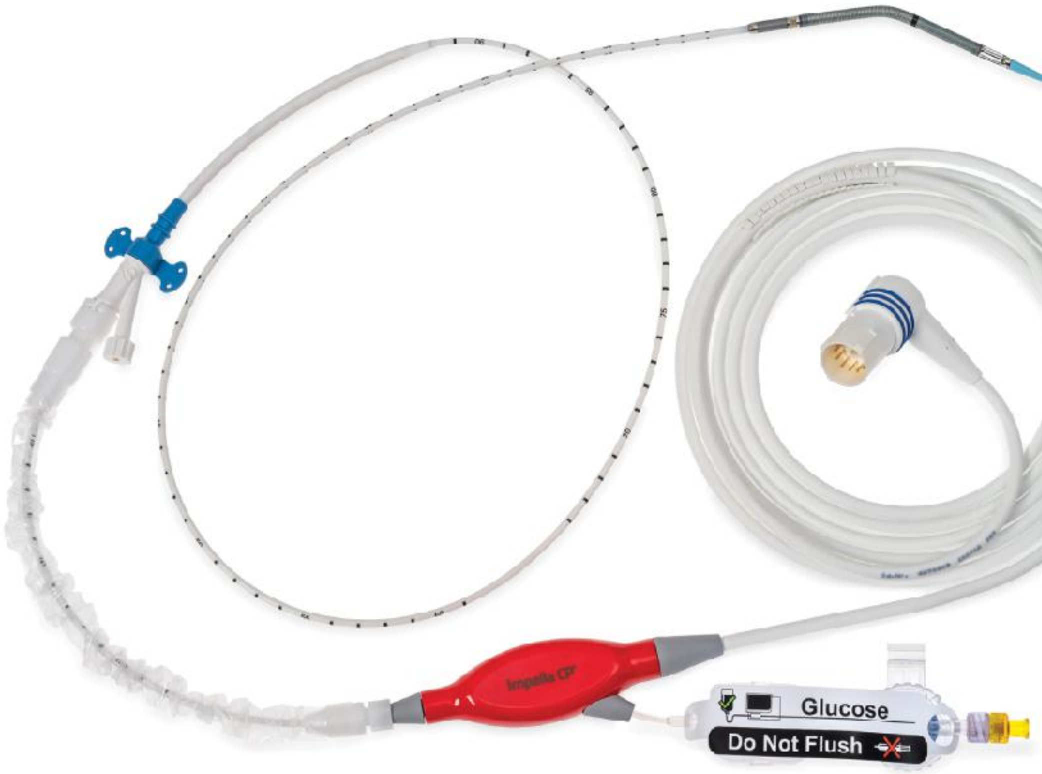

FIGURE 16-19 Impella CP with SmartAssist.

Reproduced with permission from ABIOMED.

The Impella system is not specifically designed for transport. However, with a thorough understanding of its operation, device positioning, and monitoring, safe patient transport via ground or air is possible when this system is in use.

Features and Concepts

The Impella system includes a catheter that functions in conjunction with an automated Impella controller (AIC) and purge fluid infusion pump. There are several different Impella catheters **FIGURE 16-20**. The Impella 2.5, Impella CP with SmartAssist, Impella 5.0, Impella 5.5 with SmartAssist, and Impella LD are all left-side heart devices. The Impella RP is a right-side heart device.

A

B

FIGURE 16-20 A. A left-side heart Impella catheter. **B.** The right-side heart Impella catheter.

Reproduced with permission from ABIOMED.

The Right-Side Heart Catheter

The Impella RP right-side heart catheter is the only microaxial pump device approved by the Food and Drug Administration (FDA) for use in patients with right-side heart failure. It is important to note that this device is inserted and positioned differently than the left-side heart devices previously discussed in this section. With the right-side heart device, the catheter pump is advanced antegrade under fluoroscopic guidance and positioned across the tricuspid and pulmonic valves through a sheath inserted in the femoral vein. The pump inflow is positioned in the inferior vena cava and the outflow in the pulmonary artery; thus, the pump aspirates blood from the inferior vena cava and expels it into the pulmonary artery, bypassing the right ventricle (RV).

The AIC allows for management and monitoring of pump operation and catheter position via multiple parameters: performance level, Impella flow, placement signal, and motor current. These parameters, as well as the system power and purge system features, are described as follows:

- *Performance level* on the AIC is analogous to pump speed or rpm in other MCS devices. Depending on the specific catheter, the performance level (P-level) will range from P-0 to P-8 or P-9. Left-side Impella catheters should never be set at less than P-2 while placed across the aortic valve; P-levels lower than P-2 can lead to aortic insufficiency. The Impella RP should never be set to less than 1.5 L/min of flow.
- *Impella flow* is a mean flow value, calculated from both the systolic and diastolic flows.
- *Placement signal* is used to determine proper placement of the catheter and should be monitored during transport. However, the specific waveform characteristics will vary with the model of catheter in use. Regardless of the waveform morphology and

pressures observed, the pressure should not be used to infer the hemodynamic status of the patient.

- *Motor current* is displayed as a pulsatile waveform, which is also used to determine proper placement of the catheter and should be monitored in transport. Changes in the motor current waveform can be observed when the aortic (or pulmonic, in the case of the Impella RP) valve opens and closes.
- *System power* indicates the status of AC or battery power. The AIC can be powered via AC power or an internal rechargeable battery, facilitating its ongoing operation in the space between the bedside and transport vehicle. Best practice is to keep the AIC connected to an AC source and charging whenever possible. Under normal conditions, the AIC battery will provide power for about 60 minutes.
- *Purge system* details the current infusion rate of the purge solution and the purge pressure in millimeters of mercury (mm Hg). A purge solution is required to prevent blood from entering the motor housing; it is infused into the Impella catheter, creating a fluid barrier around the microaxial blood pump. If blood were allowed to enter the motor housing, thrombus formation and pump failure would result. The purge solution generally consists of 5% to 20% dextrose in sterile water with 50 units/mL of heparin. An additional IV heparin infusion is often necessary to achieve adequate systemic anticoagulation to prevent clot formation within the catheter. Coagulation studies should be monitored frequently to ensure the proper continuous anticoagulation, and adjustments in anticoagulants require consideration of the contribution from the microaxial blood pump device to the total hourly anticoagulant infused.

Transport Considerations

Transport of the patient with the Impella system requires the transport team to be equipped, at a minimum, to continue the current level of patient hemodynamic support and monitoring in place at the referring facility. Changes in atmospheric pressure do not affect the ventricular assistance capability of Impella catheters, allowing for transport via ground or air.

A thorough assessment of the patient and catheter position should be performed prior to equipment exchange or manipulation of support. Special attention should be given to the catheter insertion site to assess for bleeding and hematoma, as well as perfusion distal to the insertion site. Providers should note the catheter insertion depth and ensure the catheter is locked and sutured to the patient to help prevent migration during transport. Excessive or uncontrolled bleeding from any site, waveform dampening, or motor current tracing that appears as ventricular in nature on the AIC are harbingers of instability in transport and can be sufficient reasons to defer transport. The absence of a motor current waveform or the presence of a tracing appearing as a ventricular waveform can indicate that the pump is malpositioned. Incorrect positioning of the Impella catheter must be remedied before proceeding with transport.

If the transport team will conduct an AIC swap (ie, a transfer from the referring facility's control module to the transport team's control module), the crew must complete post-transfer assessments of the patient and pump to identify any change in catheter positioning or patient stability.

When preparing the patient for transport, patient positioning and extremity immobilization should be considered to limit the possibility of catheter migration and consequential dislodgement of the pump: The head of the transport cot should remain elevated less than 30°, and the lower extremity containing the Impella catheter should be immobilized to minimize the potential for catheter migration during transport. All lines and tubing for the Impella device should be visible to facilitate quick and accurate assessment for leaks and kinking during transport. The AIC, battery, and purge fluid infusion pump must also be protected from extremes in temperature, moisture, and vibration, which could affect their continued functioning in transport.

Complications

As mentioned earlier, the potential for dislodgement or malpositioning of the catheter during transport requires ongoing attention by the CCT team. Abrupt changes in the placement signal or motor current waveform can suggest malpositioning of the Impella catheter. If malpositioning is suspected, the catheter and purge solution should be continued as a preventive measure against thrombus formation. The P-level should be decreased to P-2 (or a minimal flow of 1.5 L/min for the Impella RP catheter). With a malpositioned catheter, the supportive function of the system is lost and the patient likely will need to be supported medically. The accepting facility should be notified of the change so that its staff can prepare for immediate repositioning of the catheter on the patient's arrival. Repositioning the catheter in the transport environment should not be attempted.

A catheter motor failure is another possible complication that can arise during transport. In this situation, the patient will obviously lose the supportive function of the system and, therefore, will likely require inotropic and/or vasopressor agents to support hemodynamics. An additional complication in this scenario is caused by the catheter remaining in place across the aortic valve; aortic insufficiency should be anticipated. This caution bears repeating: *Providers should not attempt to reposition the catheter in the transport environment.*

Dysrhythmias

No adjustments to the Impella device are necessary if defibrillation or cardioversion is required. However, if the patient requires chest compressions, then the P-level should be decreased to P-2 prior to beginning compressions.

Common Alarms

The following list is not exhaustive but highlights alarms commonly encountered when transporting a patient with an Impella system.

- **Suction alarm.** Patient hypovolemia and catheter malpositioning can present with lower-than-expected flows and evolve into a

suction event. Suction events occur when tissue occludes the inlet of the pump. Attempts at breaking the suction can be made by decreasing the P-level by one or two increments. If suction alarms continue to occur, the transport team can continue to lower the P-level; however, the level should not decrease below P-2. Patients experiencing suction events should be assessed for euvolemia and given additional volume if indicated. Abiomed, the manufacturer of the Impella system, recommends maintaining central venous pressure (CVP) of at least 10 mm Hg; a CVP of less than 10 mm Hg could indicate that augmenting intravascular volume may help resolve suction alarms.

- **Purge alarm.** This alarm indicates that the purge pressure is either too low or too high. A low purge pressure generally results from a leak in the system; providers should assess for any leaks or disconnections in the system. A high purge pressure can be caused by kinking of the infusion tubing or the yellow purge sidearm. If the integrity of the infusion system is confirmed, then the low or high purge pressure can be corrected by increasing or decreasing the rate of the infusion pump, respectively.
- **Air in purge system alarm.** This alarm occurs when air is drawn into the purge fluid system, which commonly occurs when the purge fluid bag is laid on top of the AIC in transport. The CCT team should proceed with the *de-air* procedure, as instructed on the AIC, to resolve this alarm.

Implantable Left Ventricular Assist Devices

The demand for MCS has grown steadily over the past 30 years. Implantations of these devices are expected to continue to rise due to the epidemic of heart disease, particularly heart failure (HF), in the United States and worldwide. Heart transplantation remains the gold standard in the treatment of patients with end-stage HF. However, the number of patients awaiting donor hearts for transplantation significantly outnumbers the number of donor hearts available, and that gap continues to widen. Moreover, globally there has been a constant decline in the number of heart transplantations performed. An estimated 50,000 people worldwide are awaiting heart transplantation, with as many as 4,000 people awaiting transplantation in the United States at any given time.

Fortunately, continued improvements in the **left ventricular assist device (LVAD)** have provided increasingly more effective and longer-duration treatment for these patients in the absence of heart transplantation. According to the current Interagency Registry for Mechanically Assisted Circulatory Support (Intermacs) database, patients with HF who have undergone an implantation of a current-generation, continuous-flow LVAD have a 30-day mortality survival rate of 95%, a 1-year survival rate of 83%, a 2-year survival rate of 73%, and a 5-year survival rate of 46%. In this population, 29% will remain supported on MCS at 4 years, and 33% of those patients will have undergone cardiac transplantation. The explantation rate of LVADs at the 5-year mark is less than 5%.

History of LVAD Systems

Dr. Michael DeBakey is recognized as one of the pioneers in the development of the LVAD. In 1966, DeBakey performed a double-valve replacement in a middle-aged female, who postoperatively developed cardiogenic shock. He successfully implanted a pneumatically powered, paracorporeal LVAD from the left atrium to the right subclavian artery. On postoperative day 10 from LVAD implantation, the patient recovered and the LVAD was removed.

Dr. John Norman implanted the first LVAD as a bridge to transplantation in 1978. A young man developed "stone heart" after a double-valve replacement, leading to the implantation of the LVAD. The LVAD remained in place for 6 days until the patient underwent a heart transplantation.

Indications for LVAD Use

An LVAD can be used for a variety of reasons. If the LVAD is used as MCS until the native heart recovers its pumping ability, the indication is referred to as **bridge to recovery (BTR)**. When myocardial recovery does not occur and the device is used for prolonging the patient's life until a heart transplant can be secured, the use is referred to as **bridge to transplantation (BTT)**. The final indication for an LVAD is **destination therapy (DT)**, which refers to long-term use of MCS in a patient with HF who does not meet the heart transplantation criteria.

MCS with LVAD is safe and effective for patients with end-stage HF that is refractory to medical therapy. Approximately 2,500 LVADs are implanted annually. LVADs were originally indicated as BTR or BTT therapy, but as the volume of people awaiting heart transplantation continues to increase in the United States, the number of patients receiving such a device as BTT until a donor heart is available will also continue to rise. This trend dovetails with the increasing use of the LVAD as DT.

Stratification

The American Heart Association's (AHA) Heart Failure Stages and the New York Heart Association's (NYHA) Functional Classification System are the two most widely used methods of classifying HF.

The NYHA developed its original HF classification system in 1928. This tool categorized patients into four groups, Classes I to IV, based on functional capacity. Class I patients do not demonstrate symptoms after ordinary physical activity. Class II patients have cardiac disease resulting in slight limitation of physical activity. Class III patients have marked limitation of physical activity. Class IV patients are unable to tolerate any physical activity without discomfort.

The NYHA revision in 1994 included the addition of what are now referred to as the AHA Heart Failure Stages. These stages were revised in 2001. This rating system evaluates the progression of a patient's HF symptoms, with phases designated as Stage A to Stage D. Stage A includes the presence of HF risk factors but not heart disease. These patients do not have any symptoms. Stage B patients have heart disease with structural changes, but also do not have any symptoms. Stage C patients have structural heart disease and symptoms. Stage D patients have advanced heart disease with continued HF symptoms that require aggressive medical therapy. The AHA Heart Failure Stages system uses an objective assessment method to retrieve data for classifying patients, including data from ECGs, stress tests, echocardiography, and radiology imaging.

The Intermacs registry has also developed patient profile levels to assist with selection of ideal candidates for LVAD implantations. These levels range from 1 to 7. Level 1 patients are in cardiogenic shock and require circulatory support. This level, which is often referred to as "crash and burn" status, accounts for approximately 15% of all implantations. The 1-year survival rate for these patients is 74%. Level 2 patients require inotropic support and are declining. Level 3 patients are stable while on inotropic support. Patients in Levels 2 and 3 have a 1-year survival rate of 82%. Level 4 patients take oral therapy with resting symptoms. Level 5 patients are exertion intolerant. Level 6 patients are able to participate in activities requiring limited exertion. Level 7 patients have NYHA Class III HF: They have minimal symptoms, are hemodynamically stable, and account for only 1% of all implantations. Patients in Levels 4 through 7 have a 1-year survival rate of 84%. Of note, Levels 2 through 4 account for 80% of LVAD implantations.

Generations of LVAD

There have been substantial advancements over the first three generations of LVADs **FIGURE 16-21** and **FIGURE 16-22**. These improvements include a significant decrease in the size of the device, advanced performance with improved durability, and advanced clinical applicability. In terms of patient outcomes, the current generation of LVADs has achieved decreased mortality, decreased adverse reactions, and improved quality of life.

Description

First-Generation LVAD

The first-generation LVAD was also known as a volume displacement pump. These devices were either intracorporeal or paracorporeal membrane pumps that were driven pneumatically or electrically. They generally consisted of pump chambers with one-way valves that controlled inflow and outflow. This arrangement provided a fill to empty mode of mechanical flow, creating an augmented pulsatile flow delivery similar to that of the native heart function.

Limitations of the first-generation LVAD included increased probability of bleeding, cerebrovascular accident (either embolic or hemorrhagic), and infectious complications. Other limitations and challenges included extensive surgical dissection, decreased mobility, venting requirement due to air pressure changes related to the pneumatic pumping mechanism, durability concerns, large size, and significant noise emission. These limitations led to the development of the second-generation LVAD.

Second-Generation LVAD

This discussion pertains to the HeartMate II, which is the only FDA-approved second-generation LVAD for BTR, BTT, and DT.

In the second-generation LVAD, the pulsatile-flow technology of the first-generation LVAD gave way to continuous-flow technology. The HeartMate II's axial-flow technology is based on the Archimedes screw concept, which describes the use of a positive-displacement pump to trap fluid from a source and then force the fluid to move to a discharge location. In the HeartMate II, the magnetized rotor spins and pulls blood from the LV through the pump until it reaches the outflow graft, leading to the arterial circulation.

Inside the rotor impeller, in order from the LV to the aorta, are the following vital components: IFC, inflow stator, inflow bearings, rotor, outflow bearings, outflow stator, and outflow cannula **FIGURE 16-23**. The motor rests within the pump housing, directly above and below the rotor.

Description

The decrease in pump size, including a minimal number of moving parts when compared to pneumatic technology, allows for a smaller intra-abdominal pump pocket when implanted. This smaller pump also offers improved comfort, longer operating time, and possibility of use in smaller patients than those who were eligible for the larger first-generation LVADs. The rotary pump relies primarily on a single part, the internal rotor, which is suspended by contact bearings. The pump speed of the rotor is generally set between 9,000 and 10,000 rpm. Simplifying the design of the second-generation LVAD and relying on a single moving part was crucial in providing improved durability. The combined mechanical and magnetic positioning of the rotor stretched this device's durability up to the 5-year mark.

The motor chamber of the first-generation LVAD required venting of air to safely operate the push plate pump and its valves. These components were also very loud. The second-generation LVAD no longer requires venting and is substantially less noisy. The elimination of parts that continually open and close, together with the removal of the pumping chamber, directly improved patients' quality of life and increased the longevity of the LVAD.

A limitation of the second-generation LVAD is its slightly lessened ability to prevent a disabling stroke, as compared to the pulsatile-flow LVAD. Additional major limitations that were addressed during development of the third-generation LVAD include pump thrombosis, gastrointestinal (GI) bleeding, and ventricular unloading.

Third-Generation LVAD

This discussion pertains to the HeartWare and the HeartMate III, which are the only FDA-approved third-generation LVADs for BTR, BTT, and DT.

The third-generation LVAD continues to advance the continuous-flow technology; however, the rotating elements have transitioned from an axial flow to a centrifugal-flow design to provide cardiac support. The centrifugal-flow pump consists of a blood inlet port, an outlet port, and a pump house that contains a single rotating disk impeller **FIGURE 16-24**. The impeller rapidly spins around a fixed axis, essentially "throwing" the blood off the blade tips into circulation.

This design stands in contrast to the axial continuous-flow impeller, which operates like a propeller in a pipe that “pushes” the blood forward.

© Jones & Bartlett Learning.

Description

Depending on the type of LVAD or the patient’s condition, the pump speed is generally set at a rate of 2,400 to 9,000 rpm. The centrifugal pump design allows for intrapericardial placement and enables the device to maintain lower rotor speeds. The intrapericardial placement of the smaller third-generation LVAD also has significant implications for reducing infection risks, minimizing surgical implantation methods, and providing MCS options for pediatric patients.

One of the key advancements of the third-generation LVAD is the introduction of the magnetically levitated rotor, which in turn provides noncontact bearings. Freeing the rotor from the pump housing allows for the near elimination of frictional wear and heat generation and minimizes the potential for thrombus formation. Advancements within the centrifugal-flow design have allowed for wider blood flow passages to help reduce shear stress on red blood cells. Furthermore, the speed modulation technology included in these devices creates an intrinsic pulsatility and reduces rpm speeds, thereby helping to reduce stasis and minimize the formation of thrombi. These improvements addressed the nonpulsatility effects associated with the second-generation LVAD: GI bleeding, aortic insufficiency, and pump thrombosis. The benefits of these changes were measured by the MOMENTUM 3 trial: 77% of patients receiving the HeartMate III had not experienced a disabling stroke or reoperation 2 years after implantation, versus 65% of patients receiving the HeartMate II. Two-year survival was comparable but slightly better for the HeartMate III (79%) versus the HeartMate II (77%).

Both third-generation LVADs incorporate speed modulation technology, with the rpm being altered at preprogrammed intervals to promote increased ventricular mixing and “washing” of the LV and the device. The HeartMate III uses an artificial pulse algorithm where the rpm changes every 3 seconds to create an intrinsic artificial pulse. The HeartWare LVAD uses the Lavare cycle to create an intrinsic artificial pulse. The Lavare cycle is a pump speed modulation algorithm designed to change the set speed over 3 seconds and repeat the cycle every minute. During a 2-second low-speed phase, the set speed decreases by 200 rpm. After 2 seconds, the pump speed then increases by 400 rpm for a 1-second high-speed phase. The decrease in pump speed allows the LV preload to increase, alters the LV blood flow patterns, and mixes stagnant blood. This mixing also creates a “washing” within the LV and decreases the probability of thrombogenesis. During the period of increased rpm, there is increased pressure within the pump, which creates a “washing” of blood within the pump and impeller. After the 1-second high-speed phase, the rpm returns to the set baseline speed until the next 2-second low-speed phase is repeated the following minute.

Special Populations

In 2020, the HeartMate III was approved by the FDA for use in pediatric patients with advanced refractory LV HF. This is a tremendous step forward in providing pediatric patients with advanced HF an additional option for treatment.

LVADs in the Community

There are more than 24,000 patients with LVADs in the United States. Advancements in treating HF have increased the number of patients living in the community with a variety of LVADs. These devices have increased patients’ quality of life and allowed many to return to their everyday activities of living, working, and traveling. Given the prevalence of LVADs, emergency medical services (EMS) providers must be prepared to respond to an LVAD emergency. This emergency may or may not involve the device itself. The EMS provider should have a basic knowledge of how the devices work and be aware of the types of complications that patients with LVADs may experience.

Generally, a patient with an LVAD will have substantial knowledge of the device and likely will have a designated caregiver with a working knowledge of how the LVAD functions and how to manage the device. While the patient and caregiver may be excellent sources of information, the EMS provider should also know how to troubleshoot the device, know which emergency interventions can and cannot be performed, and be aware of how to contact designated LVAD support staff. An emergency phone number can often be found on the back of the patient’s controller, but the number may also be stored in the patient's or caregiver's phone, or otherwise maintained in an accessible location, such as attached to the patient's bag of LVAD equipment. This emergency phone line should promptly connect the EMS provider to a trained representative who can assist with decision making as it relates to this patient and their specific equipment.

There are an estimated 500 VAD coordinators in the world and about 155 hospitals in the United States that implant LVADs. These limited numbers make it a challenge to train all community providers in managing LVAD emergencies. Many states offer EMS providers continuing education courses on LVADs, but such education may not be a requirement at the state level. Given the increased number of patients with LVADs who lead active lives in their communities, EMS and CCT services should have a standardized, universal LVAD management training system.

Considerations for LVAD Placement

In addition to risk stratification using the NYHA and Intermacs classifications to select candidates for LVAD implantation, there are other considerations related to LVAD placement. Age, aortic valve regurgitation, RV function, infection, bleeding disorders, irreversible hepatic or renal failure not due to poor CO, metastatic cancer, cerebral accident with neurologic deficits, and psychosocial status with support are all additional factors in determining LVAD candidacy.

Many geriatric patients have multiorgan dysfunction or other comorbidities that may negatively affect outcomes. Nevertheless, many patients have received LVAD implantation well into their 70s and 80s. Carefully assessing social support and level of frailty is crucial in selecting the appropriate geriatric candidate for LVAD therapy. Untreated aortic regurgitation is a contraindication to LVAD implantation. In such a case, either the aortic valve must be repaired at the time of the implantation or the valve must be oversewn during the LVAD implantation. The RV must be able to pump strongly enough to move blood from the right side of the heart through the lungs and over to the left side of the heart. Although no consensus has been reached on the level of RV dysfunction that represents an absolute contraindication to receiving an LVAD, factors that increase the likelihood of ventricular failure after LVAD implantation include elevated CVP, severe renal dysfunction, and ventilator dependence. Systemic infections, either bacterial or fungal, are contraindications to LVAD implantation.

To avoid pump thrombosis, patients will be placed on anticoagulants, usually warfarin. International normalized ratio (INR) targets vary by the patient's condition and the LVAD program's protocols; standard LVAD INR targets are between 2.0 and 3.0. These patients are usually placed on aspirin in addition to the warfarin. Patients with preexisting conditions that involve bleeding disorders are at an unacceptably high risk for LVAD implantation. Patients with LVADs are also at a higher risk of acquiring von Willebrand disease and have an increased risk of developing arteriovenous malformations, particularly in the GI tract. Patients with chronic kidney disease who are receiving dialysis are not considered candidates for LVAD implantation because they would be at higher risk of device infection and overall risk of poor outcomes. Finally, psychosocial instability, including factors such as an ongoing alcohol or substance use disorder, lack of a care plan, and noncompliance, may also be cited as a reason to not implant an LVAD.

Adverse Events

Bleeding

Bleeding is one of the most common adverse events and causes of hospital admission after LVAD implantation. The most common source of bleeding in these patients is the GI tract. Multifactorial mechanisms may contribute to this complication, with shear stress on red blood cells leading to acquired von Willebrand deficiency, arteriovenous malformation, and anticoagulation being the major causes of GI bleeding in patients with LVADs. The combination of increased shear stress, increased intraluminal pressure, and a narrowed pulse pressure is believed to be the cause of arteriovenous malformations.

Because endothelial dysfunction and elevated baseline activity of the coagulation system, which increases the risk of thromboembolic events, have been found in patients with LVADs, prophylactic treatment with anticoagulants and antiplatelet agents may be warranted. Anticoagulant medications used generally include warfarin, heparin, and direct thrombin inhibitors. Antiplatelet medications generally include clopidogrel, aspirin, and dipyridamole. Patients with LVADs will most likely be prescribed both aspirin and warfarin. The prescribed aspirin dose may vary between 81 and 325 mg orally daily. Direct contact between their blood and the LVAD leads to a hypercoagulable state and predisposes these patients to platelet activation. There is also an increase in activated endothelial cells, leading to elevated levels of inflammatory markers, which can promote coagulopathies. As mentioned previously, patients with LVADs are generally prescribed warfarin based on INR goals between 2.0 and 3.0, although this therapy is often reduced or discontinued if the patient experiences a GI bleed.

Studies have also revealed the significant relationship between GI bleeds and subsequent thromboembolic events, with the latter being related to the alterations in anticoagulation observed after the initial GI bleed. Preventing GI bleeds may result in fewer thromboembolic events and improved outcomes. The challenge remains maintaining the appropriate balance of antiplatelet and anticoagulation therapy.

LVAD Infections

Infection remains one of the most common LVAD complications contributing to major morbidity and mortality. By the 2-year mark, the incidence of major infection related to LVADs increases to 51% for axial-flow devices, 55% for centrifugal-flow hybrid levitation devices, and 41% for centrifugal-flow full-magnetic levitation devices. Infection accounts for 7% of all LVAD-related deaths in the first year after device implantation and 15% of all LVAD-related deaths thereafter. The most commonly encountered pathogens are *Staphylococci* species, *Pseudomonas aeruginosa*, and *Enterococcus* species.

Most LVAD-specific infections are isolated to the driveline, with subsequent infection involving the pocket and internal surfaces of the pump. The driveline transmits communication between the pump and the controller. It also provides energy from an external source (ie, batteries or AC power unit). Driveline infections occur frequently because the exit site where the driveline enters through the skin and abdominal wall creates a conduit for the entry of bacteria and the prosthetic material of the driveline creates an environment that supports bacterial biofilm formation. Such an infection can affect the driveline site and continue ascending to the subcutaneous tunnel, the abdominal pocket, the implanted pump itself, and the remainder of the body.

Multiple studies have identified predisposing factors for LVAD infections. Elevated body mass index is the most commonly cited independent predictor of infection. Recent studies have also revealed that age has emerged as a strong predictor of percutaneous site infection. For every 10-year decrease in patient age, the risk of percutaneous site infection has been found to rise by 20%. It is believed that younger patients are more active and more likely to suffer trauma at the driveline exit site, further compromising the integrity of the driveline–integument barrier. Prevention includes using anchors to immobilize the driveline in all patients and using binders as determined by specific LVAD implantation programs.

A systematic multidisciplinary approach that spans the operative technique, including postoperative management, patient education, and long-term follow-up, continues to be paramount in combating driveline infections in patients with LVADs. The CCTP should be able to recognize the signs and symptoms of infection, particularly as they pertain to the LVAD driveline. During the assessment of the LVAD's driveline, both the patient and care providers should don gloves and a mask. Providers should inspect for erythema, bleeding, or purulent drainage and note any wound odor.

Ischemic and Hemorrhagic Stroke

Strokes, both ischemic and hemorrhagic, and their sequelae are major concerns for patients with LVADs. Hypertension is a significant risk factor for stroke. The risk of stroke in patients with severe hypertension (SBP > 160 mm Hg) is four times that in normotensive patients. A MAP of greater than 110 mm Hg in patients with LVADs is considered hypertensive. Clinical management guidelines have recommended a goal MAP range of 70 to 80 mm Hg, and current International Society for Heart and Lung Transplantation (ISHLT) guidelines recommend a target MAP of less than 80 mm Hg, provided the adverse effects of hypotension can be avoided.

The mechanisms behind ischemic strokes are believed to include embolic sources such as thrombus formation at the pump, the aortic valve, and inflow or outflow grafts.

The highest priority when providing care for the patient with an LVAD and current intracerebral bleeding is a safe return to a near-normal coagulation profile. There are currently no established guidelines for the duration of cessation of anticoagulation or the timing of its resumption following resolution of a bleeding event in a patient with an LVAD. Recommendations for INR targets will vary depending on the LVAD, the patient's past medical history, and the guidelines established by the LVAD implantation program. As mentioned previously, patients are generally prescribed warfarin as their anticoagulation therapy, with INR goals between 2.0 and 3.0, and their antiplatelet therapy usually includes daily oral intake of either aspirin or a short-term alternative such as a glycoprotein IIb/IIIa inhibitor. Studies have suggested that preventing a bleed may ultimately decrease the risk of future thromboembolic events.

Providers should exercise extreme thoughtfulness when providing initial care to a patient with an LVAD who is experiencing bleeding, including in their approach toward cessation of anticoagulation during an episode of bleeding. Potential interventions, which must be carefully monitored, include (1) active reversal of INR versus observation and simple cessation of anticoagulation, (2) discontinuation of the antiplatelet medication, and (3) careful timing of anticoagulation therapy resumption after a bleeding episode.

Cardiac Arrhythmias

Atrial and ventricular arrhythmias are common in LVAD recipients, originating from the preexisting myocardial substrate or from the complex electrical remodeling that occurs after LVAD implantation.

There is a high prevalence of atrial arrhythmias in these patients (21% to 54%), with 20% to 30% of patients developing new-onset atrial arrhythmias following implantation of their LVAD. Most of these patients with new-onset atrial arrhythmias will have atrial fibrillation, which is believed to be caused by the post-LVAD reduction in left atrial size and volume. Pre-LVAD atrial arrhythmias are associated with post-LVAD atrial arrhythmias as well as ventricular arrhythmias.

Postoperative atrial fibrillation is not strongly associated with an immediate risk of mortality or stroke, although persistent atrial fibrillation is associated with a combined end point of HF and increased mortality. The major concern for developing thromboembolic events secondary to atrial fibrillation applies to all patients, with or without an LVAD. Limited studies and current clinical data have yielded conflicting information on whether atrial fibrillation increases the risk of thromboembolic events in LVAD recipients. In regard to treating the patient with an LVAD and new-onset atrial fibrillation, anticoagulation is required and the patient should not have INR targets readjusted due to atrial fibrillation. Rate control has been shown to be the most effective management strategy for patients with atrial fibrillation. Beta blockers are the agents most commonly used to treat atrial fibrillation associated with a rapid heart rate. Nondihydropyridine calcium channel blockers should be used with caution because of their negative inotropic effects. Digoxin is frequently used as an adjunct when treating patients with recurrent HF post LVAD implantation and has been combined with beta blockers to achieve atrial fibrillation rate control. If the patient cannot maintain hemodynamic stability due to the atrial fibrillation, then the following medications may be prescribed for rhythm control: amiodarone, dofetilide, or sotalol. Only limited studies and guidelines are available to provide strategies for rhythm control in hemodynamically unstable patients with LVADs. In consequence, management typically follows AHA recommendation guidelines for treating atrial fibrillation in patients with a reduced ejection fraction or systolic HF.

There is also a high prevalence of ventricular arrhythmias in patients with LVADs (20% to 50%), with 20% of patients developing new-onset sustained monomorphic ventricular tachycardia after implantation of their device. The majority of these ventricular arrhythmias result from the underlying substrate. Incidence is higher immediately after LVAD implantation and in the month that follows. In the setting of documented ventricular arrhythmias, no antiarrhythmic drug has been shown to improve survival better than implantable cardioverter-defibrillator (ICD) therapy. Given the history of advanced HF noted in many LVAD recipients, an ICD may already be in place during LVAD implantation. Antiarrhythmic drugs are often used in conjunction with ICD therapy to improve symptoms, reduce ICD therapies, and help prevent hemodynamic instability associated with ventricular arrhythmias. Beta blocker use has been shown to improve ventricular arrhythmias, although LVAD recipients are generally already on a beta blocker regimen when the new onset of ventricular arrhythmia occurs. Limited studies of patients with LVADs who received beta blockers for ventricular arrhythmias have shown conflicting results with the use of these medications for secondary prevention of ventricular arrhythmias. The following medications may be prescribed to treat ventricular arrhythmias in LVAD recipients: amiodarone, sotalol, azimilide, celivarone, lidocaine, and procainamide. Conclusive evidence that antiarrhythmic therapy improves outcomes remains lacking, however. Careful assessment of the symptoms and hemodynamic changes associated with ventricular arrhythmias, balanced against the risks of side effects and drug interactions, must be undertaken when selecting the appropriate medical therapy for the patient with an LVAD and ventricular arrhythmias.

Many patients with LVADs exhibit sustained ventricular tachycardia, ventricular fibrillation, or even asystole. Cases have described patients who have demonstrated a stable presentation with sustained ventricular tachycardia or fibrillation for greater than 24 hours; however, there is concern about the potential reduction in pump flow and CO during sustained ventricular arrhythmias. There is also concern regarding the potential adverse effects on RV function or possible thrombus formation in a fibrillating RV.

The decision to implant an ICD in a patient with an LVAD is generally made on a case-by-case basis. Consideration is given to the patient with a history of ventricular arrhythmias that have been associated with hemodynamic instability or other symptoms such as syncope or impaired LVAD flow. The AHA has stated that ICD implantation can be beneficial for an LVAD recipient who is experiencing sustained runs of ventricular arrhythmias. Continued research on this topic is needed, however, as are more appropriate ICD algorithms for the patient with both an LVAD and an ICD.

LVAD recipients with ICDs are frequently admitted to the hospital for ICD firing and arrhythmia management. The majority of patients with LVADs can tolerate ventricular arrhythmias, and most of these patients are awake when their ICD fires. At the present time, cardiologists are restricted from adjusting ICD programming limits due to FDA rules. Therefore, patients with LVADs and active ICDs sometimes receive a shock while they are wide awake. As one would expect, such painful experiences can have drastic effects on patients' psychological health and quality of life. Certain patients opt to have their ICD turned off to stop the painful shocks. This decision should involve members of the LVAD team, the patient, and the patient's family.

Many tachyarrhythmias, ventricular tachycardia, and ventricular fibrillation, as previously mentioned, might be well tolerated. However, if the LVAD recipient without an active ICD is in a shockable rhythm and is hemodynamically unstable, providers should follow current advanced cardiac life support protocols for defibrillation or cardioversion. The defibrillator pads should be placed in the anterior–posterior position and not over the device.

LVAD Thrombosis

LVAD thrombosis is a potentially lethal complication that may be noted by signs of inadequate circulation. It is typically associated with sustained low LVAD flow despite normovolemia (which could be caused by partial obstruction of the LVAD blood pathway by thrombus) or thrombus formation within the pump house interface, causing increased friction of the rotor or impeller. This thrombus formation will cause increased LVAD power consumption that may be intermittent or sustained, resulting in an activated high LVAD power alarm. A thrombus that is causing excessive power consumption could produce an overestimated pump flow reading. If signs of poor circulation persist despite appropriate treatment, device thrombosis should be highly suspected. When managing this emergency, providers should consult the patient’s LVAD center for guidance before transferring the patient to the appropriate LVAD center.

A number of factors contribute to the formation of a thrombus within an LVAD device, including anticoagulation therapy, surgical technique, and device engineering. The obstruction is typically attributed to a clot within the circulation path of the LVAD, including the inflow and outflow cannulas, and the pump housing itself, which includes the stators, bearings, rotor, and impeller. A thrombus located on the rotor or impeller is likely to produce power spikes or falsely elevated pump flow. A thrombus located within the IFC is likely to produce a pump flow reduction.

The thrombus can originate from within the device or from the LV, left atrium, or right side of the heart, most likely via an atrial septal defect or ventricular septal defect. The consequences vary from a small thrombus formation requiring minimal intervention to device malfunction requiring surgery and exchange of the LVAD.

Signs and symptoms of device thrombosis include HF symptoms, hemoglobinuria, an elevated LDH value greater than 2.5 times the upper limit of normal, an elevated plasma-free hemoglobin level greater than 40 mg/dL, anemia, and an elevated bilirubin level. LDH is considered the most specific biochemical indicator of pump thrombosis.

Antithrombotic management of pump thrombosis includes aggressive anticoagulation with warfarin and antiplatelet therapy with aspirin. When device thrombosis is highly suspected, the patient’s LVAD center should be consulted for care management guidance until patient transport occurs. Providers should anticipate initiating a short-term parenteral anticoagulant such as heparin. Conflicting data have been collected regarding the efficacy of direct thrombin inhibitors, such as argatroban, in managing suspected pump thrombosis. Conflicting data also exist on the efficacy of thrombolytic therapy.

The current-generation LVADs, particularly the HeartMate III, have been associated with minimal levels of shear stress and reduced hemolysis due to the framework of their fully magnetically levitated impeller. This centrifugal pump has wide passages for blood flow, frictionless propulsion with magnetic levitation, and an intrinsic pulse designed to reduce blood stasis. This design, in turn, mitigates platelet activation and helps to inhibit activation of the coagulation system.

Right-Side HF

As described previously, the RV must be able to pump strongly enough to move blood from the right side of the heart through the lungs and over to the left side of the heart. Despite precautions and evaluations of RV status before an LVAD implantation, RV failure after implantation is common, occurring in 5% to 13% of patients. Approximately 4% of patients in RV failure will require support with a right ventricular assist device (RVAD) within 2 weeks of LVAD implantation. Ideally, LVAD unloading of the LV should decrease RV afterload and improve RV contractility.

Multiple factors contribute to RV failure after LVAD implantation. One or more of the following conditions may result in RV failure: the sudden increase in RV unloading, increased RV preload, increased RV afterload, and progressive cardiomyopathy. Symptoms of right-side HF will include HF symptoms and fluid overload.

Medical management remains the mainstay for treating right-side HF after LVAD implantation. There are four major areas of focus and treatment:

- RV preload: diuretics and hemofiltration
- RV afterload: pulmonary vasodilators, optimal LV unloading with LVAD
- RV contractility: inotropes
- Rhythm: optimal atrioventricular synchrony

LVAD speed adjustments may be required to help manage right-side HF after LVAD implantation. These adjustments are usually performed at LVAD centers. LVAD unloading of the LV may result in RV reshaping and septal shifting, inducing right-side HF. Leftward septal shift secondary to high LVAD speeds may result in RV distention and tricuspid regurgitation. Maintaining hemodynamic stability with LVAD support is paramount with LVAD management. Vasodilation or poor perfusion can lead to unloading of the LV, which then leads to leftward septal shift and resultant suction events. Suction events prevent adequate LVAD filling and output. They also contribute to the onset of ventricular arrhythmias.

When medical therapy in conjunction with LVAD speed adjustments is unsuccessful in treating right-side HF, right-side MCS may be indicated. Right-side MCS can be used in conjunction with an LVAD as a bridge to right-side heart recovery, bridge to heart transplantation, bridge to durable biventricular support, or bridge to the implantation of a total artificial heart.

ECMO can be another alternative for acute right-side HF support after LVAD implantation. ECMO indications include primary RV failure or RV failure secondary to primary pulmonary pathology, including the presence of systemic oxygen desaturation.

Device Malfunction

Device malfunction is not limited to pump failure; other components of the LVAD system may also be subject to failure. The controller is the most common source of LVAD malfunction, accounting for approximately 30% of instances. The battery (19%), patient cable (14%), and pump (14%) are also leading culprits. According to the FDA, malfunctions of the following LVAD components/mechanisms have resulted in product recalls: battery malfunction, loose driveline connector, malfunction of the system controller, loose power supply connector ports, malfunction of the driveline splice kit, problems with the percutaneous lead connection, disconnection of the bend relief system and outflow graft, and outflow graft occlusion. Malfunction of these components could lead to pump inactivation, and subsequently to HF symptoms, cardiogenic shock, and death. Thorough assessment of all LVAD components is essential when providing patient care.

Recognition of LVAD complications as they specifically relate to the pump, the controller, the battery, and the percutaneous lead requires a basic understanding of how these components function **FIGURE 16-25**. As discussed previously, the patient or the patient's caregiver will have a thorough understanding of those components. While these individuals may offer invaluable assistance, the CCTP is responsible for providing safe and appropriate care during prehospital and interfacility transport of the patient with an LVAD.

Description

Mental Health

Everyday life with an LVAD presents challenges for patients. Living with an LVAD requires constant monitoring, consistent medical follow-up, and adjustment to overwhelming lifestyle changes. Depression is common in patients with HF and has been associated with increased morbidity and mortality. Post-LVAD anxiety and depression are prevalent predictors of decreased quality of life. Depression may affect cognitive status and motivation, making it difficult for patients to understand and adhere to medical recommendations. This functional impairment may be particularly problematic given the complicated medical regimens and significant lifestyle changes required after LVAD placement. Depression and anxiety vary throughout the course of the patient’s care, intensifying just before LVAD implantation, decreasing after immediate implantation, and rising again when adjustment problems overwhelm coping skills.

Studies of patients who underwent LVAD implantation as DT and BTT, where symptoms of depression were measured preoperatively, revealed that signs of clinical depression were more prevalent in the DT group. These results might reflect that patients and caregivers preparing for LVAD implantation as BTT consider this intervention to be a temporary means to achieve medical stability until heart transplantation is possible. In contrast, patients receiving an LVAD as DT know the device will be in place for the remainder of their lives.

Family members may also feel overwhelmed by the responsibility of managing the device and the fear of it malfunctioning on their watch. Studies show that caregivers experience emotional strain particularly during the first 3 months after implantation. This includes an increase in stress levels due to all of the adjustments made at home for the patient and the other family members.

Patients could benefit from psychological support before and after LVAD implantation to further improve their quality of life and mental recovery.

Respiratory Failure

Respiratory failure commonly occurs either before or after implantation of LVADs. According to Intermacs data, more than 5% of patients require respiratory support within 48 hours before implantation, and 6.1% of patients experience respiratory failure within the first week after implantation. More importantly, both intubation before and respiratory failure after LVAD implantation are independently associated with a significantly increased risk of adverse clinical outcomes, including mortality at 1 year (2.5 times increased risk of death). Studies also reveal that the risk of respiratory failure is twice as great if the patient with an LVAD develops an infection. An LVAD recipient in respiratory failure is five times as likely to experience renal failure, and the LVAD recipient with a neurologic adverse event is most likely to experience respiratory failure.

The incidence of adverse reactions relating to respiratory failure within the first 60 days after LVAD implantation remains high, and these adverse reactions rarely occur in isolation; furthermore, an initial adverse reaction will often be followed by subsequent adverse reactions. It is therefore imperative that the CCT recognize adverse events early, and avoid inadvertently triggering a cascade of adverse events, so as to help reduce the overall morbidity and mortality of patients with LVADs.

Point-of-Care Ultrasonography

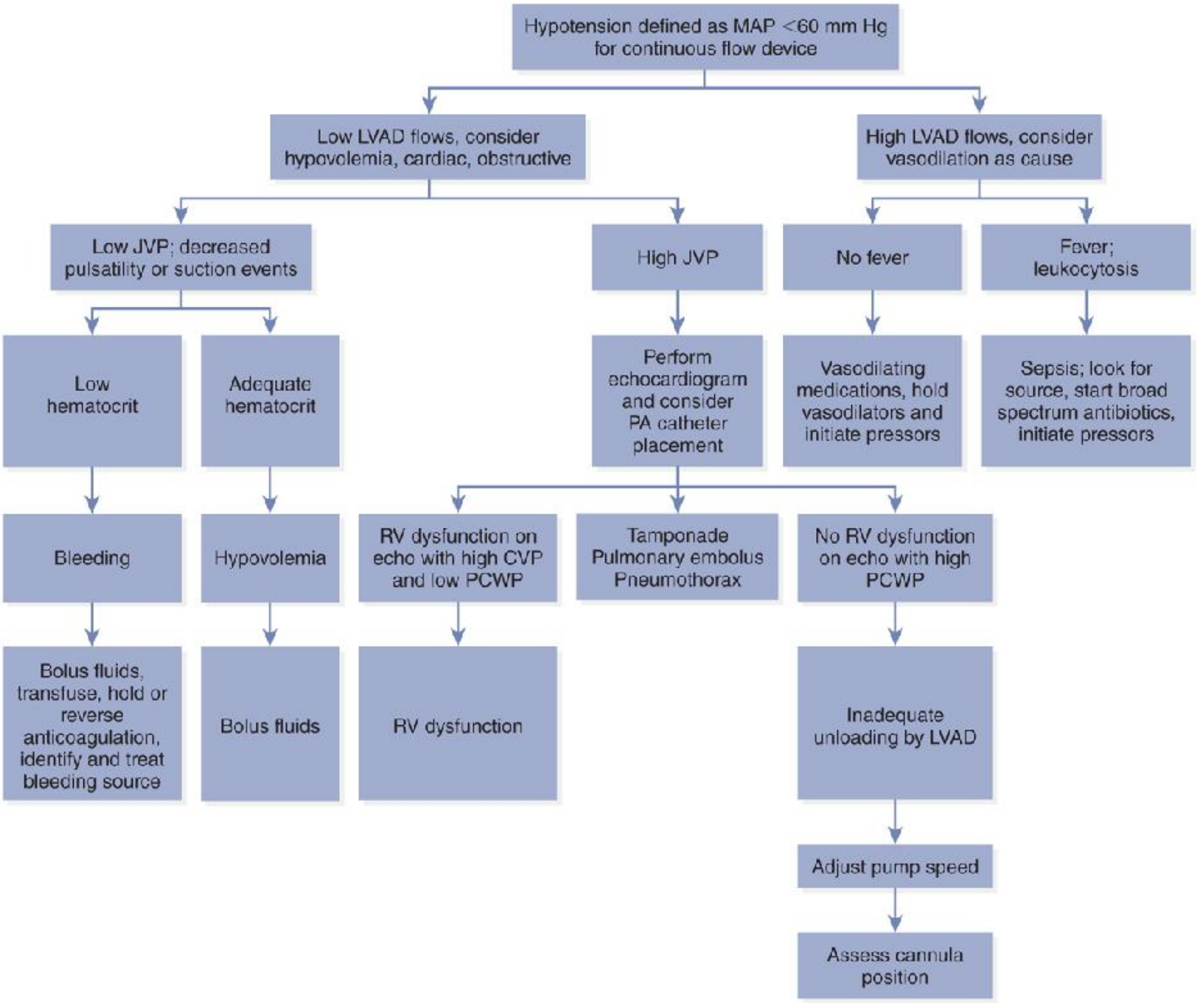
Point-of-care ultrasonography (POCUS) is a valuable tool in assessing the patient–pump balance. It can be used to determine the following:

- Native RV and LV function.
- Hypovolemia: Decreased RV size suggests low preload.
- LVAD-induced RV failure: Decreased LV size with the septum bowing toward the LV suggests a possible suction event.
- RV failure or high pulmonary vascular resistance (PVR): Large RV and small LV suggest RV failure.
- Device failure: Large RV and LV suggest pump thrombosis or obstruction.

Recognizing LVAD Dysfunction

Hypotension (Shock)

The differential diagnosis for post–LVAD implantation hypotension includes a broad range of conditions. Hypotension in the patient with an LVAD is defined as a MAP of less than 60 mm Hg **FIGURE 16-26**. Hypovolemia should be at the top of the CCTP's differential diagnosis list as an etiology of hypotension. Generally, in patients with LVADs, hypotension is secondary to hypovolemia; the CCTP should anticipate a decrease in the LVAD flows, a decrease in the pulse index, and a potential suction event. Hypotension with decreased LVAD flows can also present with RV failure, arrhythmias, tamponade, or a device-related complication. If the pump flow falls below 2.5 L/min, the low-flow hazard alarm will be displayed, the pump running symbol will remain green, the red heart warning light will illuminate, and a steady tone alarm will sound.



Hypotension defined as MAP <60 mm Hg for continuous flow device
Low LVAD flows, consider hypovolemia, cardiac, obstructive
High LVAD flows, consider vasodilation as cause
Low JVP; decreased pulsatility or suction events
High JVP
No fever
Fever; leukocytosis
Low hematocrit
Adequate hematocrit
Perform echocardiogram and consider PA catheter placement
Vasodilating medications, hold vasodilators and initiate pressors
Sepsis; look for source, start broad spectrum antibiotics, initiate pressors
Bleeding
Hypovolemia
RV dysfunction on echo with high CVP and low PCWP
Tamponade Pulmonary embolus Pneumothorax
No RV dysfunction on echo with high PCWP
Bolus fluids, transfuse, hold or reverse anticoagulation, identify and treat bleeding source
Bolus fluids
RV dysfunction
Inadequate unloading by LVAD
Adjust pump speed
Assess cannula position

FIGURE 16-26 Algorithm for managing hypotension in the patient with a left ventricular assist device (LVAD).

Abbreviations: CVP, central venous pressure; JVP, jugular venous pressure; MAP, mean arterial pressure; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; RV, right ventricle

Description

Hypotension can also present secondary to vasodilatory shock resulting from either sepsis or vasoplegia. LVADs are afterload sensitive; therefore, the CCTP should anticipate an increase in LVAD flows if vasodilation is present and adequate preload exists. Hypotension will persist once the LVAD's augmented forward flow is overcome by increased systemic vascular resistance. When vasodilatory shock is suspected, appropriate fluid resuscitation and vasopressors should be administered to maintain a MAP of 65 to 80 mm Hg.

Decreased pump preload can also occur secondary to bleeding. As discussed previously, patients with LVADs are at a high risk of bleeding due to the need for anticoagulation, acquired von Willebrand disease, and arteriovenous malformations in the GI tract. Providers should assess for bleeding from the GI tract, nares, and thorax, and throughout the body. Increased pump afterload can be due to systemic hypertension, kinking of the outflow cannula, or thrombus. Pump malfunction can also result in hypotension. Arrhythmias that affect RV filling will generally affect LV filling, which could ultimately result in hemodynamic instability, although not all patients with arrhythmias will present with hemodynamic instability.

It is not uncommon for a patient with an LVAD to be in ventricular tachycardia or fibrillation and remain conscious. The LVAD may be able to provide enough forward flow despite ventricular tachycardia or fibrillation and other arrhythmias. Given this possibility, the decision to cardiovert or defibrillate should be based on the patient's mental and perfusion status. Hypotension can also result from increased PVR. Increased PVR can result from hypoxemia, hypercarbia, or obstruction of pulmonary blood flow. Pulmonary embolism is the usual culprit of obstructed pulmonary blood flow. Increased PVR will decrease LV preload, which will result in a decrease in overall LVAD flow.

Hypertension

Intermacs has defined new-onset hypertension in patients with LVAD as the presence of a MAP greater than 110 mm Hg. Clinical management guidelines recommend a goal MAP of 70 to 80 mm Hg. The current ISHLT guidelines recommend a target MAP of less than 80 mm Hg, provided the adverse effects of hypotension can be avoided. The guidelines also recommend standard HF pharmacotherapy to maintain optimal MAP control. Evidence has shown that maintaining MAP goals protects against adverse events such as stroke, pump thrombosis, and aortic insufficiency.

Ventricular Recovery

Ventricular recovery after LVAD implantation is the most desirable goal in treating the patient with end-stage HF. With the improvements in the durable LVAD, there has been a substantial increase in the number of LVAD implantations performed. There are also more patients with HF and a higher Intermacs profile who are accepting LVAD implantations. Newer minimally invasive implantation techniques, in conjunction with the overall growth in the number of MCS providers, favors an increase in the ventricular recovery of patients with LVADs. Ventricular recovery occurs in approximately 1% to 5% of these patients, allowing for explantation of their device. The type of cardiac pathology present has proved to be a determining factor in ventricular recovery. Recovery mechanisms vary due to the different etiologies of cardiac pathology, the different proportions of patients who recover, and the overall time of recovery: Patients with dilated cardiomyopathy can recover after several months of LVAD support. By comparison, research shows that patients with severe acute myocarditis or noncoronary shock can recover after only weeks of LVAD support.

Results of BTR treatment in patients with LVADs show encouraging safety and long-term survival outcomes. Studies reveal that 10-year survival outcomes after LVAD explantation in selected patients are superior to the corresponding outcomes in BTT recipients. With a careful selection process for LVAD implants and an aggressive cardiac reconditioning effort, BTR success rates should continue to rise.

Inflow Cannula Malpositioning

Ideal IFC positioning lies on a line from the apex to the center of the mitral valve. Malpositioning of the IFC includes deviations toward the superior free wall, the inferior wall, the septum, or the lateral wall.

IFC malpositioning has been associated with a number of adverse events, including ischemic stroke, suction events, low flows, speed reductions, and thromboses. Axial pumps are associated with a substantial number of IFC-malpositioning implantations as compared to the centrifugal-flow hybrid levitation pumps. Such malpositioning incidents are largely due to the axial pump’s requirements for an intra-abdominal pump pocket and the relatively inflexible IFC position. The smaller centrifugal-flow pumps are designed for direct intracardial placement, which minimizes IFC movement when compared to the axial pumps.

LVAD Pump Parameters

Pump Flow

The displayed pump flow is a calculated value that is directly related to the set rpm and power. An increase in power produces an increase in calculated flow. The spinning impeller creates the pump flow and ultimately generates the forward flow of blood. The device flow is directly proportional to the rpm and inversely related to the difference in the inflow and outflow cannulas, as described by the following equation:

Device flow = Rotor speed

$$(\text{Pump}_{\text{inflow}} - \text{Pump}_{\text{outflow}})$$

Hypovolemia, cardiac tamponade, RV failure, thrombus, or a kink within the IFC will result in a low flow rate. A low flow rate can also result from an increase in afterload (elevated SVR). Increased afterload may result from uncontrolled hypertension, a kink, or a thrombus in the outflow cannula.

Confirming Pump Function

Anytime the pump is running, a green light will be illuminated on the controller and the CCTP will be able to hear and feel a hum when listening or placing a hand over the pump.

Pump rpm Setting

The rpm setting determines pump flow. This set rate is determined by either the cardiac surgeon or the physician caring for the patient with HF and is adjusted as flow needs change. Ramp studies are increasingly used to evaluate heart and LVAD function and possible malfunction of the LVAD. Ramp studies measure cardiac hemodynamics and assess changes in heart size at various rpm settings. The results help to indicate possible pump dysfunction, IFC malpositioning, appropriate or inappropriate LV unloading, hypovolemia, aortic valve function, and LV compliance.

Output from the LVAD depends on preload, afterload, and pump speed. However, it should be noted that the pump speed is fixed and does not fluctuate with loading conditions of the heart.

Pump Power

The pump power of the LVAD is the measurement of the current required to maintain the pump's rpm at a set speed. Generally, an increase in pump power is caused by formation of a thrombus within the pump. Decreases in pump power most often result from a low battery.

Pulsatility Index

With the centrifugal-flow full-magnetic levitation, the pulsatility in flow is quantified as the **pulsatility index (PI)**. PI is calculated as follows, where PP represents pump pressure:

$$\text{PI} = \frac{\text{Maximum PP} - \text{Minimum PP}}{\text{Average PP}}$$

The PI corresponds to the magnitude of flow pulse through the pump. It fluctuates with changes in fluid status and the heart's native contractility. PI increases when preload and contractility increase; conversely, it decreases when preload and afterload decrease, such as with an obstruction that causes low flows and abnormal pump power.

Troubleshooting Abnormal LVAD Conditions

Management of specific problems and device alarms is discussed next. **TABLE 16-4** offers a brief overview of these conditions.

TABLE 16-4 | Troubleshooting LVAD Events

Condition	Possible Causes	Considerations
Low LVAD flow	Right heart failure Arrhythmia Hypovolemia High pulmonary vascular resistance	Assess right ventricular function. Obtain an electrocardiogram. Interrogate the implantable cardioverter–defibrillator. Assess volume status. Assess patient's native pulse.
High LVAD flow	Vasodilation Sepsis/infection Aortic insufficiency	Treat the root cause. Obtain an echocardiogram.

Condition	Possible Causes	Considerations
High pump power	Device thrombosis Clot ingestion	Obtain an echocardiogram. Assess the native left ventricular flow. Provide patient support. Consider anticoagulation. Exchange the device.
Low pump power	Device dysfunction	Assess power cables and power sources. Change components as needed.
High pulse index	Heart recovery Arrhythmia Hypervolemia Incorrect pump speed	Obtain an echocardiogram. Assess the rhythm. Check external components.
Low pulse index	Right heart failure Hypovolemia Incorrect pump speed	Obtain an echocardiogram. Assess volume status. Optimize pump speed.
Suction event	Hypovolemia Inlet obstruction Arrhythmia Right heart failure	Obtain an echocardiogram. Assess volume status. Assess for hemolysis.

Abbreviation: LVAD, left ventricular assist device

Suction Events

Suction event complications are generally associated with low-flow events that occur secondary to arrhythmias and hypovolemia. Decreased LV preload can cause collapse of the LV and decreased flow to the LVAD. Ventricular arrhythmias can also result from suction events, potentially further compounding decreased preload. The controller alarms will reveal low flows, low speeds, and low power **FIGURE 16-27**. Suction events will also trigger an automatic transient decrease in rpm to a set lower speed limit. Managing the underlying etiology and providing appropriate fluid resuscitation will improve preload and intravascular volume.

Description

Cable Failure and Disconnection

Consider the basic design of the modern LVAD: A miniaturized blood pump is attached to the heart and driven by an electric motor, which is powered by a cable driveline that exits the patient’s body through the skin to be connected to an external power source.

Now consider the specific connections and points of attachment: Centrifugal-flow LVADs have inflow conduits that are inserted into the LV through an apical cuff. The pump is then secured to the apical cuff. The pump is connected with a power supply via a driveline cable. The driveline passes from the pump through the musculus rectus abdominis and fascial layers into the patient’s abdominal region. The cable then exits the body through a small incision in the skin. The cable sheath, which is usually made of silicone or polyurethane, is covered in the implanted part with a woven or nonwoven material, which ensures optimal ingrowth. The driveline is immobilized close to the exit site of the skin by means of a fixing system that is designed to protect the exit site from mechanical manipulation. The exit site of the cable is protected from possible infection by a mandatory sterile dressing. The cable then connects to the LVAD controller.

LVAD System Alarms

Battery Alarm

The yellow battery icon indicates there is less than 15 minutes of power remaining, and a beep will sound every second when this alarm is activated. The red battery icon indicates there is less than 5 minutes of power remaining, and a steady tone will sound when this alarm is activated. When a battery alarm is active, the pump will default to a lower rpm speed to conserve power. It will return to the original set speed once adequate power is restored. When a battery alarm is active, check all connections and replace batteries as instructed. Do not disconnect both batteries at the same time because doing so may turn off the pump. If charged batteries are unavailable, switch to the power module.

Cable Disconnect Symbols

If the black power cable disconnect symbol is illuminated, the black side does not have power and the advisory alarm will be activated. The advisory alarm will beep and the yellow diamond will illuminate.

If the white power cable disconnect symbol is illuminated, the white side does not have power and the advisory alarm will be activated. The advisory alarm will beep and the yellow diamond will illuminate.

If the driveline cable disconnect symbol is illuminated, the driveline has been removed from the controller and the hazard alarm will be activated. The hazard alarm will emit a steady tone and the red battery icon will illuminate.

Summary

In patients with HF, MCS may be required. Although CCTPs will transport patients who rely on MCS devices to ensure adequate perfusion, the operation and management of these devices are outside of the typical CCTP's scope of practice. The CCTP's primary role is to assist in emergent care and transport of the patient or to provide interfacility transport. By preparing carefully and monitoring them diligently, the CCTP can ensure the best outcomes for these vulnerable patients.

Patients on MCS can be safely transported by ground or air and by using various team combinations when the team has the appropriate resources and skills. Frequent training and competency demonstrations should be routinely augmented with simulation and quality reviews. Medical oversight of CCT teams should be provided by professionals with experience in the care and management of patients requiring MCS.

CASE STUDY

You are assigned to a ground CCT unit. You have just been called to a critical access hospital that operates a cardiac catheterization laboratory (catheterization lab) without on-site cardiac surgery. On arrival, you find a 56-year-old male patient who presented there 3 hours ago with an acute coronary syndrome. He has a past medical history of diabetes and hypertension. His symptoms began 72 hours ago with chest discomfort, epigastric pain, and increased work of breathing. Ground EMS handed him off with the following vital signs: heart rate, 86 beats/min; BP, 92/62 mm Hg; respiratory rate, 24 breaths/min; SpO_2, 96%. EMS administered 325 mg of aspirin and three doses of sublingual nitroglycerin without resolution of symptoms. The patient's prehospital 12-lead ECG revealed a sinus rhythm with Q waves in leads III and aVF; T-wave inversion across leads II, III, and aVF; and ST-segment depression in V_3–V_6. EMS initiated a heart team alert prior to your arrival.

In the emergency department, the patient's symptoms persisted. His skin was paler than its baseline color and his extremities were cool. Providers administered 600 mg of clopidogrel orally and initiated a heparin drip. The patient was promptly transported to the cardiac catheterization lab.

In the cardiac catheterization lab, arterial access was established via the right femoral artery. The patient was found to have triple-vessel coronary artery disease with 80% occlusion of the right coronary artery, 100% occlusion of the left anterior descending artery (resembling thrombus), and 70% occlusion of the circumflex artery. A thrombus aspiration of the left anterior descending artery was performed. During the procedure, the patient experienced transient episodes of ventricular tachycardia associated with hypotension, hypoxemia, and syncope. He was placed on high-flow oxygen by mask, and an amiodarone and phenylephrine infusion was initiated. The left ventriculogram revealed a severely depressed ventricle, and a left-side microaxial percutaneous catheter pump (Impella) was placed. The patient's vital signs are now heart rate, 88 beats/min; sinus rhythm with frequent multiform premature ventricular complexes; BP, 98/56 mm Hg; MAP, 60 mm Hg; respiratory rate, 26 breaths/min; and SpO_2, 96%.

The Impella CP device is set to P-8 with a flow of 3.5 L/min. The device parameters show a placement signal of 108/77 mm Hg (87), LV 117/2 mm Hg, and motor current of 822/699 mA. The purge flow is 11 mL/h of D_5W with 25 units/mL of heparin with a purge pressure of 503 mm Hg.

You have initiated transport for a 45-minute drive to a quaternary care center. En route, the patient experiences more sustained episodes of ventricular tachycardia lasting 20 to 30 seconds, along with hypotension in the 70s. The Impella device begins issuing the "suction" alarm.

1. What considerations prior to transport should be considered with a patient on MCS?
2. For patients with active ventricular unloading with a heart pump, what factors can cause inadequate pump support?
3. Which troubleshooting steps can providers take to ensure adequate flow and function of the heart pump?

Analysis

This patient presented with an acute coronary syndrome with evidence of inadequate tissue perfusion and unresolved coronary artery supply–demand mismatch. This cardiogenic shock presentation places the patient at risk of worsening organ dysfunction and death. The initiation of MCS is vital to improving this patient's outcome; however, the CCT team should avoid unnecessary delays in further treatment.

Considerations for transport of a patient with cardiogenic shock receiving MCS include addressing both the patient and the pump system. Patient considerations include obtaining an adequate handoff from the sending team, ensuring adequate airway and ventilation, maintaining adequate vascular access, providing pain relief and comfort, clearly understanding the therapeutic agents and infusions involved, and formulating a plan to move the patient without causing any complications. The CCTP should be able to anticipate common adverse events related to the pathology the patient is experiencing. This patient is at increased risk of worsening cardiac arrhythmias, pulmonary edema, right-side HF, and complications related to anticoagulants. Considerations for maintaining optimal device function include maintaining adequate preload through volume and right-side heart output. Heart pumps are also sensitive to increases in afterload, and CCTPs should be aware of the target hemodynamics and have the resources needed to titrate to them. Pumps can also become malpositioned during patient transfer or movement or as a result of device migration. Externalized devices should be secured according to the agency policy and the manufacturers' instructions for their use. The power supply for transport should be deemed adequate and tested with a margin of backup before loading the patient.

Inadequate pump support can be caused by inadequate patient volume, inadequate pressure, worsening HF, pump malposition, thrombosis, ingestion of a clot, or malfunction of the pump system. Anticipating, recognizing, and treating these patient or device problems can be challenging in the transport environment. Team members should have appropriate technical resources available to them, staffing adequate to handle the situation, and the ability to communicate with experts during the transport.

Troubleshooting pump systems is best done in a systematic fashion, by following two paths. The first path is the functional path of power supply to terminal pump performance. The second is the blood flow path to and through the device. In the first path, the power source, power supply, cables, connections, gas delivery, tubing, obstructions, device settings, alarm conditions, device position, and device function should all be examined. In the physiologic blood path, patient volume status, pneumothorax, hemothorax, cardiac rhythm, vascular thrombus, right-side heart function, PVR, pulmonary vein patency, heart valves, intraventricular thrombus, mechanical heart defect, heart recovery, cardiac tamponade, and high afterload states can all result in inadequate pump support. The ability to recognize, resolve, and communicate these conditions is crucial to the patient's survival.

In this case study, several scenarios are possible:

- The patient may have primary arrhythmias that transiently reduce the right-side output and cause the pump to have a suction event.
- The pump may have migrated farther into the ventricle, causing the arrhythmias.
- The patient may have worsening right-side HF, reducing LV volume.
- The patient may be experiencing hypovolemia related to procedural or anticoagulation complications.
- The pump setting could be too high for the available right-side heart output.

This very common device condition demonstrates the challenges in caring for patients with artificial circulation.

PREP KIT

Ready for Review

- Mechanical circulatory support (MCS) encompasses all mechanical interventions aimed at augmenting or replacing the native cardiac output from the heart. It is also referred to as mechanically assisted circulation, mechanical circulatory systems, and ventricular assist devices.
- IABP therapy involves use of a balloon connected to a pump via a catheter that has been inserted into the aorta to provide temporary assistance to a failing heart.
- IABP therapy is an advanced skill. Important responsibilities of the CCTP include securing the patient to prevent movement of the balloon and ensuring that all equipment has the necessary power supply to continue operating during transport.
- In IABP therapy, a balloon connected to a pump via a catheter is inserted into the aorta to provide temporary assistance to a failing heart. The catheter containing the intra-aortic balloon (IAB) is typically threaded into the descending aorta through the femoral artery.
- The balloon is connected to a console to shuttle helium gas, inflating the balloon at the onset of diastole and deflating it just before systole (ventricular ejection). An ECG machine determines when the balloon should be inflated and deflated.
- Inflation and deflation are timed to the cardiac cycle, resulting in significant augmentation of flow to the coronary and renal arteries during diastole (increased supply) and substantially reduced afterload during systole (decreased demand).
- One of the CCTP’s main roles in transporting a patient receiving IABP therapy is to ensure proper timing by reading the patient’s ECG and pressure waveforms and by continuously monitoring the patient’s condition and all devices, modifying their timing if

necessary. Other CCTP responsibilities include securing the patient to prevent movement of the balloon and ensuring that all equipment has the necessary power supply.

- Each IABP console allows the operator to control the volume of gas shuttled back and forth to the balloon with each counterpulsation cycle. This control is also referred to as augmentation or balloon volume.
- Inflation and deflation of the IAB can be set to trigger based on the ECG, pressure changes, a pacemaker, an internally preprogrammed rate, or combinations of these factors. The most reliable basis is the ECG. The provider caring for the patient chooses the trigger best suited to the patient.
- Pressure waveforms are one of the main variables evaluated to determine the effectiveness of IABP therapy. The dicrotic notch, a slight bump in the aortic pressure waveform that signals the onset of diastole, occurs during isovolumetric relaxation as the valves bulge under the pressure of the blood from the aorta and then spring back slightly.
- The IABP device can pump in several modes, called assist ratios or IABP frequency. IABP waveform evaluation is usually easiest with a 1:2 assist ratio, which allows for comparison of the pressure waves of the unassisted cycle with those of the assisted cycle. In this mode, every other contraction is augmented by the balloon pump.
- When evaluating a waveform in the 1:2 mode, the peaks created by the inflation of the IAB are usually the highest pressure peaks and are referred to as the diastolic augmentation waveforms. The pressure waveform that follows is referred to as the assisted systole waveform because the deflation of the IAB assists the ventricle in ejecting blood. The third pressure waveform is referred to as the unassisted systole waveform because the balloon pump is not moving and the waveform reflects what would normally occur without IABP intervention.

- To evaluate for correct IABP timing, the pressure peaks, slopes, and inflation and deflation points of each of these pressure waveforms must be evaluated in a systematic manner:
    - Identify systole and diastole of each pressure waveform.
    - Identify diastolic augmentation, assisted systole, and unassisted systole.
    - Identify and evaluate the point of inflation.
    - Identify and evaluate the end-diastolic dip in pressure created by balloon deflation.
    - Evaluate the slope of diastolic augmentation pressure and the slope of assisted systole.
    - Evaluate the diastolic augmentation peak pressure.
    - Compare the peak pressure of assisted systole with the peak pressure of unassisted systole.
- Early inflation is reflected on the waveform by a shortened normal pressure decrease that follows diastole or as an opened *V,* and with a lessened slope on the diastolic augmentation waveform. Early inflation can force the premature closure of the aortic valves, decrease the stroke volume, and damage the aortic valve.
- Late inflation causes little harm but does not maximize the benefits of IABP therapy. Early deflation also results in the benefits of IABP therapy not being fully realized.
- Late deflation, which can be extremely detrimental to the patient, is characterized by a widened appearance of the diastolic augmentation waveform base and a prolonged rate of rise in the assisted systolic waveform. Late deflation worsens myocardial ischemia and needs to be avoided.
- IABP therapy reduces cardiac work and myocardial oxygen consumption and improves peripheral perfusion in patients with a variety of conditions and those undergoing cardiovascular and surgical procedures.
- Patient assessment parameters useful for evaluating the effectiveness of IABP therapy include vital signs, oxygenation,

urine output, peripheral perfusion, central nervous system (mentation), and overall general condition of the patient.

- If the femoral artery is used as the insertion site, the CCTP should assess and document the presence of the distal pulses and CRT in the extremity used, and compare the pulses and CRT with those in the other leg. The CCTP should splint the knee to prevent excessive movement of the leg. The sudden loss of pulses or CRT could signal that the IAB is occluding the femoral artery, causing ischemia in the limb. Medical control should be notified immediately.
- Patients receiving IABP therapy are candidates for transport in ground ambulances or in fixed- or rotary-wing aircraft. Some issues to consider when using these vehicles include space and weight constraints, battery life and vehicle power supply, and loading, unloading, and securing the pump in the vehicle.
- Many IABPs are capable of operating on 110 V to 120 V of alternating-current power or 24 V of direct-current power, although the latter may require an adapter cable. Ensuring a match between IABP power requirements and the available power supply in the transport vehicle is crucial.
- After the IABP is placed in the transport vehicle, it is critical to secure the pump so that it remains stable for safe operation throughout transport.
- Temporary circulatory support may be provided with a continuous-flow pump. This kind of device, which consists of an axial-flow pump mounted on a catheter connected to a bedside console, is inserted like an IABP through the femoral artery.
- Extracorporeal membrane oxygenation (ECMO) is a temporizing mechanism of extracorporeal gas exchange with or without hemodynamic support. ECMO is not curative; rather, it is a supportive therapy for presumed reversible respiratory and/or cardiac failure and is a keystone of one of the following strategies: bridge to recovery, bridge to transplantation, destination therapy, or bridge to decision.

- Cannulation sites and circuit configurations vary depending on the patient and intended type of support. Common nomenclature describes the ECMO circuit configuration and support type by a combination of the letters.
    - In venovenous-ECMO (VV-ECMO) configurations, blood is drained from the venous circulation, passes through the circuit where gas exchange occurs, and is returned as oxygenated and decarboxylated blood to the venous system.
    - In venoarterial-ECMO (VA-ECMO) configurations, blood is drained from the venous circulation, passes through the circuit where gas exchange occurs, and is returned as oxygenated and decarboxylated blood to the arterial system.
    - Veno-veno-arterial-ECMO (VVA-ECMO) and veno-arterio-venous-ECMO (VAV-ECMO) support respiratory and cardiac function without the differential hypoxemia that may occur during VA-ECMO, albeit at the expense of added circuit complexity.
- A basic ECMO circuit is composed of the vascular cannulas, circuit tubing, pump, heater–cooler, and oxygenator. ECMO circuits vary in configuration and may include pressure and blood flow monitors, bubble detectors, continuous arterial and venous oxyhemoglobin saturation monitors, circuit access sites, and an emergency arterial–venous bridge.
- Patients undergoing ECMO therapy receive systemic anticoagulative therapy to both protect the major organs from thromboembolism and maintain the patency of the ECMO circuit.
- The ECMO circuit and cannulas require continual monitoring of their integrity and patency. A thorough, methodical approach for assessment of all components, connections, and securing points will aid in the early identification of potential issues.
- Venous oxygen saturation and serum lactate levels provide insights into the adequacy of systemic perfusion. Pressure monitoring can help providers detect early or acute dysfunction in the ECMO circuit and suggest clinical changes in the patient.

While additional pressures can be monitored, the four pressures that are typically assessed are P_{vein} (venous pressure), P_{art} (arterial pressure), P_{int} (oxygenator inlet pressure), and Δp (differential pressure of P_{int} and P_{art}).

- Documentation for patients receiving ECMO therapy will vary by institution, but should at a minimum include hourly notation of flow, rpm, monitored circuit pressures, trending of the preferred coagulation study, and anticoagulation dose, along with circuit and cannulation site assessments.
- ECMO-related complications that the CCTP must be prepared to troubleshoot may relate to hypoxemia (eg, hemolysis, pulmonary edema and left ventricular distention, limb ischemia, insufficient flow, recirculation, north–south syndrome) and circuit disruptions (eg, oxygenator dysfunction, air entrainment, circuit rupture, pump failure, and inadvertent decannulation).
- A microaxial continuous-flow pump is a means of temporary circulatory support that consists of an axial-flow pump mounted on a catheter connected to a bedside console; this catheter is inserted like an IABP through the femoral artery. The most commonly used microaxial continuous-flow pumps used in the United States are Impella heart pumps.
- The Impella system includes a catheter that functions in conjunction with an automated Impella controller and purge fluid infusion pump. There are several different Impella catheters. The Impella 2.5, Impella CP with SmartAssist, Impella 5.0, Impella 5.5 with SmartAssist, and Impella LD are all left-side heart devices; the Impella RP is a right-side heart device.
- The automated Impella controller allows for management and monitoring of pump operation and catheter position via multiple parameters: performance level, Impella flow, placement signal, and motor current.
- Transport of the patient with the Impella system requires the transport team to be equipped, at a minimum, to continue the current level of patient hemodynamic support and monitoring in

place at the referring facility. A thorough assessment of the patient and catheter position should be performed prior to equipment exchange or manipulation of support.

- Common alarms encountered when transporting a patient with an Impella system include the suction alarm, purge alarm, and air in purge system alarm. The CCTP must recognize the meaning of these alarms and respond appropriately.
- Left ventricular assist devices (LVADs) enable circulatory function in patients with heart failure (HF), either indefinitely or until heart transplantation can occur.
- An LVAD may serve as a bridge to recovery until the native heart recovers its pumping ability, as a bridge to transplantation to prolong the patient’s life until a heart transplant can be secured, or as destination therapy when long-term MCS is needed for a patient with HF who does not meet the heart transplantation criteria.
- Generally, the patient with an LVAD and/or their caregiver will have substantial knowledge of the device. While these individuals may be excellent sources of information, the provider should also know how to troubleshoot the device, know which emergency interventions can and cannot be performed, and be aware of how to contact designated LVAD support staff.
- All patients with LVADs receive anticoagulation therapies and, therefore, are more susceptible to traumatic hemorrhage and bleeding from all causes.
- Adverse events related to LVADs can include bleeding (typically in the gastrointestinal tract), LVAD infections (typically involving the driveline), stroke, arrhythmias, thrombosis, right-side HF, and device malfunction. CCTPs should be prepared to recognize these problems and must ensure their actions do not precipitate a chain of adverse events.
- Patients with LVADs are susceptible to depression and anxiety due to the significant changes in lifestyle and possible discomforts associated with the device.

- LVAD pump parameters that CCTPs should be prepared to monitor, and potentially troubleshoot, include conditions relating to pump flow, rpm, power, and pulsatility index.

Vital Vocabulary

aortic regurgitation Backward flow of blood through the aortic valve from the aorta into the left ventricle.

assist ratios Settings on the intra-aortic balloon pump that allow the operator to determine how often the pump inflates the balloon.

assisted systole The pressure waveform that follows the diastolic augmentation peak.

bridge to recovery (BTR) A treatment objective in which a left ventricular assist device is implanted in a patient as mechanical circulatory support until the native heart recovers its pumping ability.

bridge to transplantation (BTT) A treatment objective in which a left ventricular assist device is implanted in a patient as mechanical circulatory support to prolong life until a heart transplant can be secured.

central lumen The lumen or port of the intra-aortic balloon catheter used to guide initial catheter insertion and to monitor arterial pressure during operation.

destination therapy (DT) A treatment objective in which a left ventricular assist device is implanted in a patient with heart failure as ongoing mechanical circulatory support because the patient does not meet the heart transplantation criteria.

diastolic augmentation The increase in aortic pressure during diastole that the intra-aortic balloon inflation produces, thereby improving coronary and peripheral perfusion; it may be thought of as a “second systole.”

extracorporeal membrane oxygenation (ECMO) A temporizing mechanism of extracorporeal gas exchange with or without hemodynamic support; also referred to as extracorporeal life support.

gas lumen The lumen or port of the intra-aortic balloon catheter that carries helium between the intra-aortic balloon and the pump console to inflate and deflate the balloon.

intra-aortic balloon pump (IABP) therapy A procedure involving insertion of a balloon into the descending thoracic aorta and its connection to a pump via a catheter; this therapy helps to increase blood flow to the coronary arteries during diastole (inflation) and decrease the afterload of blood from the left ventricle (deflation).

left ventricular assist device (LVAD) A means of mechanical circulatory support in which a pump is implanted in the patient’s chest to help circulate blood from the left ventricle of the heart to the rest of the body.

mechanical circulatory support (MCS) Mechanical interventions aimed at augmenting or replacing the native cardiac output from the heart; also called mechanically assisted circulation, mechanical circulatory systems, and ventricular assist devices.

microaxial continuous-flow pump A means of temporary circulatory support that consists of an axial-flow pump mounted on a catheter that is typically inserted through the femoral artery and connected to a bedside console.

pulsatility index (PI) A measurement of a left ventricular assist device's pumping power; calculated as follows: Pulsatililty index = (Maximum pump power – Minimum pump power)/Average pump power.

relative contraindication A condition that makes a particular treatment or procedure somewhat inadvisable but does not completely rule it out.

suction event An emergency in which tissue occludes the inlet of the pump in a mechanical circulatory support device.

timing In the context of intra-aortic balloon pump therapy, a method for coordinating the intra-aortic balloon inflation–deflation cycle with the cardiac cycle (inflation during diastole and deflation synchronous with systole).

unassisted systole Pressure waveform reflecting what would normally occur without intra-aortic balloon pump assistance.

CHAPTER 17

Gastrointestinal and Genitourinary Emergencies

Lorenzo Albala, MD
Sean M. Kivlehan, MD, MPH

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the anatomy and physiology of the gastrointestinal system, including the alimentary canal and accessory organs (pp 896–901).
2. Describe the anatomy and physiology of the genitourinary system, including the urinary system and the male and female reproductive systems (pp 901–906).
3. Differentiate between upper and lower gastrointestinal bleeding (pp 920–922).
4. Describe the pathologies related to common disorders of the gastrointestinal system, including peptic ulcers, gastritis, esophageal varices, Mallory-Weiss syndrome, diverticulitis, appendicitis, inflammatory bowel disease, ulcerative colitis, and Crohn disease (pp 908–915).
5. Assess the signs and symptoms of the various gastrointestinal conditions (pp 924–926).
6. Describe laboratory results as they relate to specific gastrointestinal system disorders (pp 925–926).
7. Describe the management of the various gastrointestinal conditions (p 926).
8. Describe gastrointestinal system imaging, including endoscopy, colonoscopy, angiography, and scintigraphy, as well as other in-hospital assessment and management techniques (pp 918–919).
9. Describe the pathologies related to diseases of the gastrointestinal system, including intestinal obstructions, ileus, liver disease, cholecystitis and choledocholithiasis, and pancreatitis (pp 922–938).
10. Describe the pathologies related to common disorders of the genitourinary system, including kidney injury, renal failure, urinary tract infections, testicular torsion, nephrolithiasis, penile fracture, and priapism (pp 940–948).
11. Assess the signs and symptoms of the various genitourinary pathologies (pp 940–948).

12. Describe the management of the various genitourinary pathologies (pp 940–948).
13. Describe laboratory results as they relate to specific disorders of the genitourinary system (pp 942–946).
14. Describe various gastrointestinal- and genitourinary-related feeding and drainage tubes, including their assessment, maintenance, and potential complications (pp 948–957).
15. Discuss flight considerations for patients with feeding or drainage tubes (p 957).
16. Explain acid–base physiology (pp 957–958).
17. Examine how the body’s chemical buffer system mitigates acid–base imbalances (pp 958–959).
18. Describe how to interpret blood gas samples (pp 960–962).
19. Describe the pathologies related to acid–base imbalances, their clinical features, and their treatment (pp 959, 964–965).
20. Discuss flight considerations for patients with gastrointestinal and genitourinary tract complications (p 966).

Introduction

The gastrointestinal (GI) and genitourinary (GU) systems are exquisitely tuned to process the body’s waste and alimentation. Both systems are composed of a vast network of specialized cells for absorption and filtering, neutralization of infections and toxins, and excretion of waste. Harmony between the two systems maintains stability in the body’s internal environment, a state known as **homeostasis**. Unfortunately, various disease processes and injuries can cause significant impairment to either organ system, significantly limiting the body’s ability to maintain homeostasis. These conditions require a careful assessment and diagnosis followed by appropriate management—a process that is inherently difficult because the signs and symptoms that accompany abdominal conditions are often vague and nonspecific. Without prompt treatment, patients with GI or GU pathologies may experience pain, altered mental status, and shock. Critical care transport professionals (CCTPs) must possess a detailed understanding of GI and GU anatomy, physiology, and diagnostics to successfully manage a patient with a GI/GU condition, as well as any complications that may arise during transport of such a patient.

Anatomy and Physiology

Gastrointestinal System

Intricately complex yet stunningly efficient, the GI system consists of an interconnected network of organs and ducts devoted to the digestion of food and the extraction of its nutritional content. The alimentary canal (also referred to as the GI tract) consists of the mouth, pharynx, esophagus, stomach, small intestine, and large intestine; food travels through these structures and finally exits the body via the rectum. The alimentary canal is lined with continuous specialized tissues that allow for the absorption of digested nutrients from food while maintaining a protective barrier against waste and microorganisms. During mechanical and chemical digestion, food turns into the basic molecular building blocks required by the body's cells. Enzymes that aid in digestion are secreted by a variety of accessory organs, including the salivary glands, liver, gallbladder, and pancreas.

Unnecessary side products from the digestion process are either defecated or excreted by the GU system. Cooperative action by the liver and kidneys allows for safe passage of toxic nitrogen-containing compounds during their exit from the body.

GI Tract Tissues

Although the alimentary canal contains numerous specialized cells and tissues, four layers are seen almost continuously from the esophagus to the rectum: the mucosa, the submucosa, the muscularis externa, and the serosa **FIGURE 17-1**.

Description

The **mucosa** forms the first and innermost layer that is exposed to the lumen, or cavity, of the canal. This moist mucous membrane consists of three sublayers: a thin layer of columnar epithelium interspersed with mucus-secreting goblet cells (surface epithelium), a loose areolar connective tissue harboring capillaries and lymph nodes (lamina propria), and a layer of smooth muscle that forms endless folds and wrinkles in the tissues underneath to maximize absorption of nutrients (muscularis mucosae).

The **submucosa** consists of connective tissue just beyond the mucosa. Blood and lymphatic vessels weave through this layer to connect the vessels of the mucosa to systemic circulation. The submucosal nerve plexus resides here, permitting innervation of smooth muscle and secretory cells. The elastic character of the submucosa allows for restoration of a structure's original shape after it is distended by the presence of food.

The **muscularis externa** forms the muscle bulk of the GI tract. It is divided into two layers of smooth muscle: an inner circular layer and an outer longitudinal layer. The arrangement of these two layers facilitates segmentation and peristalsis, the body's mechanical digestion methods (discussed in the next section).

The **serosa** (commonly referred to as the visceral peritoneum) consists of areolar connective tissue lined with simple squamous epithelium, called the mesothelium. The serosa is meant to be a protective layer, covering all peritoneal GI organs. In certain situations, this peritoneum can become inflamed, a condition referred to as **peritonitis**.

Alimentary Canal

The alimentary canal maintains a chemical environment that aids in the digestion of food, yet does not alter the environment of the rest of the body **FIGURE 17-2**.

Description

Mechanical digestion begins the moment food enters the oral cavity. Mastication (chewing) tears and grinds food into more manageable chunks. The increase in the surface area of the food that results from this process facilitates chemical digestion, which begins when food within the mouth is moistened with saliva. Saliva contains salivary amylase, an enzyme that breaks down starch.

The food bolus, once sufficiently chewed, is pushed into the oropharynx by the tongue in preparation for swallowing. Once initiated, swallowing becomes a largely involuntary process, albeit a fairly complex one. More than 22 muscles are used to block off the nasopharynx with the soft palate and uvula, the larynx with the epiglottis, and the mouth with the tongue, thereby forcing food into the esophagus.

The esophagus is a 10-inch (25-cm) tube of muscle that connects the oropharynx to the stomach. The muscles of the esophagus receive a substantial flow of blood via several arteries, with this blood then being returned through a large network of veins in the submucosa. **Peristalsis**, a series of wavelike contractions of the esophagus, carries food to the stomach in less than 8 seconds. The bolus of food arrives in the stomach via the gastroesophageal sphincter, which closes following the passage of a bolus, thereby preventing backflow.

The stomach stores food while continuing chemical and mechanical digestion through the actions of a variety of enzymes and muscles. Bound superiorly by the esophagus and inferiorly by the small intestine, the stomach is a 6- to 10-inch (15- to 25-cm) J-shaped widening of the GI tract **FIGURE 17-3**. When this organ is full, it can expand to have a volume as large as 4 L. Mechanical digestion is continued and completed by the stomach muscles. A bolus of food enters the stomach at the cardia region via the cardiac sphincter. The stomach terminates at the pyloric sphincter, which regulates the exit of materials from it. The stomach is unique in that it is the only portion of the GI tract to contain a third muscle layer, which is arranged oblique to the inner and outer layers. The extra muscles aid in the mechanical digestion of food while it is in the stomach.

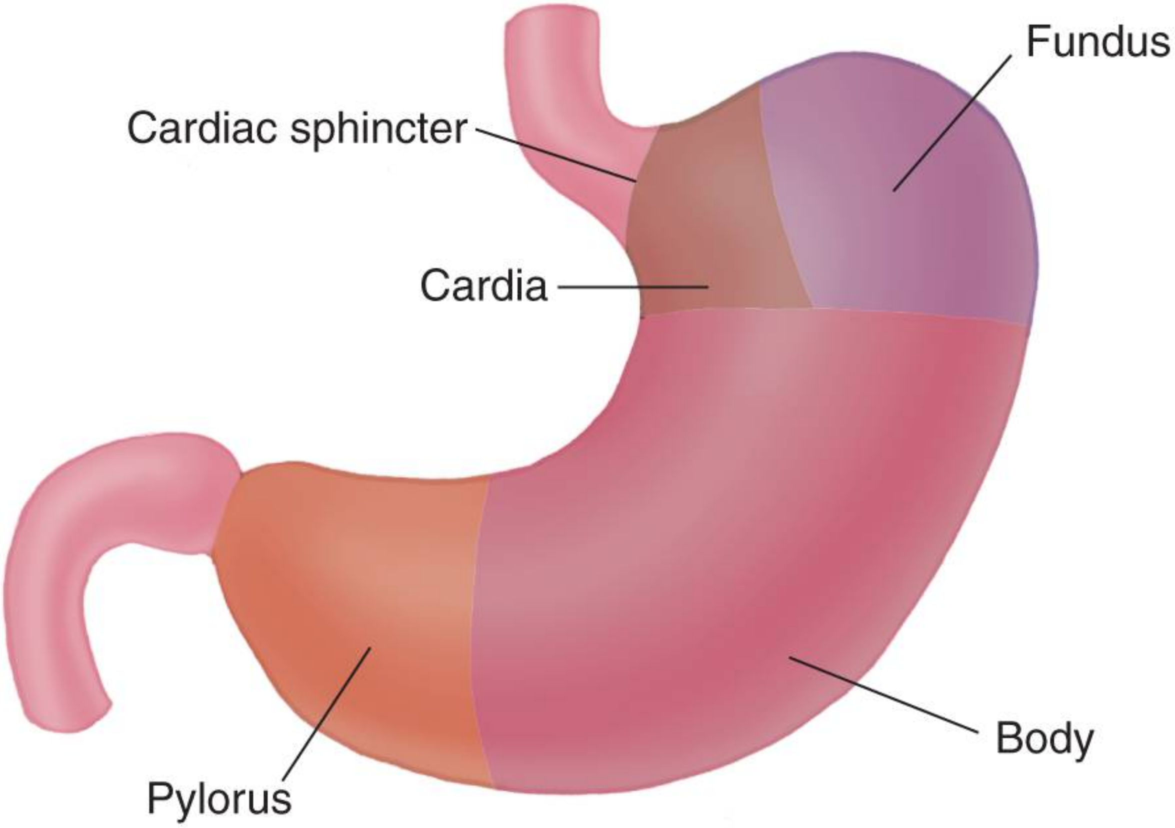

FIGURE 17-3 Anatomy of the stomach.

© Jones & Bartlett Learning.

Throughout the stomach, glands consisting of specialized mucous neck cells secrete various substances, collectively termed gastric juice. Components of this juice include mucin, hydrochloric acid, intrinsic factor, pepsinogen, and lipases, all of which aid in the digestive process. The end product of the stomach’s chemical and mechanical digestion is chyme, a liquid mixture of partially digested food, gastric juice, and water that is ready for entry into the small intestine.

The small intestine is a long, 1-inch-wide (2.5-cm-wide) canal that twists throughout all four quadrants of the abdomen. Digestion is completed in this organ, and the bulk of nutrient absorption takes place here. The small intestine is divided into three areas: the duodenum, the jejunum, and the ileum. The superior mesenteric artery provides the blood supply to all three of these regions via its vast network of vessels in the mesentery.

Chyme begins its journey through the small intestine at the duodenum. The small intestine also receives bile and pancreatic juice at the duodenum, both of which aid in further digestion.

In the large intestine, chyme is transformed into feces, which is then expelled from the alimentary canal via the rectum and anus. The large intestine is divided into six regions: cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum **FIGURE 17-4**. The more proximal sections (cecum, ascending colon, and transverse colon) are the sites of water and electrolyte absorption, whereas the latter areas (descending colon, sigmoid, and rectum) provide storage for feces and muscles for its propulsion to the rectum.

Description

Chyme is deposited into the cecum from the ileum of the small intestine, beginning the final leg of its journey through the body. The appendix is attached to the cecum, about 1 inch (2.5 cm) inferior to the ileocecal valve. The most common location for the base of the appendix, where it attaches to the cecum, can be located topographically on the abdomen of the patient at the McBurney point **FIGURE 17-5**. From the cecum, chyme is pushed upward into the ascending colon, where water and electrolytes are reclaimed from unusable end products of digestion. Anaerobic bacteria residing here prepare a significant amount of vitamins B and K for absorption as well.

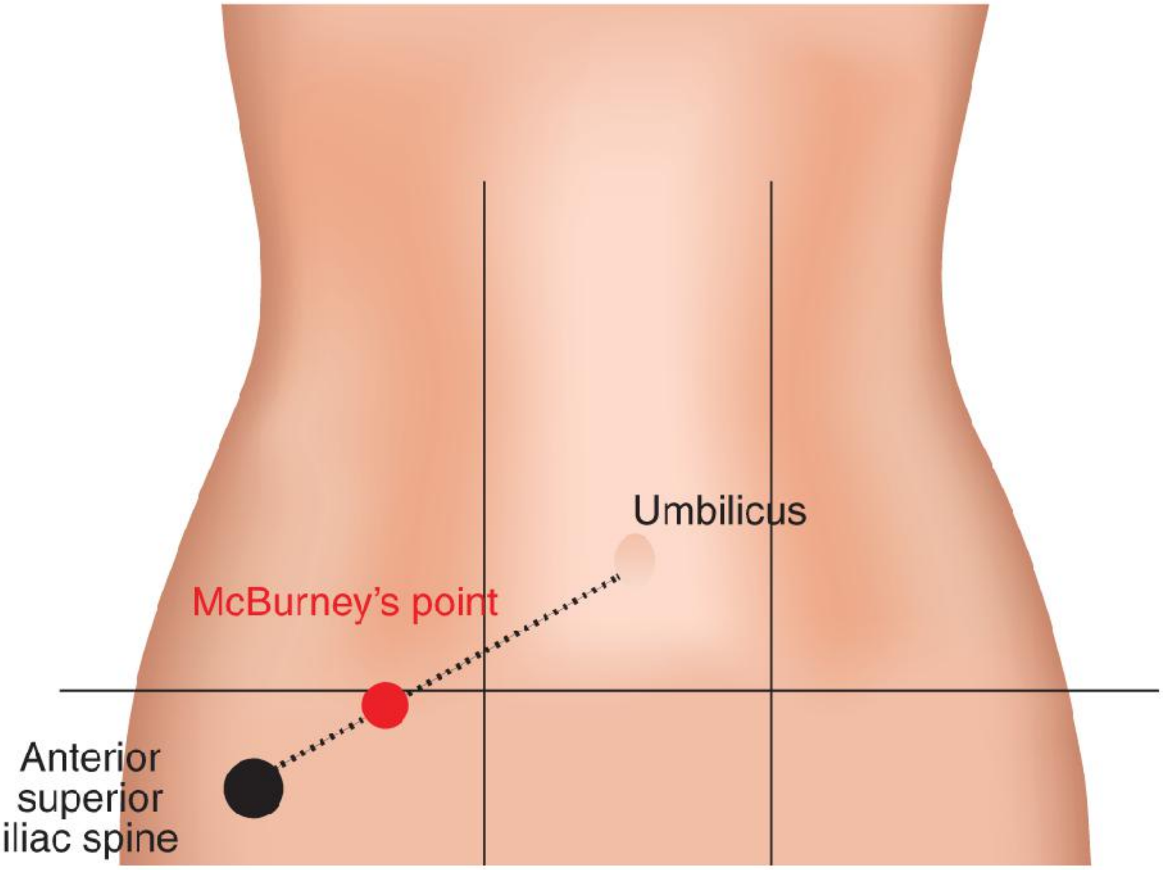

FIGURE 17-5 Location of the McBurney point.

Description

The transverse colon proceeds across the abdomen until it makes an inferior turn, after which it becomes the descending colon. These two sections function mainly to store feces. The muscularis externa begins to thicken gradually along the length of these areas to assist with the movement of the increasingly compact feces.

The sigmoid colon starts at the level of the pelvis, taking an S-shaped path into the rectum, a 5-inch (13-cm) muscular tube. A defecation reflex is stimulated by the stretching of the rectal wall due to feces buildup, resulting in the opening of the internal anal sphincter. The external anal sphincter is voluntarily controlled.

Accessory Organs

The alimentary canal does not accomplish the feat of digestion on its own. Like any other body system, it receives support from several accessory organs—namely, the salivary glands, liver, gallbladder, and pancreas.

Three pairs of extrinsic salivary glands are found in the tissues surrounding the oral cavity; they secrete saliva to initiate the chemical digestive process **FIGURE 17-6**. This saliva not only provides enzymes that break down starches in food, but also moistens food to facilitate bolus formation. In addition, it cleanses the mouth. Tiny internal salivary glands are located throughout the oral cavity as well, supplementing the secretions of the extrinsic glands. Secretion of saliva by all of these glands is amplified by stimulation of the salivatory nuclei in the brainstem, whether that stimulation takes the form of the sight, smell, or taste of food.

Description

The liver is the largest solid organ in the body, as well as the most vascular, containing more than one-fifth of a person's total blood volume at any given time **FIGURE 17-7**. It serves as a central terminal through which all blood returning to the central circulation from the alimentary canal must pass. The liver performs three functions critical to the body's functioning: metabolic regulation, hematologic regulation, and bile production. Although the liver dominates the right upper quadrant of the abdomen, the majority of its bulk actually rests within the right thoracic cage; this position allows the ribs to protect the liver from trauma to some extent. During forceful exhalation, the liver rises as high as the fourth intercostal space just below the right nipple, and sprawls past the midline approaching the left nipple. Normally, the liver can be palpated inferior to the right ribs during inspiration only, as it remains within the thoracic cage during expiration.

Description

The porta hepatis forms the space between the stomach, duodenum, and liver, and provides the gateway into the liver for the hepatic portal vein, hepatic artery, and common hepatic duct. These three vessels bifurcate on entry, separating the liver into right and left functional lobes that are distinct from the superficial lobes. The hepatic portal vein and hepatic artery continue to branch out until they eventually form the liver’s functional unit, a lobule. Inside a lobule, the incoming oxygen- and nutrient-rich blood is drained into liver sinusoids, where it comes in direct contact with hepatocytes and Kupffer cells. Hepatocytes, which are among the most metabolically active cells in the body, account for 80% of the cells in the liver. They are incredibly proficient cells: They synthesize and store proteins and phospholipids, produce and secrete bile, transform fundamental molecules into macromolecules (such as glucose into glycogen), store fat-soluble vitamins, and detoxify and process exogenous and endogenous substances (eg, turning nitrogen-containing wastes into urea). Kupffer cells are macrophages that reside in the sinusoids; they engulf bacteria and spent erythrocytes. The liver sinusoids drain blood into central veins that will eventually fuse to form the hepatic vein and ultimately the inferior vena cava, which returns the blood to the systemic circulation.

Bile is a fat emulsifier required for the digestion of fats within the small intestine. Bile secreted by the liver drains into the common hepatic duct, which passes it into the common bile duct. From there, the bile is either sent directly into the duodenum or stored in the gallbladder. The body produces as much as 2 pints (1 L) of bile per day, and excess amounts are stored in the gallbladder, a small muscular sac located just inferior to the right lobe of the liver and protruding from under the liver at the level of the ninth rib. Water and ions are reabsorbed here, concentrating the bile. Bile enters and exits the gallbladder via the cystic duct, which connects to the common hepatic duct, or bile duct, allowing transit to the duodenum.

Pancreatic juice is a solution containing digestive enzymes secreted by the pancreas, a retroperitoneal organ found in the left upper quadrant. The head of the pancreas is framed by the duodenum, its body runs along the inferior aspect of the stomach, and finally its tail reaches the spleen. The release of pancreatic juice is an exocrine function, but the pancreas also has an equally important endocrine function—the production of insulin and glucagon.

At a microscopic level, the pancreas contains millions of acini lobules, each consisting of a ring of secretory cells around an intralobular duct through which the secreted pancreatic juice drains into the main pancreatic duct. This duct empties into the common bile duct; thus, it shares a pathway to the duodenum with bile. Zymogen granules within the acinar cells secrete trypsinogen, chymotrypsinogen, procarboxypeptidase, pancreatic amylase, lipases, and nucleases, which mix with water and bicarbonate to make up pancreatic juice. Enzymes such as trypsin within the duodenum convert the various proteins to their active forms in a process driven by the surrounding pH, preventing inappropriate self-digestion by these powerful enzymes. Collectively, these enzymes account for most of the digestion that occurs in the small intestine. The bicarbonate balances the acidity of newly arriving chyme from the stomach, and the water serves to further dilute the chyme prior to its absorption.

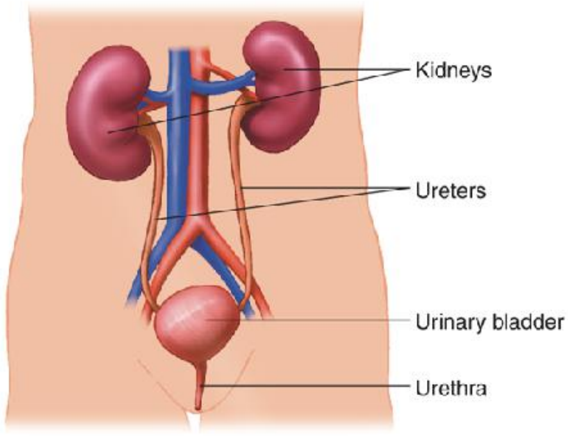
The pancreas can be adversely affected by mutations in the CFTR gene, which are commonly associated with the condition known as cystic fibrosis. While cystic fibrosis’s detrimental effects on the lungs are well known, some of the most common symptoms of the disease actually involve the digestive tract and, in particular, the pancreas. The thick mucus associated with cystic fibrosis can obstruct the flow of pancreatic enzymes necessary for proper digestion. Scarring and damage to the pancreas may occur as well, leading to islet cell dysfunction and insulin-deficient diabetes mellitus.

Scattered throughout the acini lobules are islets of Langerhans, cells of the pancreas that secrete a variety of endocrine hormones directly into the bloodstream. Numerous insulin-secreting beta cells in the pancreas work alongside alpha cells, which produce glucagon, and delta cells, which produce somatostatin. Insulin facilitates the absorption of free glucose molecules into cells from the bloodstream. Glucagon stimulates glycogen production in the liver during times of glucose surplus. Somatostatin has numerous regulatory functions, including the inhibition of overall pancreatic function.

Genitourinary System

Urinary System

The many nutrients and ions absorbed into the bloodstream by the tissues of the alimentary canal serve a useful purpose in the body for only a finite time. Eventually, because of metabolic reactions, the molecules and atoms are either incorporated into useful products or left over as waste. The renal system provides a path for these wastes to leave the body **FIGURE 17-8**. The kidneys continuously filter blood, managing its volume, maintaining an appropriate balance between acids and bases, and discarding toxins and excessive amounts of substances by producing urine. The kidneys are extremely vascular; approximately one-fourth of the total cardiac output passes through them every minute. Although the kidneys filter approximately 200 L of fluid per day, only about 2 L is actually excreted. The remainder of the urinary system—the ureters, urinary bladder, and urethra—provides for transport and storage of urine during its journey out of the body.



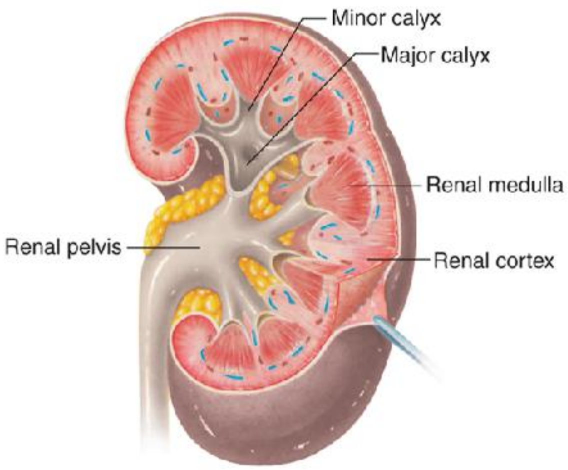


FIGURE 17-8 Organs of the urinary system.

© Jones & Bartlett Learning.

Description

The kidneys are a pair of retroperitoneal organs that stretch from the T12 to the L3 vertebrae. The position of the liver forces the right kidney into a slightly lower location than the left kidney's position. The adrenal glands, seated on top of the kidneys, are important in endocrine function because they produce catecholamines in response to stress. Although the 12th ribs provide the kidneys with some protection, they remain relatively vulnerable to external trauma. Three layers of tissue provide some measure of protection from such trauma:

- The renal fascia, the outermost layer, consists of dense fibrous connective tissue that encloses the kidneys and adrenal glands, securing them to the abdominal walls.
- A layer of adipose tissue directly beneath the renal fascia provides a cushion from sudden movements.
- The renal capsule, which is made up of more fibrous connective tissue, coats the kidney itself.

Internally, the tissues of the kidneys can be divided into three zones: the outermost renal cortex, the medulla, and the innermost pelvis. The functional unit of the kidney, the nephron, lies across the border between the cortex and medulla. The renal pelvis is an open space that allows for both pooling of urine and its drainage into the ureter. **FIGURE 17-9** and **FIGURE 17-10** show the nephrons of the kidney and the glomerulus, respectively.

© Jones & Bartlett Learning.

Description

On entering the kidney, the renal artery immediately branches off into vessels of decreasing diameter. They culminate in the afferent arterioles that feed blood into the glomerulus, a meshwork of capillaries contained within the glomerular capsule. This meshwork forms the interface between arterial and venous vasculature, where an interplay between the arteriovenous (AV) pressure differential and delicate structures specialized for filtration create a gradient for fluid and solutes. These filtration structures include accessory cells (podocytes) that prevent the passage of certain macromolecules, while pores in the capillary walls prevent erythrocyte and large-protein passage into the filtrate. The filtrate is funneled from the glomerular capsule to the proximal convoluted tubule. As a consequence of this arrangement, the kidneys are extremely sensitive to vascular pressures: Any decrease in systemic arterial pressure or increased venous congestion reduces the pressure gradient and, therefore, the amount of blood the renal tissues "see." Beyond its formidable filtration function, the urinary system informs and modifies the body's vascular tone and volume status.

Once filtered, the blood exits the glomerulus by way of the efferent arterioles, which then divide into the peritubular capillaries. The filtrate-carrying proximal convoluted tubule descends into the renal medulla, and subsequently straightens out. Within the medulla, it turns 180° to take a parallel path back to the cortex. This portion of the tubule, called the loop of Henle, is where the bulk of ion filtration and absorption occurs. A series of osmotic gradients between the lumen of the loop of Henle and the medullary tissues result in ion exchange as material moves along this pathway, which plays a significant role in the dilution and concentration of urine. Loop diuretics such as furosemide act on the loop of Henle, inhibiting solute transport systems (which reduces their reabsorption of ions) and triggering increased excretion of water.

The loop of Henle becomes the distal convoluted tubule upon its reentry to the cortex, and eventually makes its way to the collecting duct. The peritubular capillaries, which are entangled with the proximal and distal convoluted tubules as well as the loop of Henle, reabsorb water and solutes not meant to be excreted.

The effectiveness of the glomerulus in filtering blood provides a benchmark for the evaluation of overall renal function, termed the **glomerular filtration rate (GFR)**. The normal GFR in an adult is approximately 125 mL/min. Various pathologies can affect the GFR, and a decrease in this rate will result in several metabolic alterations. Inulin is freely filtered in the kidneys, and inulin clearance is the gold-standard test for measuring the GFR in patients. However, measurement of inulin clearance entails a rigorous process that is impractical for day-to-day clinical application. As a result, numerous equations have been developed to estimate the GFR.

One such test frequently employed in assessing glomerular function, and therefore renal function, is creatinine clearance. **Creatinine** is the metabolized form of creatine that is eliminated through the urine. The normal elimination rate for men is 95 to 145 mL/min, and the normal rate for women is 75 to 115 mL/min. In practice, creatinine clearance is used to assess the GFR, even though it does not provide an exact measurement (it generally underestimates the GFR by 10% to 20%). A patient with low creatinine clearance is assumed to have a low GFR, and vice versa.

Specialized cells known as juxtaglomerular cells are present in the walls of the afferent and efferent arterioles. These cells secrete renin in response to stretching of the vessel walls. Renin is an enzyme that plays an important role in the activation of the renin-angiotensin-aldosterone system, which helps regulate blood pressure (BP). In between the afferent and efferent arterioles and the distal convoluted tubule is another class of specialized cells, the macula densa. These cells detect chemical changes in the concentration of the filtrate. This region, which is collectively referred to as the juxtaglomerular apparatus, is present in every nephron.

The sensors of the juxtaglomerular apparatus are the key element of a finely tuned feedback loop programmed to optimize **renal perfusion pressure**. As in all other organs, blood flow to the kidneys is dictated by renal perfusion pressure divided by resistance to flow through that organ. The renal perfusion pressure is the pressure differential between the arterial input and venous output. As discussed later in this chapter, any significant decrease in the pressure gradient negatively affects GFR and blood flow to the renal tissues.

The ureters, a pair of long muscular tubes running to the urinary bladder, are essentially a continuation of the renal pelvis. Through gravity and peristalsis, urine is jettisoned into the bladder. The ureters enter the base of the bladder at a region called the trigone. The ureters' distal segment tunnels through the multiple layers of bladder muscle, limiting backflow as the bladder wall stretches. The urethra also drains the bladder from the trigone, so there are three connections to the bladder at this point (hence the prefix "tri"). The bladder is a hollow, muscular organ located directly posterior to the pubic symphysis. Its layers of muscle are impressively elastic, with a urine storage capacity of more than 17 ounces (0.5 L), and can be palpated in the lower abdomen when distended.

The urethra is another muscular tube, about 8 inches (20 cm) long in men and 1 to 2 inches (3 to 5 cm) long in women. It drains the bladder, providing the route by which urine exits from the body **FIGURE 17-11**.

Description

Male Reproductive System

The purpose of the male reproductive system is to generate sperm and provide a means for its delivery to a fertilizable egg in the female partner. The testes are the principal male reproductive organ; they consist of a pair of ovoid structures, suspended external to the body in a sac of skin called the scrotum **FIGURE 17-12**. This housing outside the body means that sperm production occurs in an environment at 91°F (33°C), considerably cooler than the overall body temperature. Each testis is covered by two distinct layers of tissue: the outer tunica vaginalis, which folds over itself, and the inner tunica albuginea, a tough fibrous capsule that protects the testis and penetrates it. The tunica albuginea divides the testis into hundreds of lobules. Inside these lobules, sperm are created in the seminiferous tubules. The testes receive their blood supply from the testicular arteries and drain into their complementary veins. These blood vessels branch from the abdominal aorta, and travel with autonomic nerve fibers to and from the testes through the spermatic cord.

Description

Newly made sperm drain into the efferent ductules and then move to the epididymis, where they will mature. When stimulated by smooth-muscle contractions arising from ejaculation, sperm are forced into the ductus deferens (vas deferens), which exits the scrotum via the spermatic cord. The ductus deferens travels anterior to the pubic bone and then posterior to the bladder, finally joining with the seminal vesicle duct to form the ejaculatory duct. The two ejaculatory ducts pass through the prostate gland and terminate in the urethra, which serves as an exit route for both sperm and urine in the male.

The male reproductive system also includes five accessory glands: a pair of seminal vesicles, a pair of bulbourethral glands, and the prostate gland. Taken collectively, the secretions of the seminal vesicles, bulbourethral glands, prostate gland, and sperm are termed semen. Semen is the transport medium by which sperm enters the female's reproductive system, permitting the sperm's introduction to an egg and potential fertilization.

The final leg of the semen's journey in the male sends it through the penis, which also contains the urethra. Three vascular spaces made up of erectile tissue surround the urethra within the penis: the corpus spongiosum and a pair of corpora cavernosa. When the male is sexually stimulated, the parasympathetic system triggers release of nitric oxide, a potent vasodilator. As the three compartments become engorged, the normally flaccid penis becomes erect. Malfunction in this system can lead to priapism, as discussed later in this chapter.

Female Reproductive System

The female reproductive system produces and stores eggs, preparing them for fertilization by a sperm. In addition, the uterus of the female provides a home for the developing embryo during gestation. The main female reproductive organs are the ovaries, which are located on either side of the uterus within the peritoneum **FIGURE 17-13**.

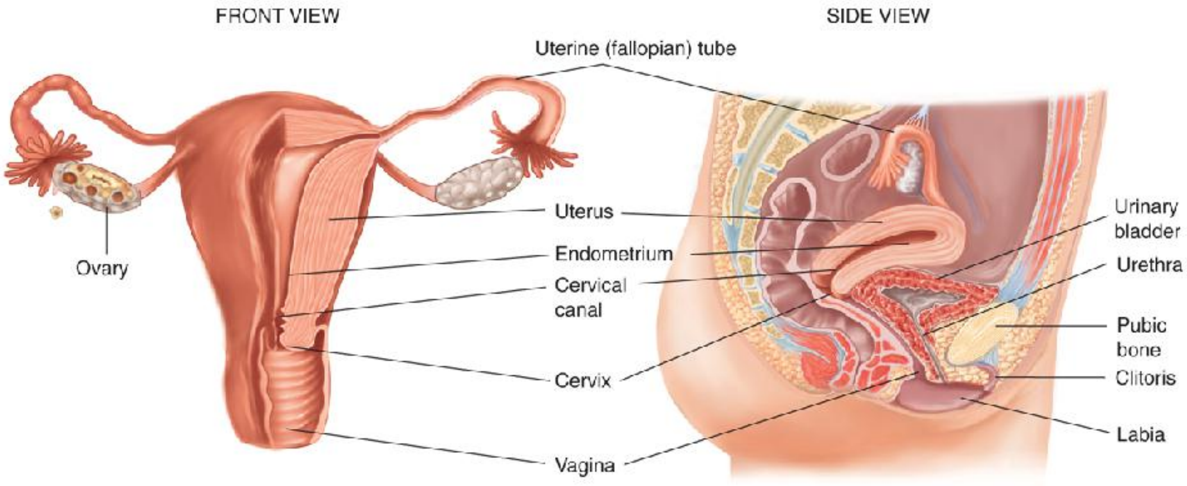

FIGURE 17-13 The female reproductive system.

© Jones & Bartlett Learning.

Description

Ovarian follicles within the ovary contain oocytes, or immature eggs. During the process of ovulation, an oocyte is dispelled from a vesicular follicle and the ovary each month in a female of childbearing age. This oocyte enters one of the paired fallopian (uterine) tubes, originating adjacent to the ovaries and terminating in the uterus. Cilia within the fallopian tubes project the oocyte toward the uterus. When the oocyte is fertilized and becomes implanted outside of the uterus, it can lead to a potential obstetric emergency called ectopic pregnancy.

Situated between the bladder and the rectum, the uterus is a hollow muscular organ in which embryonic development occurs following fertilization. The uterus is divided into four portions: the superior most fundus, the central body, the inferior isthmus, and the cervix. The cervix is a cylindrical structure approximately 2 to 3 cm in length with a narrow central canal that connects the uterus to the vagina. The uterus consists of three thick tissue layers: the outermost perimetrium, the muscular myometrium, and the inner endometrium. A developing embryo will lodge within the endometrium for the duration of gestation. The uterine arteries provide the uterus with its significant blood supply through a network of arcuate arteries. Every month a major portion of the endometrium of the uterus is shed and regenerated through the menstrual (uterine) cycle unless fertilization has occurred. Collectively, these structures are exquisitely sensitive to a cycle of hormones dedicated to achieving pregnancy, and they undergo impressive change and growth during pregnancy and labor.

The vagina connects the uterus to the external vaginal orifice. During intercourse, the vagina receives semen from the penis, guiding it into the uterus for possible fertilization. The vagina also serves as the birth canal during childbirth. In females, the urethra exits the body just anterior to the vagina, separating the urinary and reproductive tracts.

Anatomy of the female reproductive system is discussed further in Chapter 22, *Obstetric and Gynecologic Emergencies*.

Special Populations

Injuries and conditions that involve the GI and GU systems may be more difficult to diagnose in pregnant patients, individuals with psychiatric illness, and children. In the last two populations, communication is a significant barrier to localizing the disease or injury. For example, a person with decompensated schizophrenia may be unable to clearly describe pain symptoms or chronologic history. The same is true for very young children, and infants may be fussy or crying inconsolably. Obtaining collateral information (eg, trauma, eating history) and a careful exam, while keeping more common pathologies in mind (eg, appendicitis in children) will make care less daunting.

Morbidly obese patients and older adults present an additional challenge, especially in the diagnosis of abdominal emergencies. Older adults, especially those with altered mental status, may exhibit less rebound and guarding. Often, advanced imaging via computed tomography (CT) is the safer diagnostic approach in older adults and people with morbid obesity.

In pregnant patients, as the gravid uterus expands, the abdominal viscera stretches to accommodate the growing uterus. As the viscera stretches, the pain perceived by the pregnant patient may indeed be referred pain. For example, a large left lower lobe pneumonia may be “felt” by the pregnant woman in the middle of the abdomen. Keep in mind that pregnant females may develop the same abdominal problems as the general population—from appendicitis to cholecystitis to gastroenteritis. Because of the anatomic changes they have experienced, it may be difficult for females in later stages of pregnancy to pinpoint the exact source of their pain.

The abdominal/uterine area of a pregnant patient should never be painful. During your assessment of a pregnant patient, palpate the uterus and abdominal region very gently. Severe tenderness may reflect a uterine/placental or abdominal injury. During the perinatal period, it may also reflect chorioamnionitis and infection of the amniotic membranes.

Such an infection can lead to profound and overwhelming sepsis in the pregnant patient. CCTPs should ask every patient in their second or third trimester the following four questions as part of the history:

- Have you noticed leakage of fluid from your vagina?
- Are you having vaginal bleeding?
- Are you having (frequent) contractions?
- Do you feel the baby moving? (Movement is expected only after 20 weeks' gestation.)

Conditions Affecting the Alimentary Canal

Epidemiology and Pathophysiology

The GI tract contains a multitude of structures operating under harsh conditions. A variety of pathologies can disrupt its normal activities, many of which reach the clinical level only after a breach of the protective layers of intestinal mucosa occurs. Disturbance of the mucosa can expose the mesenteric vasculature, nerves, lymph, and inner tissue layers to the extreme changes in pH levels and digestive enzymes found in the GI lumen. This exposure accounts for the common symptoms of GI abnormalities: abdominal pain (most common presenting symptom), tenderness, and bleeding. Depending on the etiology of GI bleeding, this symptom may lead to significant morbidity and mortality.

GI bleeding is classified into two categories based on the location of the bleeding: upper or lower GI bleeding. The source of upper GI bleeding is proximal to the **ligament of Treitz**, which supports the junction of the duodenum and the jejunum. Any bleeding distal to this location is referred to as lower GI bleeding. The disease process, diagnostics, and management all vary depending on the origin of the bleed.

Acute upper GI bleeding is more common than lower GI bleeding, but the two forms share a comparable mortality rate of 6% to 10% per year, with rates increasing with age and underlying comorbidities. Extrinsic factors such as alcohol and tobacco use, diet, and use of nonsteroidal anti-inflammatory drugs (NSAIDs) increase the incidence of upper GI bleeding. Recent GI surgery and critical illness increase the risk as well. In patients younger than 60 years without significant comorbidities, the mortality rate is less than 0.1%. The amount of bleeding can vary greatly depending on the etiology, from microscopic amounts of blood to massive hemorrhage.

Severe lower GI bleeding requiring hospital admission is relatively rare, accounting for fewer than 1% of hospital admissions in the

United States. Differentiating between upper and lower GI bleeding can prove difficult, however, because the majority of GI bleeding presents with rectal bleeding of some kind. Lower GI bleeding may present with bright red blood at the rectum. Most upper GI bleeding presents with dark or tarry stools from digested blood products, but brisk upper GI bleeding may also present with bright red blood at the rectum. Endoscopy is the ideal method of locating the bleeding source, although some other imaging techniques can identify active, clinically significant bleeds.

Conditions Affecting the Upper GI Tract

Gastritis

Inflammation of the gastric mucosa, termed **gastritis**, is a common precursor to upper GI bleeding. Causes of gastric inflammation vary widely and can be broadly separated into acute or chronic pathologies. Common causes of gastritis are listed in **TABLE 17-1**.

TABLE 17-1 Causes of Gastritis

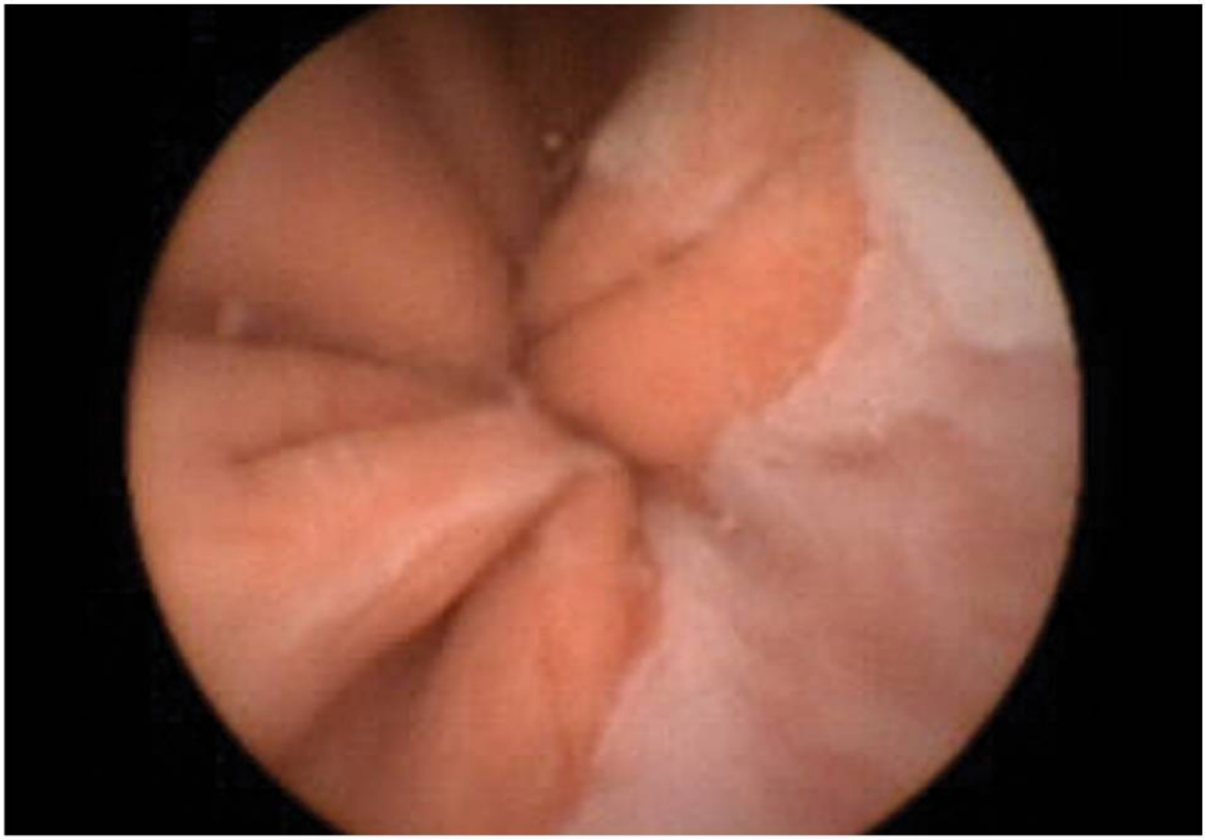
Alcohol abuse
Helicobacter pylori infection
Atrophic gastritis
Reactive gastritis
Radiation exposure

© Jones & Bartlett Learning.

Mucin-producing cells, bicarbonate secretion, prostaglandins, and rapid cell turnover are some of the protective mechanisms that mitigate the corrosive effects of hydrochloric acid and pepsin in the digestive system. When this equilibrium is disturbed, inflammation and necrosis of the epithelial cells occurs because of the ensuing immune system response **FIGURE 17-14**. This process is generally consistent no matter what actually precipitates acute gastritis.



A

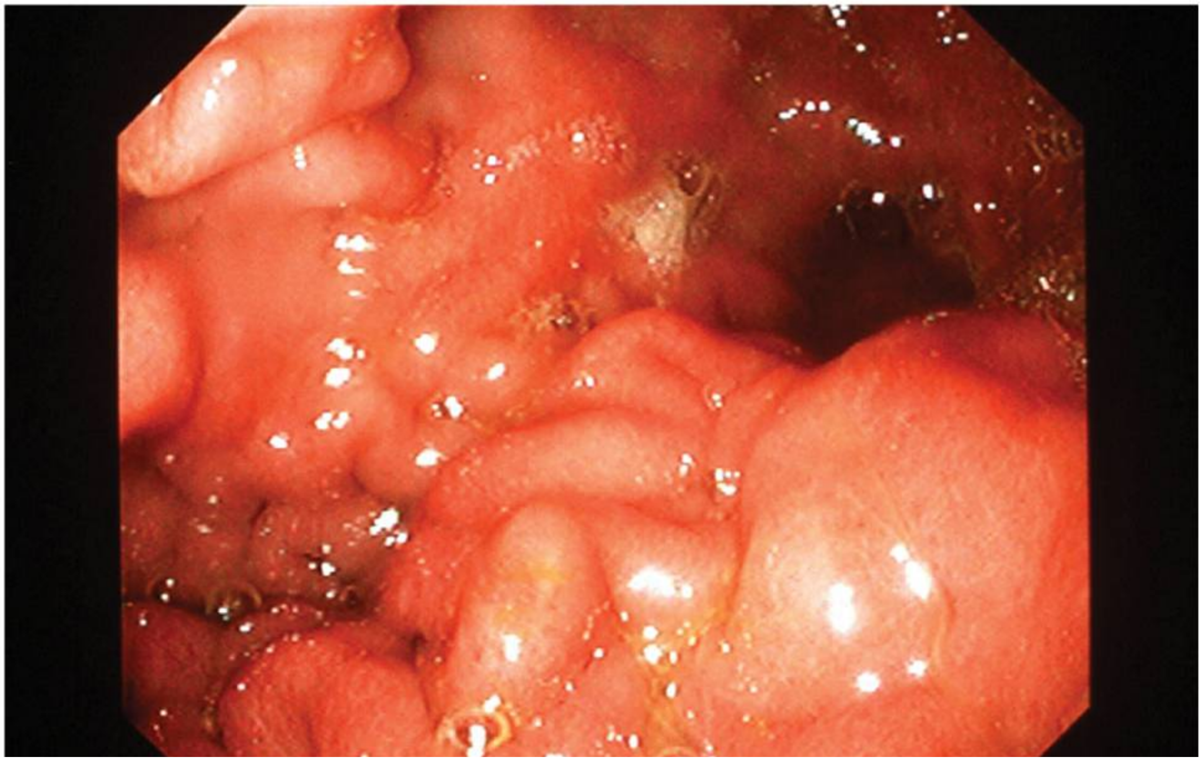


FIGURE 17-14 A. Normal stomach. **B.** Gastritis.

A: © David M. Martin, MD/Science Source; **B:** © Jean-Francois Rey/Science Source.

Upper GI bleeding may occur in patients with acute gastritis who experience rapid onset of mucosal inflammation or sudden breakdown of protective barriers. Ingestion of corrosive chemicals, for example, can cause chemical burns leading to sloughing of the gastric mucosa, which is often associated with pain and nausea. Depending on the chemical, these burns can cause significant inflammation and subsequent necrosis of tissues, accompanied by varying degrees of hemorrhage. Chemical burns commonly affect external perioral tissues, the oral cavity, and the tongue as well. Some household cleaners, and most industrial cleaners, are potent enough to trigger this process. Blood in the vomit may be bright red or dark brown. In fact, digested blood products in the vomit may be described as coffee-ground emesis.

Many cases of acute gastritis are actually an exacerbation of a chronic GI condition. For example, extensive tissue damage is found in as many as 20% of people with chronic alcoholism. Minor bleeding occurs frequently and often goes unnoticed in these patients, but an episode of severe hemorrhage can occur suddenly after even a small intake of alcohol. The bacterium ***Helicobacter pylori*** causes acute gastritis during the primary period of infection. The initial immune system response to the invading bacteria triggers an inflammation of the mucosal tissues, which is self-limiting and typically resolves within 11 to 14 days. Occasionally, the bacteria are fully eliminated from the body following the immune defense. Patients who develop ongoing symptoms of gastritis may need testing and antimicrobial treatment for *H pylori*.

Conditions involving long-term histopathologic changes to the gastric lining, such as chronic atrophic gastritis, can lead to downstream complications related to malnutrition, such as pernicious anemia. Pernicious anemia is a form of anemia resulting from malabsorption of vitamin B_{12}, an essential building block of red blood cells. Atrophic gastritis has a prevalence of 2% in older adults, but its pathogenesis remains unclear. In some cases, it has been linked to certain autoimmune disorders, as well as *H pylori* infection.

Another common etiology for epigastric discomfort and GI bleeding is **reactive gastritis**, which occurs when the stomach lining is chronically irritated by NSAIDs, alcohol, and bile. Patients undergoing abdominal radiation therapy may experience radiation gastritis, which resembles acute gastroenteritis and usually occurs within days of treatment. Patients with radiation gastritis may develop ulcerations, much as patients with other forms of gastritis do.

Peptic Ulcers

Peptic ulcer is the leading cause of upper GI bleeding **TABLE 17-2**. These ulcers are characterized by an erosion of the mucosal lining of the GI tract in either the stomach (gastric ulcer) or the duodenum (duodenal ulcer). Once that defensive lining becomes disrupted, exposure to the acids and pepsin in the pylorus and duodenum can cause ulceration. An ulceration that is deep enough can penetrate a blood vessel, leading to major or minor bleeding. Continued ulceration can result in perforation of the gastric or duodenal wall, causing intra-abdominal leakage of gastric juices and peritonitis. Finally, scar tissue from past ulcers can cause narrowing or obstruction in the GI tract.

TABLE 17-2 **Causes of Upper and Lower GI Bleeding**

Type of Bleeding	Cause

Type of Bleeding	Cause
Upper GI bleeding	Aortoenteric fistula Peptic ulcers Duodenal ulcers Gastritis Esophageal or gastric varices Gastric malignancy Mallory-Weiss syndrome
Lower GI bleeding	Diverticulosis Angiodysplasia Inflammatory bowel diseases (colitis) Hemorrhoidal bleeding Malignancy

Abbreviation: GI, gastrointestinal

© Jones & Bartlett Learning.

Peptic ulcer disease is common in the United States, with a lifetime prevalence of 5% to 10%. Although psychological stress is commonly considered a contributing factor to ulcer formation, there is a lack of evidence to support this theory.

However, two major risk factors have been identified for peptic ulcers: the presence of *H pylori* and NSAID use. *H pylori* is the most prevalent cause of chronic bacterial infection globally, affecting gastric acid secretion and mucosal defense mechanisms. This pathogen is associated with both gastritis and peptic ulcers, with its presence increasing the likelihood of these conditions when combined with other risk factors **TABLE 17-3**. Patients with *H pylori* infection have a 6- to 10-fold increased incidence of peptic ulcer disease compared to uninfected individuals. A highly motile spirilla bacterium, *H pylori* colonizes the mucosa of the stomach and duodenum **FIGURE 17-15**. Both *H pylori* and NSAIDs such as aspirin and ibuprofen hinder the mucosa's defenses against irritation by inhibiting production of prostaglandins, the hormones that mediate the inflammatory response in tissues. When prostaglandin production is reduced, injury to the mucosal layer goes unchecked, leading to irritation (gastritis) and ulceration. Alcohol and tobacco use have deleterious effects on the mucosal barrier and are independent risk factors for peptic ulcer disease.

Stress-related erosive syndrome is believed to be a frequent cause of peptic ulcers in patients in the intensive care unit (ICU). In fact, endoscopy performed within 72 hours of the onset of illness has shown that 75% to 100% of critically ill patients exhibit gross gastric lesions. Poor mucosal perfusion because of multiple comorbidities, trauma, or burns may be exacerbated by large-volume fluid resuscitation and gut edema, further reducing the efficiency of the mucous barrier. This general decrease in resistance to gastric juice allows numerous shallow ulcers to form throughout the esophagus, stomach, and duodenum. Ulcers associated with severe burns are termed Curling ulcers, whereas those accompanying episodes of increased intracranial pressure are called Cushing ulcers. Preventive use of histamine (H_2)-receptor antagonist or proton pump inhibitor prophylaxis has made these complications relatively rare in recent years. Less common causes of ulcers include hypersecretion of acid into the GI lumen, such as by a tumor, as seen in Zollinger-Ellison syndrome.

Esophageal Disease

Just as erosion of mucosal lining into a blood vessel will lead to GI bleeding, so will the reverse process—swelling of esophageal veins that intrudes into the lumen of the esophagus **FIGURE 17-16**. Such an exposed vein, known as an **esophageal varix**, is susceptible to sudden rupture, resulting in significant hemorrhage. Esophageal varices are the second-most common cause of upper GI bleeding. Mortality following a variceal rupture approaches 30%. Unlike other causes of GI hemorrhage, in which active bleeding typically stops without intervention in most cases, esophageal varices spontaneously stop bleeding only 50% of the time.

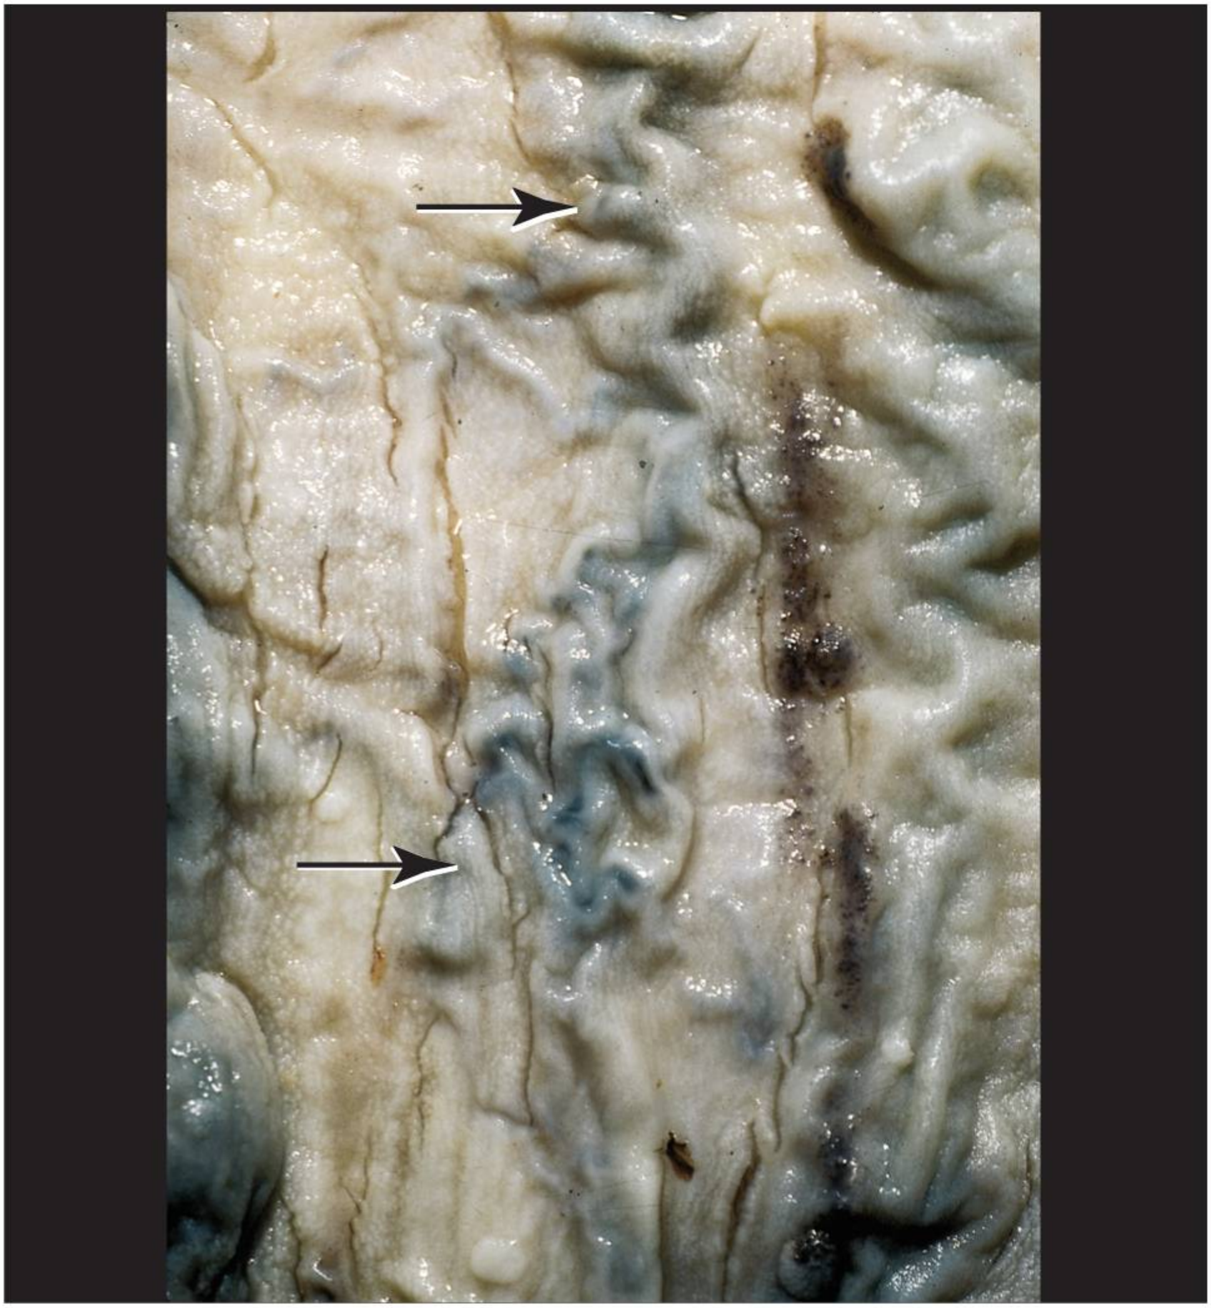

FIGURE 17-16 Mucosal surface of the esophagus illustrating varices, which appear as tortuous elevations of the mucosa (arrows).

Courtesy of Leonard V. Crowley, MD.

Esophagitis is another common etiology of upper GI bleeding. It is typically a result of severe gastroesophageal reflux disease and alcohol abuse, but may also stem from irritation caused by pills (pill esophagitis) or infection.

Varices result from increased venous pressure in the hepatic portal system. When **portal hypertension** occurs, venous blood will use alternative pathways for its return to the vena cava via the **azygos system**. The azygos system drains a portion of the esophageal venous blood, and overuse of this system causes pooling and distention of these veins. The lower portion of the esophagus also drains blood into the left gastric vein, which is adversely affected by hepatic portal hypertension. Minor increases in hepatic portal venous pressure can result in varices, with the risk of rupture growing exponentially as the pressure continues to rise. Although varices can occur anywhere along the esophagus, stomach, and duodenum, ruptures leading to GI hemorrhage most frequently occur at the gastroesophageal junction.

Portal hypertension typically occurs when large swaths of hepatic cellular architecture are disrupted, which tends to result from deposition of scar tissue in cirrhosis. In **cirrhosis**, buildup of fatty acids and chronic destruction of liver tissue and fibrosis progressively obstruct venous blood flow. In the United States, liver cirrhosis is primarily caused by chronic alcohol use or hepatitis C. Patients with cirrhosis may develop classic physical findings, including abdominal ascites, jaundice, and caput medusae.

Mallory-Weiss syndrome involves a longitudinal laceration of the esophageal mucosa, typically in the distal esophagus at the gastroesophageal junction **FIGURE 17-17**. The tear develops as a result of repeated significant changes in local pressure, such as those seen with repeated forceful vomiting. These individuals may notice streaks of bright red blood in their vomitus. More significant bleeding may occur if the patient is on anticoagulant medication or has an underlying coagulopathy. Mallory-Weiss syndrome, which occurs mainly in middle-aged adults, has a mortality of less than 10%. These upper GI bleeds often cease on their own. Comorbidities that increase the likelihood of a tear include hiatal hernias, bulimia, chronic alcohol use, and increasing age.

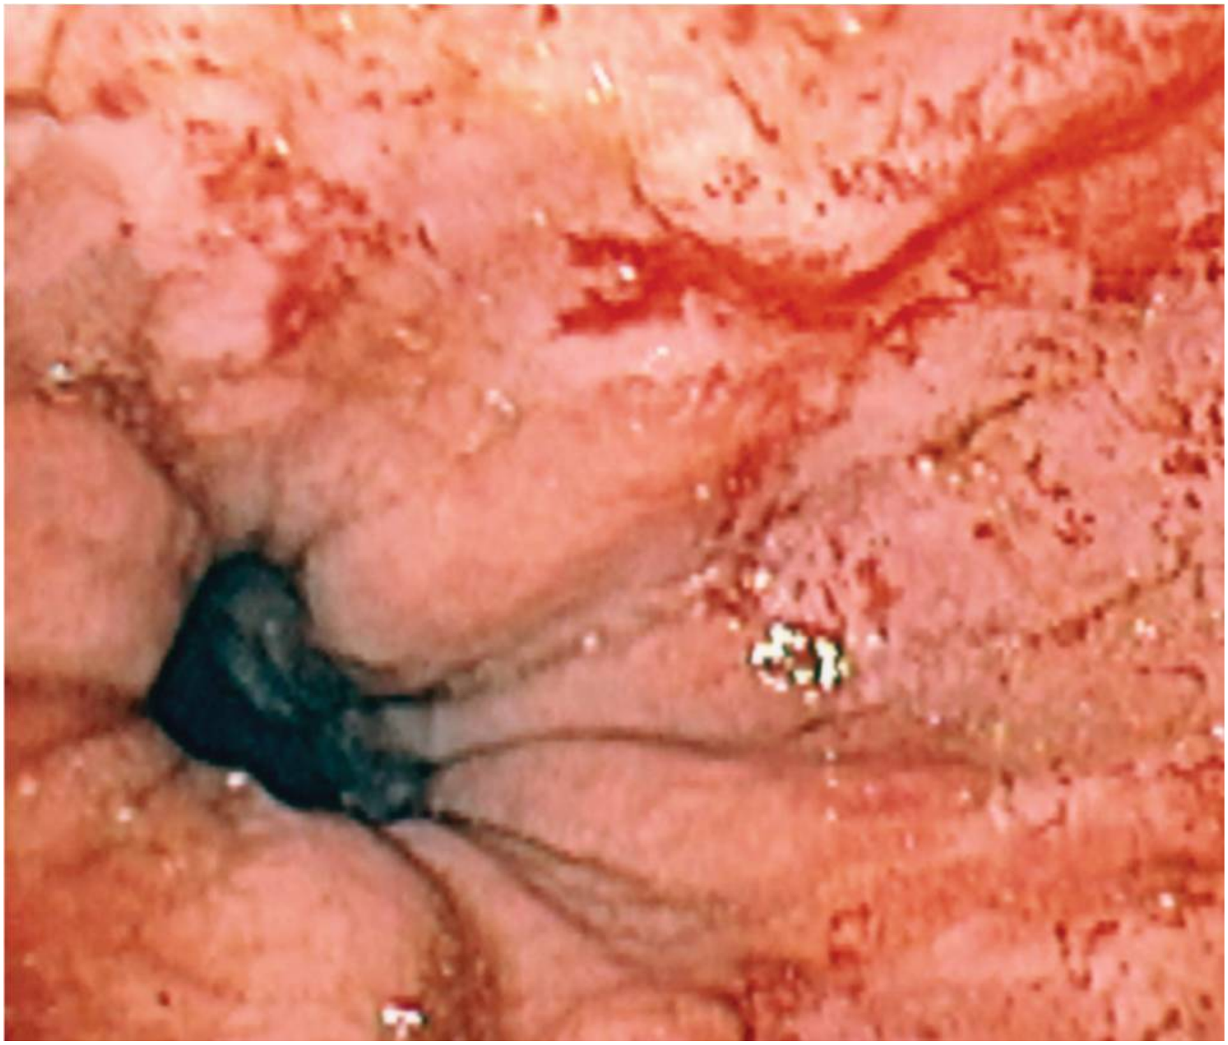

FIGURE 17-17 Mallory-Weiss syndrome.

© David M. Martin, MD/Science Source.

When patients experience particularly forceful vomiting, spontaneous rupture of the esophagus, also known as **Boerhaave syndrome**, may occur. These perforations may also occur as a result of caustic ingestion or pill esophagitis; in approximately one-half of all cases, they are iatrogenic (eg, resulting from endoscopy or stricture dilation). Patients with Boerhaave syndrome can present as quite ill, with severe chest and upper abdominal pain, fever, odynophagia, and shock.

Another cause of esophageal perforation is foreign body ingestion and esophageal impaction. While foreign body ingestion typically occurs in children, it is generally associated with eating in adults (eg, fish and chicken bones, toothpicks). Foreign body ingestion and impaction of food occur more commonly in older adults and individuals with psychiatric illness or alcohol intoxication. They are usually associated with an inability to swallow liquid or solids (dysphagia) and regurgitation. Although most obstructions resolve spontaneously, patients with severe obstruction or with underlying strictures caused by anatomic anomalies or tumors may require endoscopic intervention. Patients with worsening obstruction may develop perforation, pain, and bleeding.

Conditions Affecting the Lower GI Tract

Lower GI bleeding is characterized by bleeding distal to the ligament of Treitz. It can occur in the jejunum, ileum, large intestine, rectum, and anus. Several conditions can cause bleeding, and the severity of such bleeding can vary greatly.

Diverticulosis and Diverticulitis

Diverticulosis is a common disease of the lower GI tract in older adults **FIGURE 17-18**. Diverticula are small outcroppings of the mucosal lining of the large intestine, typically in the descending colon and sigmoid colon **FIGURE 17-19**. These sac-like protrusions are a consequence of strong haustral muscle contractions, which push tissue against a mucosa that weakens with age. Generally painless, diverticula can be found in 50% to 70% of people older than 80 years. Lifestyle risk factors known to increase the incidence of diverticulosis include a low-fiber diet, chronic constipation, lack of physical activity, and smoking.

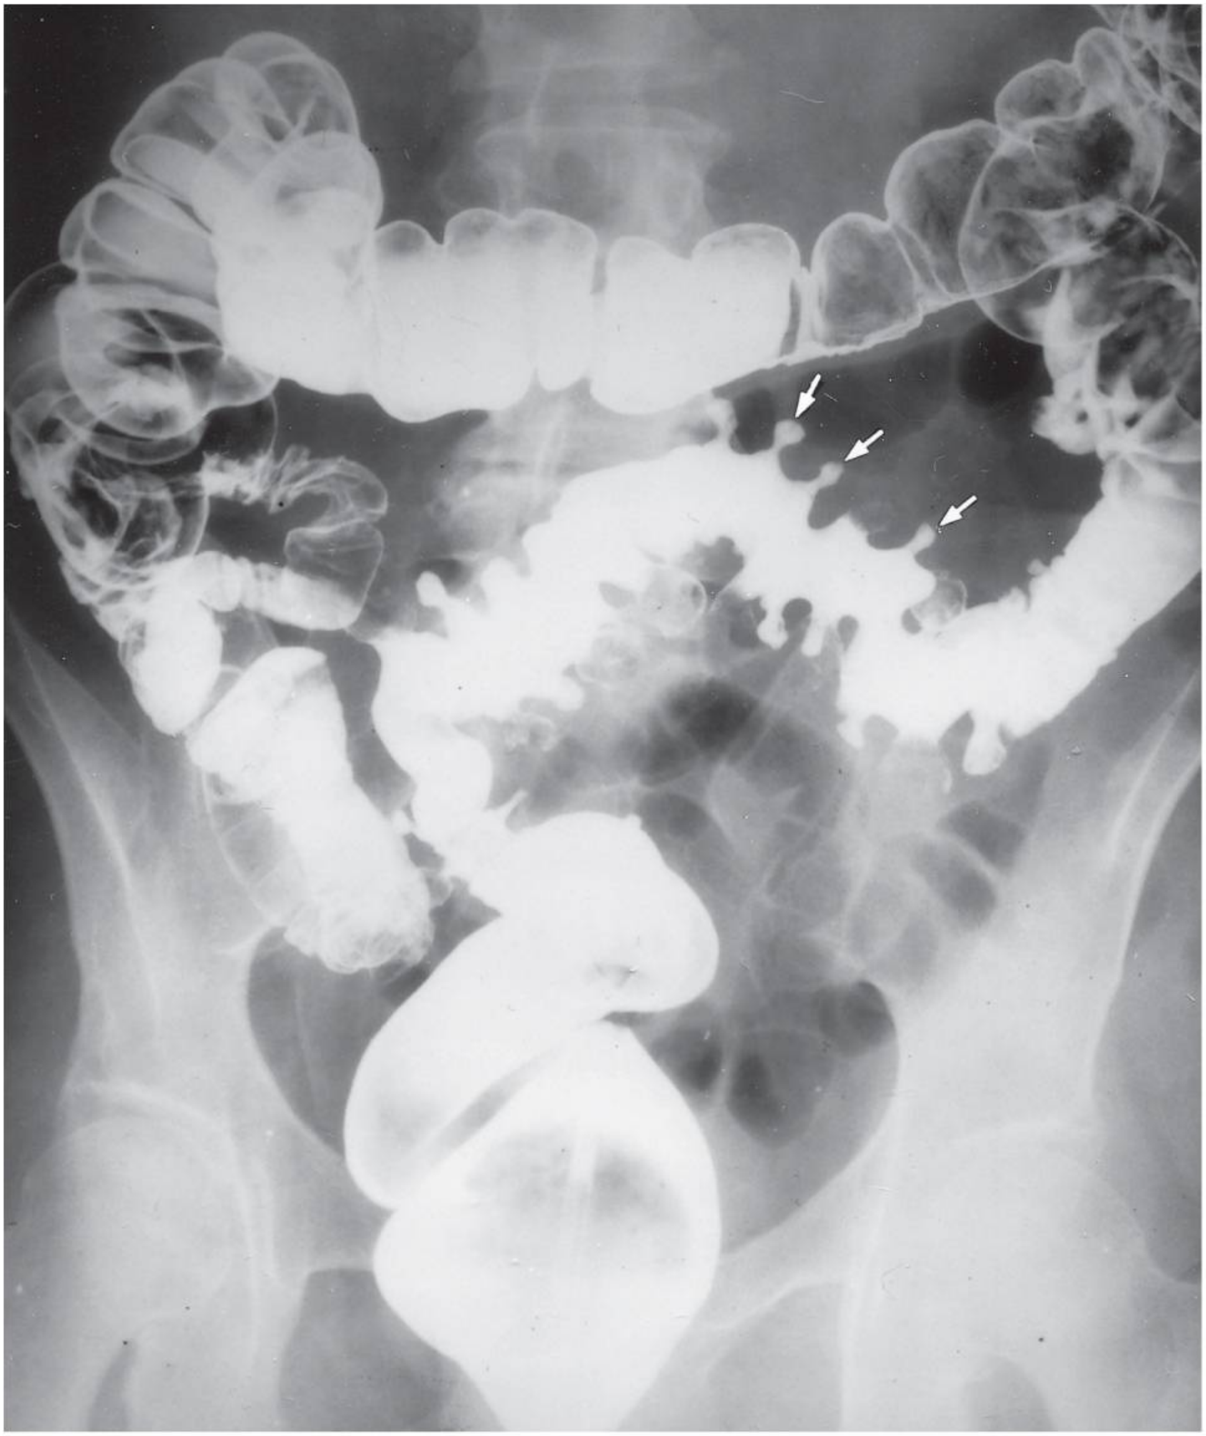

FIGURE 17-19 Diverticula of the colon demonstrated by injection of barium contrast material into the colon (barium enema). Diverticula filled with contrast material appear as projections from the mucosa (arrows).

Courtesy of Leonard V. Crowley, MD.

Diverticulitis, an inflammation of the diverticulum, occurs in as many as 15% of patients with diverticulosis. It is thought to be caused by microscopic or macroscopic perforation of the diverticulum, as a result of focal inflammation. Diverticulitis can be acute or chronic, and can lead to complications such as abscess formation, fistula, or peritonitis. **Diverticular bleeding** occurs in another 15% of patients with diverticulosis, with massive GI bleeding observed in one-third of those cases. Bleeding, which can be venous or arterial, results from structural weakness of the vessel wall as it is stretched into the herniated wall of the diverticulum.

Angiodysplasia

Angiodysplasia is a malformation of submucosal blood vessels in the GI tract **FIGURE 17-20**. Although it can occur anywhere in the alimentary canal, more than three-fourths of all cases present in the cecum and ascending colon. These thin-walled, winding vessels are highly susceptible to rupture. Angiodysplasia is the most common vascular abnormality in the GI tract, and its incidence increases with age. The most common site for angiodysplasia in the GI tract is the colon.

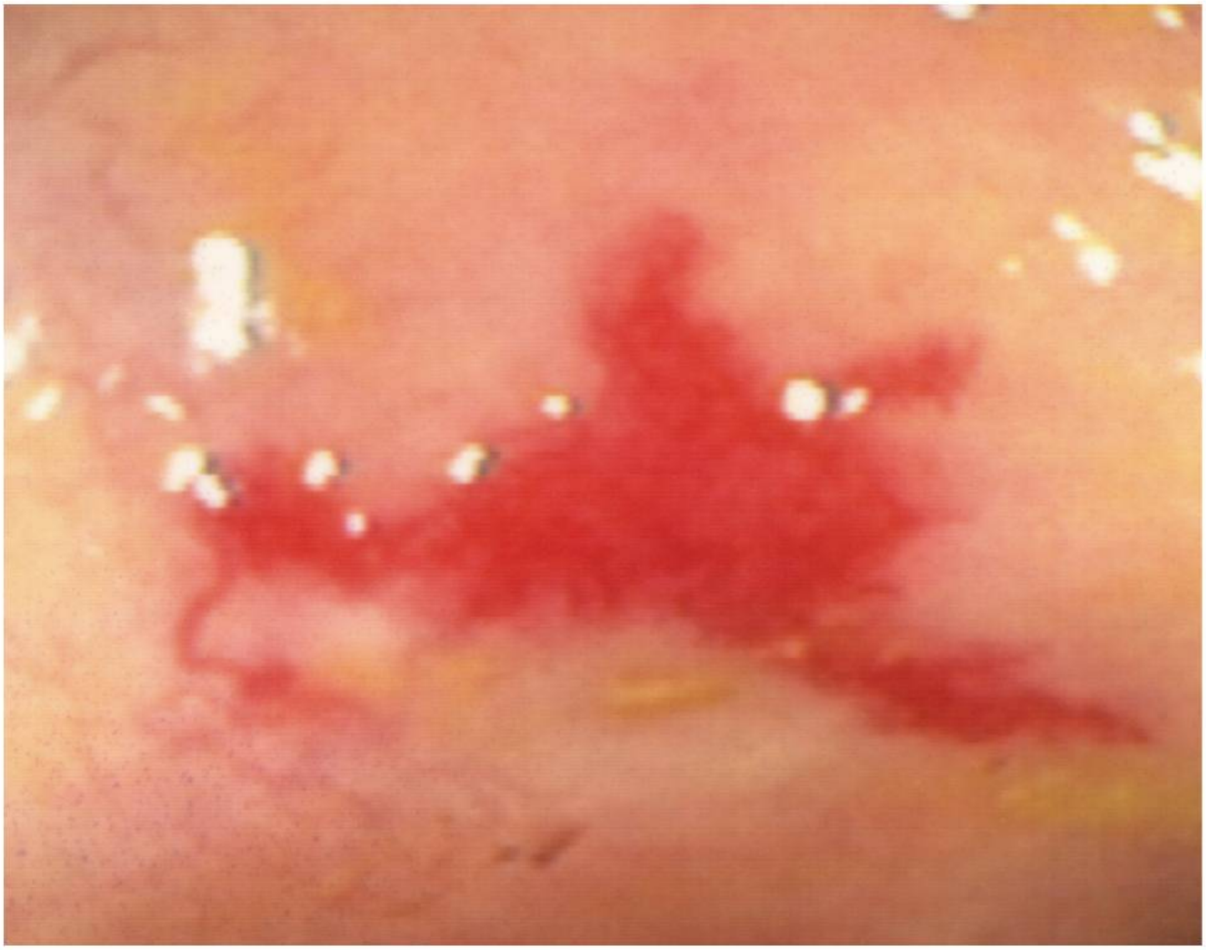

FIGURE 17-20 Angiodysplasia.

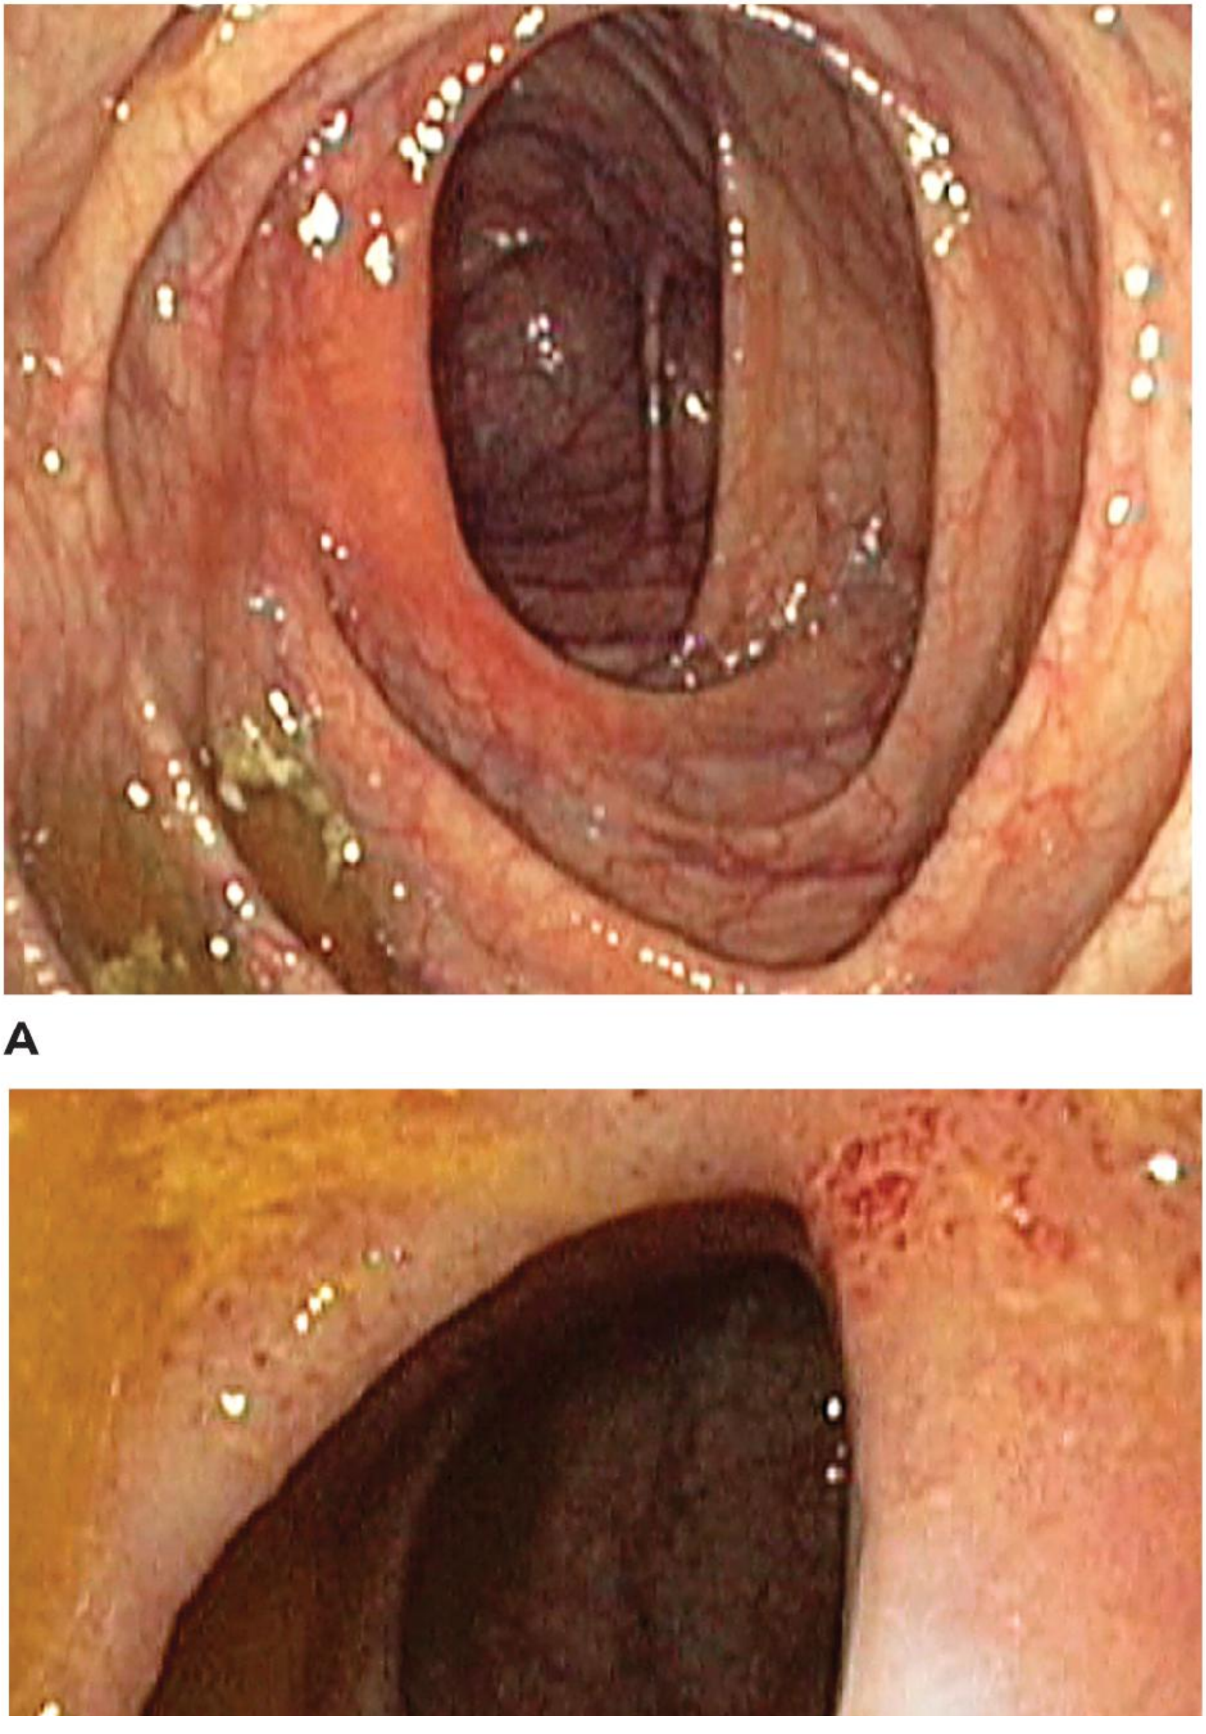
© David M. Martin, MD/Science Source.

Appendicitis

The appendix is a blind pouch, extending from the cecum, that can become inflamed and infected, causing **appendicitis**. The classic presentation is relatively rapid onset of right lower quadrant or periumbilical pain, associated with nausea, vomiting, and fever. Appendicitis is one of the most common reasons for emergency abdominal surgery in the United States and affects as much as 8% of the population over the course of their lifetime. The age range of patients who commonly develop appendicitis is bimodal, with most developing it in their teens and 40s. Advanced cases can lead to perforation, peritonitis, and sepsis.

Inflammatory Conditions of the GI Tract

Inflammatory bowel disease (IBD) is a collective term covering two colonic pathologies that are together responsible for approximately 10% of the cases of lower GI bleeding: ulcerative colitis and Crohn disease **FIGURE 17-21**. IBD is more common in white individuals, with a typical onset between 15 and 30 years of age. Common causes of inflamed colon (**colitis**) are listed in **TABLE 17-4**.



A

© Jones & Bartlett Learning.

Ulcerative colitis is an inflammation of the mucosal and submucosal tissues of the rectum, commonly extending to involve the colon. In this condition, ulcers—which occasionally bleed—form throughout the colon. Patients usually present with frequent small bouts of diarrhea, which may be bloody (in as many as 50% of patients), associated with severe intermittent abdominal pain that comes and goes (colicky pain) and tenesmus. Inflammation spreads into the colon in 35% of cases, a condition termed pancolitis. Other complications may include proctitis, fistula and abscess formation, and extraintestinal complications (such as uveitis or polyarthritis).

Crohn disease is a less organized inflammation of the GI tract in which all layers of the mucosa may be affected. This inflammation is not contiguous, as in ulcerative colitis, but rather results in scattered ulcerations and fibroses throughout the GI tract. Minor bleeding occasionally occurs from these ulcers as well as from small tears that may develop in the mucosa. Cardinal symptoms include abdominal pain, diarrhea, fatigue, and weight loss. Approximately 1% to 4% of patients diagnosed with Crohn disease experience significant GI bleeding.

As ulcerative colitis and Crohn disease move into chronic stages, scar tissue formation can result in a thickening of the mucosa and create bowel obstructions. Because both diseases share similar symptoms, as many as 15% of cases are diagnosed as indeterminate colitis.

Gastroenteritis is an illness caused by bacterial, viral, or parasitic infection, and characterized by vomiting and diarrhea. Such infections are typically self-limited in immunocompetent individuals, and treatment is supportive with oral rehydration therapy. Unfortunately, this illness is associated with significant morbidity and mortality in low- and middle-income countries, particularly in children. Severe dehydration or hemodynamic compromise requires not only intravenous (IV) hydration, but also careful consideration of alternative diagnoses.

A variety of infectious diseases can also cause colitis, such as bacterial infections by *Shigella*, *Salmonella*, and *Campylobacter*. These infections are self-limiting and rarely result in significant bleeding. Viral causes include the Norwalk-type virus and cytomegalovirus in immunosuppressed patients. Patients on prolonged antibiotic therapy may experience growth of *Clostridioides difficile*, which can cause profound diarrhea and dehydration, as well as permanent mucosal damage.

Ischemic colitis is a potentially life-threatening form of colitis that results from diminished blood flow to the GI tract. Etiologies range from arterial obstruction, caused by embolic events in a patient with atrial fibrillation, to severe vessel narrowing in patients with vascular occlusive diseases, to trauma. Hypoperfusion associated with a shock state can also lead to ischemic colitis. The classical presentation of a patient with an intestinal infarct is severe abdominal pain that is out of proportion to the exam; that is, the patient will not look as ill or the abdomen, at least initially, will not be as tender as the individual’s pain would suggest. As bowel necrosis progresses, the patient may experience GI bleeding. This condition can progress rapidly if untreated and will lead to bowel necrosis, perforation, sepsis, shock, and death.

Radiation colitis occurs in 75% of patients who have received radiation doses of 4,000 rad (40 gray [Gy]) or more to the abdomen or pelvis. Chronic mucosal thickening can result from such therapy, as well as ulcerations throughout the colon. Although the major complication of this condition is abdominal pain and diarrhea, anemia and lower GI bleeding can occur as well.

Immune-mediated colitis is an adverse advent associated with immune checkpoint inhibitors, usually affecting the lower GI tract. Checkpoint inhibitors are monoclonal antibodies that boost the immune system's anticancer response. The incidence of colitis in patients who receive this therapy is as high as 25%. Patients usually develop mucus- or blood-tinged diarrhea and abdominal pain, and have a similar presentation and complications as patients with IBD.

Assessment

Signs and Symptoms

The signs and symptoms of patients who experience GI bleeding vary depending on the origin and severity of the bleeding. Slow, chronic bleeding that has been partially digested can result in black, tarry-appearing stool, called **melena**. If the bleeding in either the upper or lower GI tract is minimal, blood in the stool may be detectable only by laboratory testing.

Some ulcerative processes, such as peptic ulcer disease, will cause diffuse abdominal discomfort and will be described as a chronic stomachache or nonspecific burning and cramping. Blood products are emetogenic, meaning that even small amounts of blood may cause gastric irritation and vomiting. Emesis containing blood is known as **hematemesis**. In some cases, patients experience weight loss, anemia, and malnutrition as a result of poor nutrient absorption over damaged mucosa.

Complaints of dizziness and syncope are common in patients with GI bleeding. In addition, these patients may have fever, so temperature should be assessed in all patients with GI dysfunction or bleeding. GI bleeding is not a contraindication to obtaining a rectal temperature unless the patient is neutropenic.

Diarrhea is most commonly associated with lower GI disorders, as a result of reduced water absorption efficiency associated with damaged or infected mucosa. Dehydration frequently follows from diarrhea, as do electrolyte imbalances that can trigger cardiac arrhythmias.

Significant GI bleeding is usually acute and may present with hemodynamic instability and shock. Vomiting large amounts of bright red blood is suggestive of acute bleeding in the upper GI tract—for example, from ruptured varices, an ulcerated submucosal blood vessel, or Mallory-Weiss syndrome. **Hematochezia**, the presence of bright red blood in the stool, is usually indicative of active lower GI bleeding. However, brisk upper GI bleeding (which is too fast to be digested) may present as hematochezia as well. When it is coupled with diarrhea, the patient can experience a significant intravascular volume loss. Hypotension may or may not be immediately apparent, and testing for orthostatic changes may be helpful. Other signs of shock, such as tachycardia, diaphoresis, pallor, and altered mental status, also accompany blood loss. When paired with a decreased level of consciousness, vomiting can result in airway compromise.

When assessing for rectal bleeding, the CCTP should be aware that external sources of bleeding such as a **pressure ulcer** may exist around the anus. Pressure ulcers arise from prolonged pressure on body tissues and are commonly seen in patients confined to a bed. Unfortunately, pressure injuries occur disproportionately in patients at long-term care facilities, with their treatment incurring considerable costs for the health care system. Pressure ulcers are classified into stages 1 through 4 **FIGURE 17-22**. Stage 1 ulcers are reversible, characterized by warmth and nonblanchable erythema; stage 4 ulcers have full-thickness tissue necrosis, often with muscle and bone involvement. If ulcers are present, the CCTP should take care to avoid placing further pressure on the area while bandaging any exposed bleeding tissue. These ulcers are unlikely to produce life-threatening blood loss, but they do cause severe pain and place the patient at risk for infection. Other distal sources of bleeding include anal fissures and hemorrhoids, both of which tend to be associated with constipation and hard stools.

Some abdominal diseases produce distinctive pain in specific locations, aiding in their diagnosis. For example, peptic ulcers cause a burning epigastric pain that is associated with eating and may be relieved by antacids. Gastric ulcer pain is exacerbated with a full stomach, whereas duodenal ulcers are more painful at night, when the stomach is empty. Gastroesophageal reflux, which is reflux of gastric acid and consequent irritation of tissues proximal to the lower esophageal sphincter, frequently accompanies peptic ulcers and gastritis. Biliary obstruction with gallstones (discussed later in this chapter) may mimic reflux and gastritis symptoms. Esophageal varices present initially with painless bleeding that evolves into a burning pain and hematemesis. Appendicitis classically leads to right lower quadrant pain and tenderness. Diverticulitis typically presents with sharp intermittent pain to the lower left abdominal quadrant, commonly referred to as left-side appendicitis. The patient’s medical history and presence of risk factors for certain diseases should always be considered during the assessment to aid the prehospital provider in selecting the appropriate treatment.

Signs and Symptoms

GI Bleeding

- Diffuse abdominal pain
- Chronic stomachache
- Nonspecific burning sensation
- Vomiting, often with blood present
- Hematemesis
- Melena
- Hematochezia

- Weight loss
- Anemia
- Malnutrition
- Dizziness
- Syncope
- Fever
- Diarrhea
- Dehydration
- Hypotension

Differential Diagnosis

GI Bleeding

- Peptic ulcer disease
- Gastritis
- Esophageal varices
- Mallory-Weiss syndrome
- Zollinger-Ellison syndrome
- Gastric tumor
- Esophageal or gastric cancer
- Cirrhosis
- Angiodysplasia
- Inflammatory bowel disease
- Colon cancer
- Colitis
- Diverticulitis
- Hemorrhoids
- Abdominal aortic aneurysm
- Infectious diarrhea

Laboratory Data

Laboratory testing and monitoring are essential in the diagnosis and management of GI bleeding **TABLE 17-5**. Hemoglobin and hematocrit values may appear normal, or only mildly decreased, for several hours after acute bleeding, owing to an equivalent loss of plasma and red blood cells. Eventually, however, these values decrease as interstitial fluid shifts to blood vessels as the body attempts to maintain BP, essentially diluting the blood's oxygen-carrying capacity. Hematocrit values also fall as blood is diluted with crystalloid fluids during resuscitation. For this reason, the CCTP should avoid aggressive crystalloid resuscitation and allow for permissive hypotension. An ongoing decrease in the hematocrit value over time indicates active bleeding.

TABLE 17-5 **Normal Versus Abnormal Laboratory Values**

Test	Normal	Abnormal
Hemoglobin	14–17.5 g/dL	↓
Hematocrit	41% to 50%	↓
Prothrombin time	10–13 s	Varies
Partial thromboplastin time	<40 s	Varies
BUN	8–23 mg/dL	↑
Creatine, serum	0.6–1.2 mg/dL	Varies (unchanged or small rise)
BUN:creatinine ratio	10:1	↑
Glomerular filtration rate	125 mL/min	↓
Blood glucose	70–110 mg/dL	↑ (early)
White blood cells (leukocytes)	4,500–11,000/μL	↑

Abbreviations: ↑, above normal values; ↓, below normal values; BUN, blood urea nitrogen

© Jones & Bartlett Learning.

A coagulation profile is an important component of the workup, as it can identify deficiencies in clotting and platelet function requiring specific treatment. Prolonged prothrombin time (PT) and activated partial thromboplastin time (PTT) are suggestive of liver disease, and a liver function test should be performed in patients with these findings. The coagulation profile (PT, international normalized ratio [INR], and PTT) may also reflect the presence of anticoagulant medications the patient is prescribed, such as warfarin. The CCTP should make every effort to determine if the patient is taking anticoagulant medication, as some of these medications can be reversed. Thrombocytopenia may be chronic, or it may be a result of platelet loss from hemorrhage or consumption, as occurs with diffuse intravascular coagulation. Balanced transfusion of blood products, by supplementing clotting factors and platelets via infusion of fresh-frozen plasma and platelets, may be required in these patients.

Transport Management

GI Bleeding

- Provide airway control: suction and intubation.
- Provide ventilatory support with oxygen.
- Designate the patient as being on nothing by mouth (nil per os [NPO]) status.
- Place two large-bore IV catheters.
- If the patient is in shock or extremis, place an intraosseous (IO) line, particularly if IV access is difficult.
- Provide thoughtful fluid resuscitation, with a goal of achieving permissive hypotension.
- Draw blood samples; provide blood infusion if available, preferably instead of crystalloid fluids.
- Continuously monitor BP.
- Continuously monitor pulse oximetry.
- Continuously monitor the electrocardiogram (ECG).
- Obtain lab values.
- Place a nasogastric (NG) or orogastric (OG) tube.

BUN levels increase following upper GI bleeding owing to digestion and absorption of blood proteins in the large intestine. A decreased GFR due to hypoperfusion of the kidneys secondary to hypovolemia will exacerbate this increase. A BUN-to-creatinine ratio greater than 35:1 is highly suggestive of upper GI bleeding.

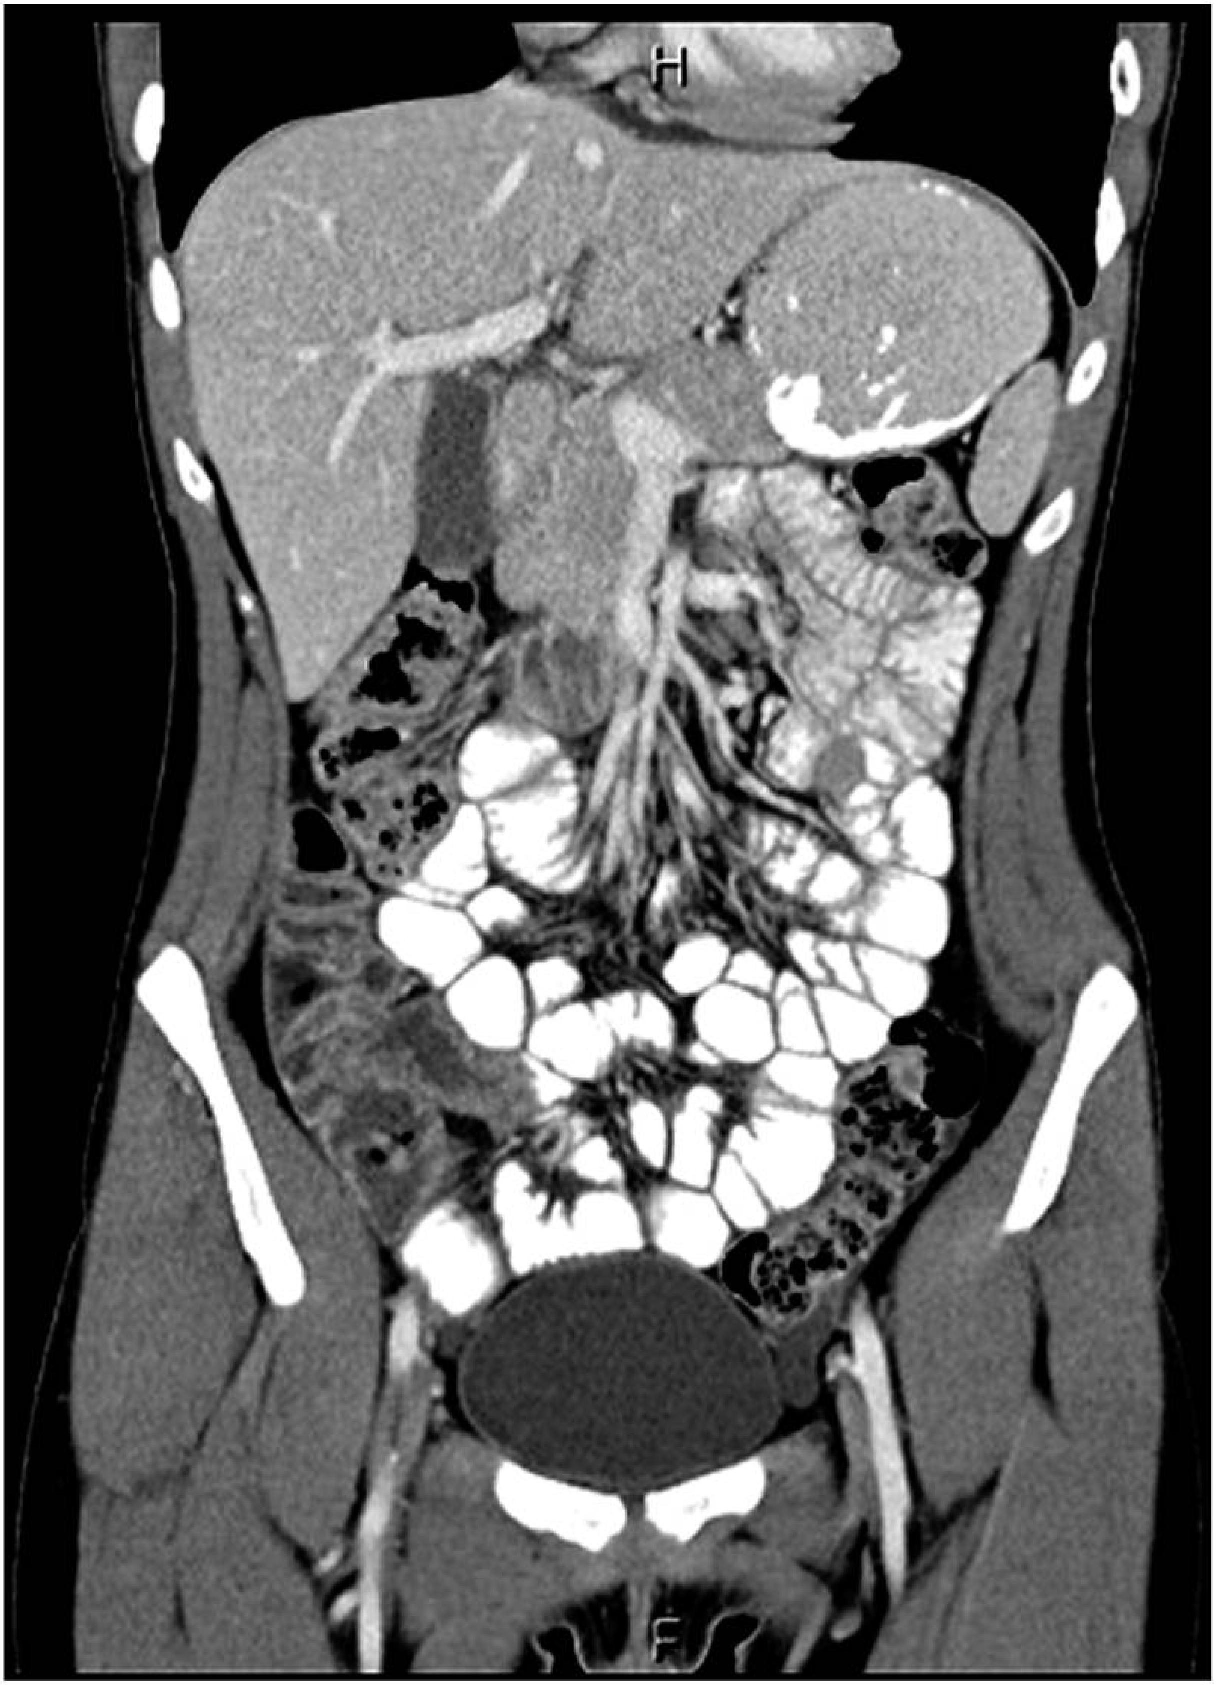
The adrenergic response to GI bleeding results in hyperglycemia, whereas an insult to mucosal tissues stimulates an increase in the white blood cell (WBC) count via an inflammatory response. Serum electrolyte disturbances can occur as well, including hypernatremia and hyperchloremia from fluid resuscitation, or hypokalemia from excessive vomiting. Significant acid–base dysregulation may be present, which may portend a worsening clinical condition and indicate the need for airway management. The CCTP needs to review the most recent lab results and trends in the chart as part of the assessment before beginning the patient's transfer.

Imaging

In both upper and lower GI bleeding, the most effective method of localizing the origin of the bleeding is to search the mucosa. Endoscopy—specifically, **esophagogastroduodenoscopy (EGD)**—enables visualization of more than 90% of the upper GI tract. In addition to diagnosing the source of bleeding, endoscopists can employ various therapies to stop the bleeding, ranging from cauterization to local application of hemostatic material or vasoconstricting injections. The endoscopist may perform gastric lavage prior to endoscopy to facilitate viewing of the internal structures. Complications from endoscopy are relatively rare, with an incidence of less than 1%, and most commonly take the form of bleeding and perforation. In the past, nasogastric lavage was often performed to differentiate between upper and lower GI bleeding sources, but it is now performed less frequently due to the risk of dislodging variceal clots.

EGD is sometimes performed first in patients with undifferentiated bleeding and melena or severe hematochezia, followed by **colonoscopy** if the EGD is negative. However, results of additional testing, as well as risk stratification and clinical scenario, may affect the diagnostic approach. Visualization of the lower GI mucosa is possible via colonoscopy, although this procedure is slightly more complicated than endoscopy. A colonoscopy is usually delayed by a few hours to allow for bowel purge preparation, which both enables the physician to view the mucosa more effectively and reduces the risk of perforation. Colonoscopy allows for visualization of the entire rectum and large intestine, up to the ileocecal junction. The diagnostic yield of colonoscopy for lower GI bleeding is significantly higher than that with radiologic evaluation. Similar treatment modalities are available via colonoscopy as with EGD.

Due to ever-improving imaging technology, CT angiography is an increasingly convenient diagnostic tool for GI bleeding, particularly when active extravasation and bleeding are occurring. When this imaging technique is used, dye injected into blood vessels will leak into the lumen of the GI tract at the site of the bleeding. Diagnostic accuracy depends on the presence of active bleeding. Nevertheless, when it is timed correctly, angiography can rapidly localize bleeding lesions anywhere in the GI tract, obviating the need for oral contrast or bowel preparation. Angiography is more frequently used to diagnose lower GI bleeding because of the lower success rate of colonoscopy as opposed to endoscopy when brisk bleeding may hinder the endoscopist. **FIGURE 17-23** shows a normal abdominal CT scan.



H

Technetium-99m–labeled red blood cell scintigraphy is a technique in which blood cells attached to isotopes are identified as they extravasate at the source of bleeding. Once popular, this imaging modality is being rapidly abandoned in favor of CT angiography in most centers. Tagged red blood cell scans do not have the advantage of providing a vascular map, which serves as invaluable guidance for interventional radiologists or surgeons during management.

Management

The fundamentals of patient care must be ensured before any specific treatment is attempted. It is important to control and maintain the patient's airway. During acute GI bleeding, particularly with massive hematemesis, airway compromise occurs primarily by either physical obstruction or mechanical obstruction. Use suctioning to clear a physical obstruction of the airway by blood or vomit. Mechanical obstruction of the airway by the tongue or head positioning because of a decreased level of consciousness, secondary to hypovolemic shock, is managed by placement of airway adjuncts and intubation. Rapid sequence intubation is indicated in individuals with a high risk of aspiration, such as patients who are lethargic and are actively vomiting.

Administer supplemental oxygen to maintain an oxygen saturation of 92% or greater in the alert, conscious patient. Assist ventilations as necessary with a bag-mask device and high-flow oxygen.

Patients with acute GI bleeding should be designated as NPO (nothing by mouth) because of the likelihood they will undergo endoscopy and/or surgery shortly after hospital admission. Two large-bore (14- to 16-gauge) IV catheters should be placed immediately. In case of difficult IV access, IO insertion is an excellent alternative. Fluid resuscitation should begin immediately in any patient who exhibits signs of shock, although this should be done carefully.

Judicious fluid administration is required because over-resuscitation can lead to hemodilution of the blood, which in turn can reduce clotting effectiveness. Increasing vascular volume too rapidly can also worsen bleeding, particularly in esophageal varices, potentially dislodging fragile clots. Aggressive fluid resuscitation in individuals without prehospital hypotension may lead to worse outcomes. Much as when treating hemorrhage caused by trauma, the CCTP should aim for permissive hypotension; that is, systolic BP (SBP) is allowed to fall low enough to avoid exsanguination, but is kept high enough to maintain perfusion. In adults with GI bleeding, boluses of 500 mL may be used to maintain a mean arterial pressure (MAP) of approximately 60 mm Hg; definitive management will entail transfusion of blood products. As in hypovolemic shock from other causes, avoiding the coagulopathy that accompanies hypothermia is paramount. Keep the transport environment warm and use warmed IV fluids, if available.

Blood samples should be drawn concurrently with IV line placement to determine a type and crossmatch, complete blood count, electrolyte levels, and PT and PTT values. Current evidence recommends withholding blood administration until the patient’s hemoglobin drops below 7 g/dL, as more liberal transfusion strategies are associated with worsened outcomes. However, as discussed earlier, blood count assays may be delayed in patients with large acute bleeds; thus, transfusion based on clinical features of shock is warranted, particularly in patients with ongoing bleeding. Platelet or fresh-frozen plasma infusion may be indicated based on lab findings as well as the volume of packed red blood cells given. In patients who require massive transfusion, balanced replacement of blood products, including platelets, cryoprecipitate, or plasma, can improve outcomes by addressing the coagulopathy that occurs with dilution (eg, due to large volumes of crystalloid or packed red blood cells). Of note, the citrate preservative in blood products may cause hypocalcemia in patients with massive transfusion, and calcium must be restored accordingly. The principles of management of hemorrhagic shock are discussed in detail in Chapter 10, *Resuscitation, Shock, and Blood Products*.

Continuous BP and pulse oximetry monitoring is required to evaluate the patient's response and the effectiveness of fluid resuscitation efforts. In patients in profound shock states, pulse oximetry results may be unreliable. Care must be taken to avoid fluid overload secondary to excessive fluid administration in patients with comorbidities, specifically those with cardiac-related conditions. Arterial line placement is helpful in hemodynamically unstable patients to provide real-time visualization of their hemodynamic status. Continuous ECG monitoring should be implemented to observe patients for worsening tachycardia as a result of worsening shock, as well as a variety of arrhythmias that may develop secondary to electrolyte imbalances or hypoxia.

CONTROVERSIES

Several states across the United States have been grappling with the issue of the level of training and licensure necessary to oversee administration of blood and blood products. Some states may not allow a person without specific credentialing to administer blood or blood products during transport. This restriction may force the sending facility to complete or even discontinue the administration of such products before transfer. Indeed, ground transport services rarely carry and use blood components; most services that carry blood components are helicopter-based. However, positive research findings and mortality benefits from whole blood transfusion in combat environments and the prehospital setting are prompting more EMS organizations to reconsider their position on replacing blood products. Facilities should be aware of their state regulations and the composition (ie, certified versus licensed) of their CCT teams when faced with these types of transfers. The referring physician might also confer with a transport physician or the CCT medical director to determine which resources are necessary to safely transport the patient.

Upper GI Bleeding

Some patients may have had an nasogastric (NG) or orogastric (OG) tube placed after intubation for gastric decompression (especially if they received prolonged ventilation via bag-mask device) and for evacuation of any blood or gastric contents. Due to the risk of exacerbating a bleeding varix or ulcer, as well as the risk of aspiration, NG and OG tubes are no longer routinely placed in patients who are not already intubated or during transport.

Endoscopy is performed at the hospital when the patient's condition is stable. It may serve both diagnostic and therapeutic functions. Once the bleeding site is located, *injection sclerotherapy*—that is, injection of small doses of either epinephrine or clotting factors into the site—can be performed via endoscopy. Epinephrine causes a local vasoconstriction that results in decreased blood flow to the area; human thrombin, fibrin glue, and similar products stimulate clotting, which will slow or stop the bleeding process significantly.

Endoscopic variceal band ligation can be used to control bleeding esophageal varices. This technique involves the placement of rubber bands around the varix, which shuts off its blood supply. Cauterization methods and hemostatic clip placement are alternatives to these treatments.

Of the vasoactive medications, two are quite effective at stopping active GI bleeding. If portal hypertension is suspected, these medications should be started early. Vasopressin induces vasoconstriction of the splanchnic arteries, which reduces mesenteric blood flow and, in turn, reduces portal hypertension. This effect can be beneficial to the patient with esophageal varices and undifferentiated GI bleeding because it substantially reduces blood flow to the region. Octreotide, a synthetic version of somatostatin, inhibits glucagon release and thus inhibits splanchnic vasodilation. This medication is used most commonly in the management of variceal bleeding in patients with a history of cirrhosis.

When variceal hemorrhage proves refractory to endoscopic and pharmacologic treatments, mechanical obstruction of hemorrhage via balloon inflation and shunt placement may be viable alternative therapies. Balloon tamponade of variceal bleeding is effective in controlling the hemorrhage in as many as 90% of patients. In this procedure, a **Sengstaken-Blakemore tube** **FIGURE 17-24** or a **Minnesota esophagogastric tamponade tube** **FIGURE 17-25** is inserted nasally and introduced to the stomach via the esophagus.

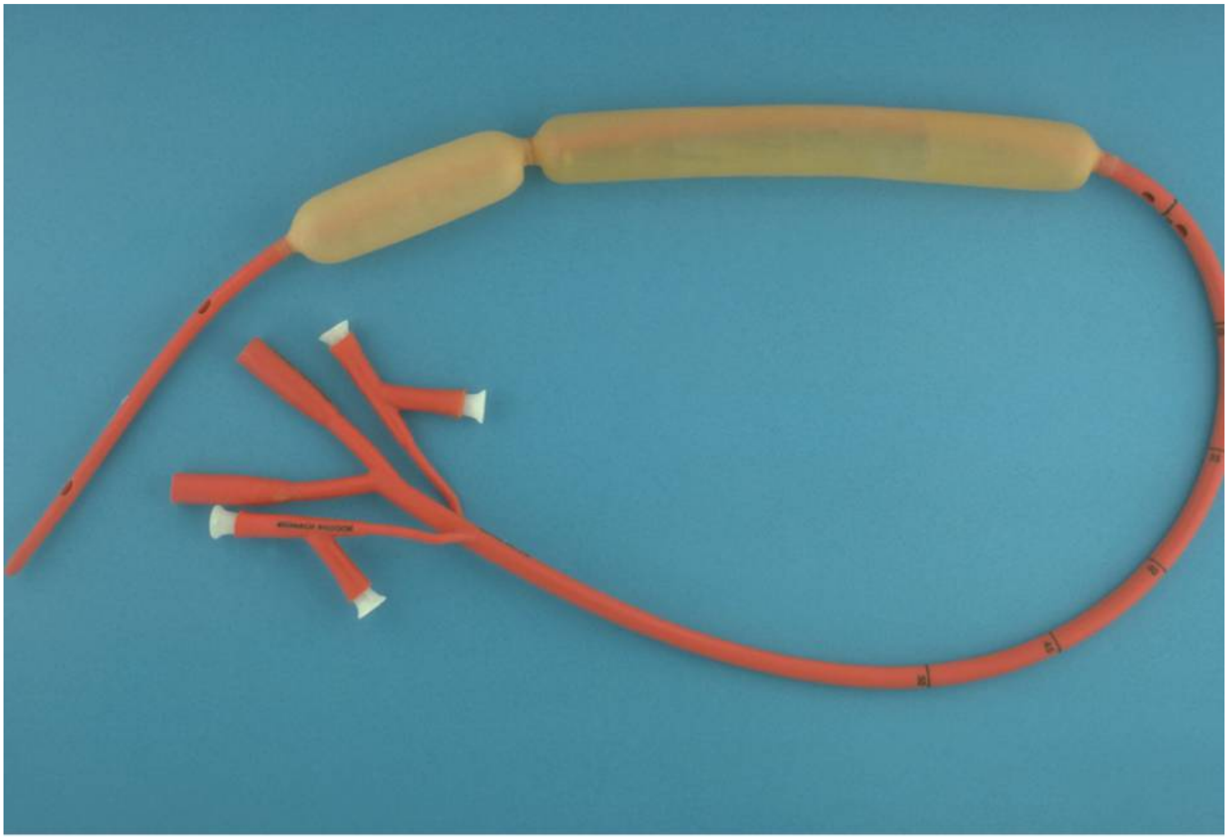

FIGURE 17-25 Minnesota esophagogastric tamponade tube.

© Mediscan/Alamy Stock Photo.

Although insertion of the Minnesota tube is not within the scope of CCTP practice, CCTPs must understand how the tube has been placed if they are transporting a patient with such a tube. The Minnesota tube is passed through the patient's mouth, just like an OG tube, to the 50-cm mark **FIGURE 17-26** and is inflated with 50 mL of air. After placement is confirmed by obtaining a chest radiograph, the gastric balloon is inflated with an additional 200 to 250 mL of air (250 to 300 mL total). The inflated balloon is sometimes sufficient to stop the hemorrhage. Traction is applied to secure the tube and tamponade the balloon against the gastroesophageal junction. If bleeding continues, the esophageal tube is inflated. Although balloon placement has a high success rate in achieving initial bleeding control, bleeding often recurs on its removal. Thus, the gastric balloon is used only as an emergent, temporary device. Patients requiring this device will be intubated and may have traction on the tamponade tube via a 1-L bag of IV fluid hanging from the IV pole or affixed to the face shield of a football helmet.

Description

A procedure more frequently employed to control variceal bleeding is the placement of a transjugular intrahepatic portosystemic shunt **FIGURE 17-27**. This minimally invasive procedure introduces a shunt between the hepatic venous circulation and the systemic venous return, which significantly reduces both the hepatic portal pressure and the pressure in esophageal varices. Such a shunt is primarily placed for GI bleeding, although some patients may undergo this procedure to relieve fluid buildup associated with severe ascites or hydrothorax. Shunt placement has a greater than 95% success rate in markedly reducing bleeding recurrence as long as the shunt remains patent. Unfortunately, as many as 35% of patients will develop hepatic encephalopathy after this procedure due to the inherent bypass of the liver parenchyma.

Proton pump inhibitors should be administered to reduce gastric acidity in any patient with GI bleeding. Prophylactic acid inhibition is common in patients admitted to an intensive care unit to prevent the development of stress ulcers. Patients testing positive for *H pylori* receive a combination of drugs including proton pump inhibitors, bismuth, probiotics, and antibiotics. Due to rising antimicrobial resistance to macrolide and tetracycline components, trials are ongoing to determine the optimal antibiotic regimen.

Lower GI Bleeding

Management of the patient with lower GI bleeding is similar to management of the patient with upper GI bleeding. Health care providers must pay special attention to the potential for fluid loss that can occur through water shifts in the colon and the associated dehydration and electrolyte abnormalities. Endoscopic methods of cauterization and coagulation with argon plasma are also used to terminate lower GI bleeding, and local infiltration with vasoconstrictive medication and clip placement is the first-line treatment for diverticular bleeds. As with any acute hemorrhage, acute resuscitation of the patient by administering blood and blood products to reduce coagulopathy are the key components of stabilization. Transcatheter embolization of bleeding vessels is an effective alternative approach when the approximate location of the bleed is localized. Surgical evaluation for resection is warranted (as a last resort) in patients presenting with severe hematochezia who cannot be stabilized for endoscopy or in whom endoscopic evaluation has failed to reveal a bleeding source, although this is rarely required.

Intestinal Obstructions

Blockage of the GI tract can occur in the small or large intestine through a variety of pathologies. The convoluted small intestines are far more susceptible to obstruction than are the large intestines, which have a wider diameter. Obstructions are classified as partial, complete, or strangulated. In partial and complete obstructions, fluid or gas is able to pass partially or not pass at all, respectively. Strangulated tissue is cut off from its own blood supply, which can lead to necrosis, perforation, and shock within hours. A closed-loop obstruction occurs when a segment of bowel is obstructed at two points along its course, leading to worsening dilation of that segment and increased risk of volvulus and ischemia. Although a partial intestinal obstruction can cause discomfort and malnutrition, a complete blockage stops normal GI function, resulting in significant morbidity and mortality if not treated promptly.

Epidemiology and Pathophysiology

Postoperative adhesions are the major cause of intestinal obstructions. Combined with hernias and tumors, these etiologies account for 90% of cases. Less frequent causes of intestinal obstructions include Crohn disease, volvulus, and intussusception. Among those patients diagnosed as having an intestinal obstruction, as many as 40% have bowel ischemia, which significantly increases mortality. Overall, intestinal obstructions are fairly common in the United States, accounting for as many as 15% of all acute surgical admissions to hospitals.

Mechanical Obstruction

A mechanical obstruction is the result of a physical blockage of the intestinal lumen. It can be classified into one of three categories: extrinsic, intrinsic, or intraluminal **TABLE 17-6**.

TABLE 17-6 Causes of Intestinal Obstruction

Type of Obstruction	Cause
Mechanical	Extrinsic • Adhesions • Hernias • Volvulus • Masses Intrinsic • Diverticula • Neoplasms • Intussusception Intraluminal • Foreign body ingestion • Fecal impaction
Nonmechanical (ileus)	Postoperative Acute colonic pseudo-obstruction Abdominal inflammation Peritonitis Heavy metal poisoning Metabolic abnormalities Spinal cord injury

© Jones & Bartlett Learning.

Extrinsic causes, which originate external to the intestines, include adhesions, hernias, volvulus, and masses. **Adhesions** are bands of connective tissue that can distort the normal anatomy of the abdomen. They are most often the result of improper healing or scar tissue growth following abdominal surgery. A **hernia** is a protrusion of an organ from its tissue lining. Some hernias may be readily appreciated, such as umbilical or ventral hernias, while others may be wholly internal. Overall, postsurgical adhesions are the most common cause of mechanical intestinal obstruction, followed by hernias. A **volvulus** is a twisting of the intestine onto itself, which usually results in strangulation. Masses often originate from surrounding abdominal organs that put pressure on the intestines and may take the form of bowel hematoma (from trauma), tumors, aneurysms, or abscesses.

Intrinsic causes of intestinal obstruction arise from the intestinal lining itself; they include diverticula, neoplasms, and intussusception. An **intussusception** is a prolapse of the intestine into an adjacent segment. Intussusception is the most common cause of bowel obstruction in children younger than 3 years, but is a much rarer diagnosis in adults.

An intraluminal obstruction is commonly the result of an ingested foreign body or a fecal impaction. Causes of intestinal obstructions include volvulus **FIGURE 17-28**, a mass **FIGURE 17-29**, intussusception **FIGURE 17-30**, and a foreign body **FIGURE 17-31**.

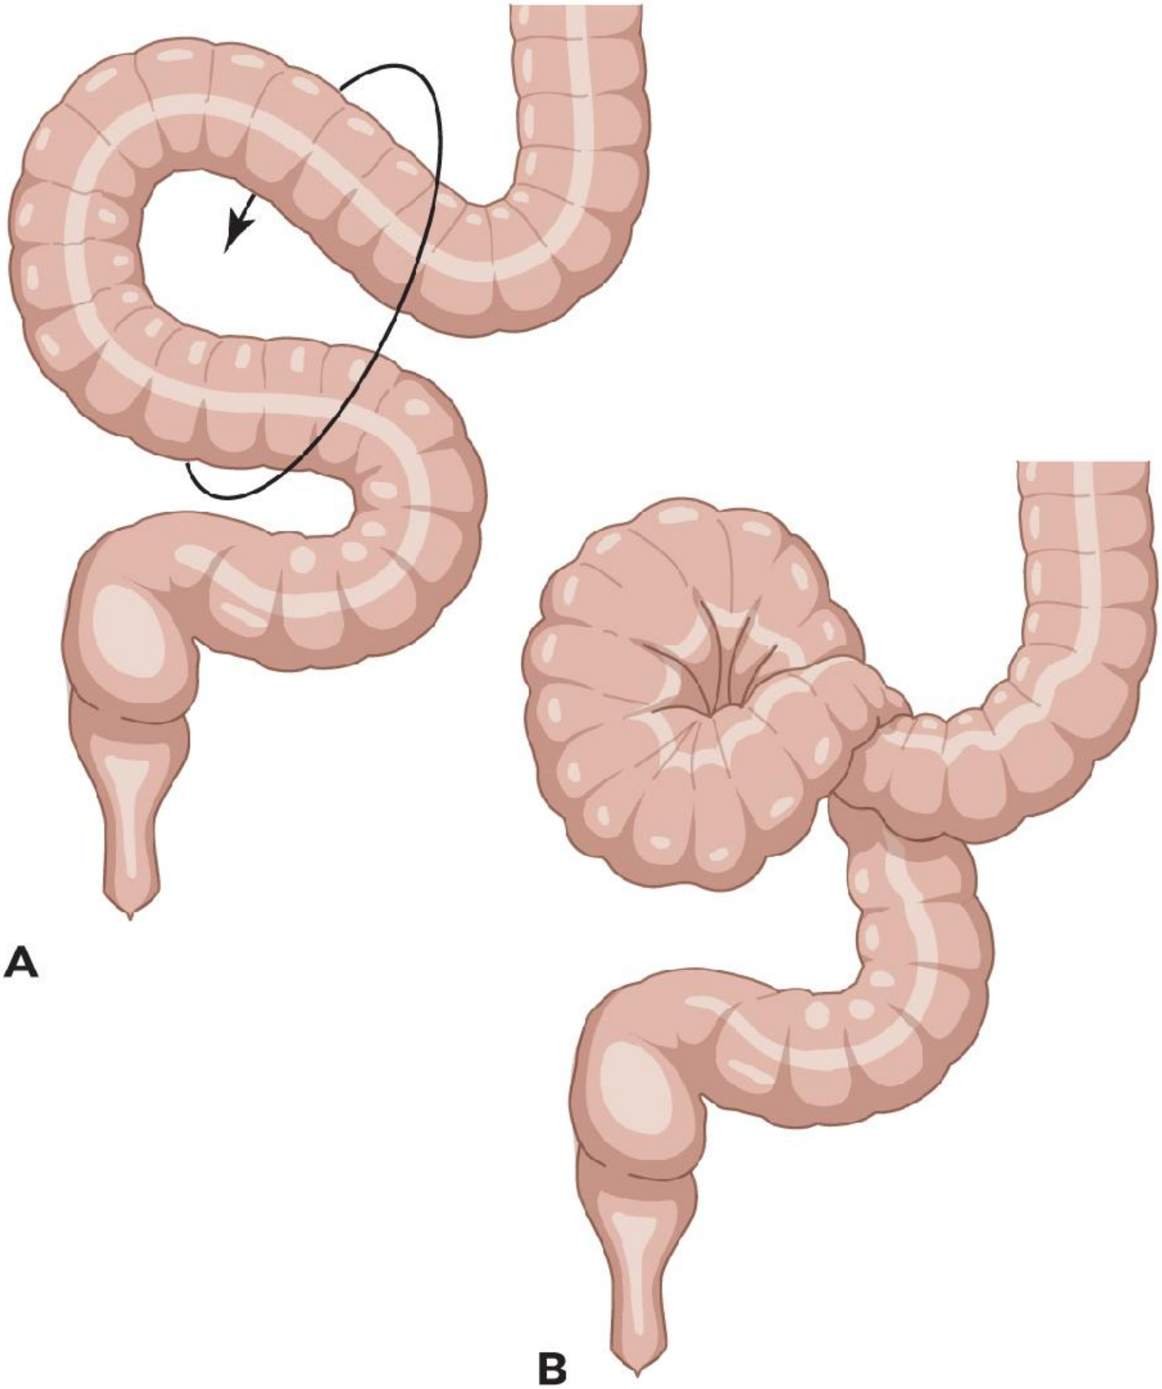

FIGURE 17-28 The pathogenesis of volvulus. **A.** Rotary twist of the sigmoid colon on its mesentery. **B.** Obstruction of the colon and interruption of its blood supply caused by volvulus.

Description

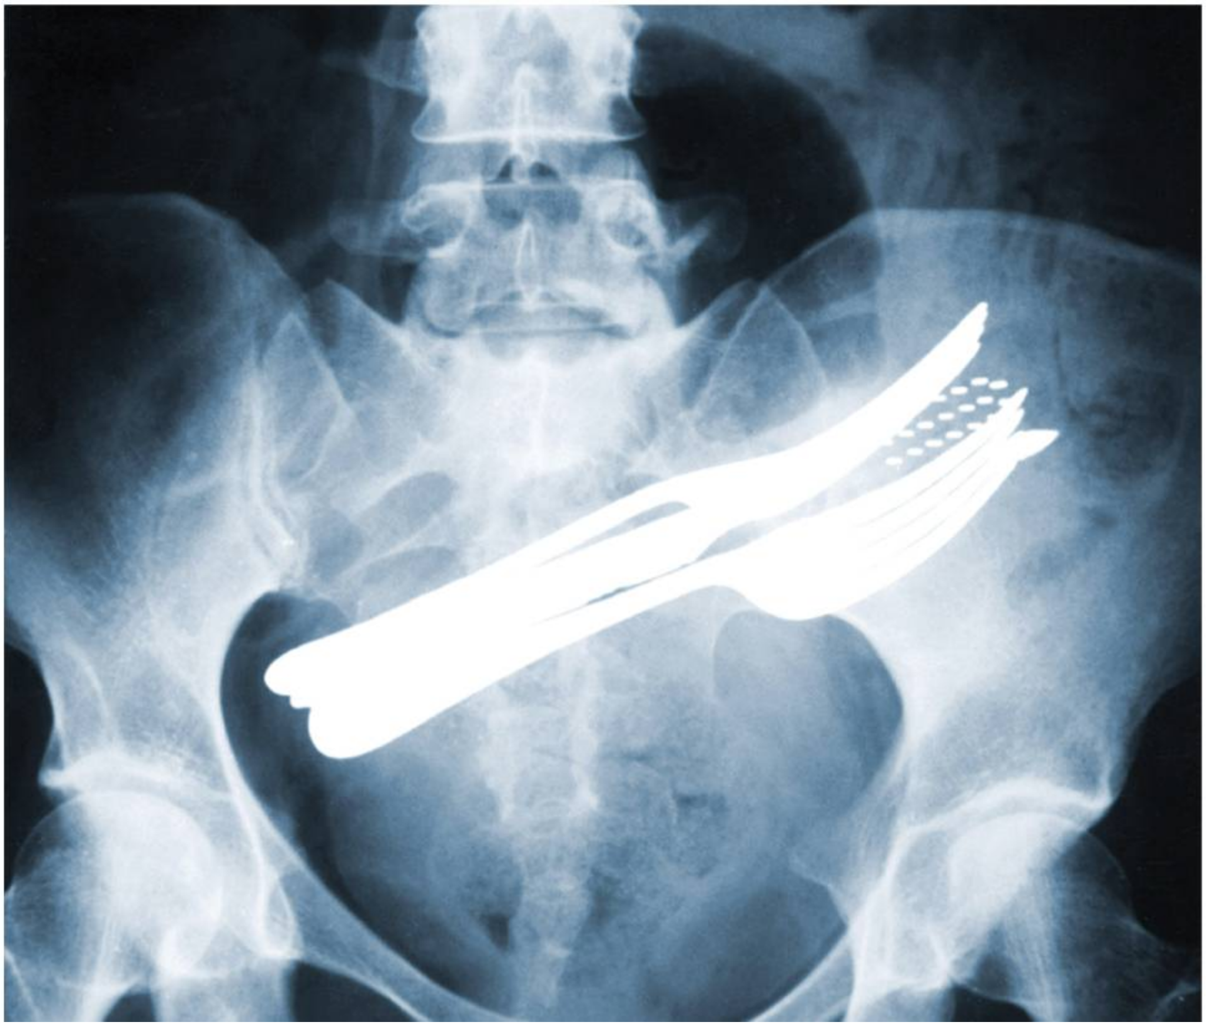

FIGURE 17-31 Radiograph of an intestinal obstruction caused by a foreign body.

© Biophoto Associates/Science Source.

Chyme, fluids, and digestive products cannot pass through or around an intestinal obstruction, so they immediately begin to accumulate proximal to the blockage. This buildup, along with swallowed air, will distend the lumen proximal to the obstruction. GI tract distention stimulates an increase in digestive juice secretion and peristalsis, worsening the situation. The continually increasing intraluminal pressure also increases the permeability of mucosal capillary beds, allowing vascular fluid to flow into the intestinal lumen. This phenomenon, which is termed **third spacing**, can lead to dehydration, electrolyte imbalances, and hypovolemia.

Over time, the stagnation of intestinal contents facilitates significant bacterial growth. As bacteria enter the mucosal tissues, infections leading to peritonitis or sepsis may occur. If luminal distention proximal to the blockage site continues unchecked, a bowel rupture can occur. The contents of the ruptured GI tract will irritate the surrounding tissues and are likely to cause peritonitis. Of course, all of these processes are more severe in immunocompromised individuals, owing to their impaired gut mucosal defenses against bacterial translocation.

Distal to the obstruction site, tissue ischemia occurs secondary to arterial occlusion. This ischemia inhibits any residual GI functioning and eventually results in necrosis.

Ileus

Ileus is the lack of movement of GI contents through the intestines in the absence of a mechanical obstruction. This condition occurs most commonly in the postoperative period, especially when patients are receiving large doses of analgesic medications, which tend to decrease gut motility. Other factors that may contribute to postoperative ileus include direct manipulation of the GI tissues during surgery, lack of physical activity after a surgery, and use of anesthetic and paralytic medications. Postoperative ileus is transient, usually lasting 48 to 72 hours after surgery. However, it can result in significant discomfort and vomiting, and may even require bowel rest and an NG tube until it resolves. This type of ileus and other types of reversible ileus are also known as acute colonic pseudo-obstruction, or Ogilvie syndrome. Other causes of ileus include abdominal inflammation, peritonitis, heavy metal poisoning, metabolic abnormalities, and spinal cord injury. Flatulence and bowel movements typically indicate resolving ileus.

Assessment

Signs and Symptoms

Moderate to severe abdominal pain accompanies distention proximal to the intestinal obstruction, with the patient eventually vomiting as a result. Excess bacterial growth causes bad breath, along with exceptionally foul-smelling vomit. The vomit may contain large amounts of bile and have an appearance similar to feces depending on the location of the obstruction.

When an obstruction is present, the intestinal mucosa becomes inflamed secondary to ischemia and necrosis. This inflammation, along with bacterial infiltration into the tissues, can cause a fever as the patient's immune response progresses. Shock, as a result of third spacing of fluids or vomiting, manifests with tachycardia, altered mental status, cool and clammy skin, and hypotension.

In a patient with an intestinal obstruction, the abdomen is tender and distended on palpation, with diffuse pain typically being noted. If bowel perforation and peritonitis have occurred, the abdomen may become rigid to palpation. Initially, hyperactive and high-pitched bowel sounds may accompany an obstruction, followed by an eventual cessation of sound as GI function is increasingly inhibited. An incarcerated hernia occurs most commonly when gut tissue protrudes through a small defect. Although patients with hernias may be able to reduce those protrusions without incident, the herniated tissue can sometimes become inflamed and edematous, making reduction extremely difficult (and painful), if not impossible. This incarceration can lead to obstruction and strangulation of the bowel, and emergency management involves analgesia and (in some cases) procedural sedation to attempt reduction. If this fails, surgical reduction is necessary.

Laboratory Data and Imaging

Laboratory testing is performed mostly to determine the degree of dehydration and electrolyte imbalance from an intestinal obstruction. Hemoglobin and hematocrit values become elevated as the blood becomes more concentrated following excessive vomiting. Metabolic alkalosis frequently occurs as electrolyte shifts compensate for the loss of hydrogen ions through vomiting. White blood cell counts indicate inflammation as the extent of tissue ischemia and necrosis expands.

Plain radiography can provide a rapid screening tool for intestinal obstruction by detecting abnormally high air volumes proximal to the obstruction site, although this modality is only about 50% sensitive. **Enteroclysis**, or a small bowel series, used to be the gold standard for imaging of such obstructions, but is now being supplanted by CT. In this procedure, a barium contrast is instilled in the patient orally or via NG tube. The progression of the contrast through the intestines can be monitored with serial radiographs, allowing for observation of the blockage. Abdominal ultrasonography can also be used to diagnose an intestinal obstruction with great accuracy, although locating the transition point (the point of obstruction) is challenging.

A CT scan can be used to diagnose a bowel obstruction with exceptional specificity and is the gold-standard imaging modality for this indication. An abdominal CT scan is useful in differentiating the cause of the obstruction and potentially diagnosing additional pathology, such as intra-abdominal infection or tumor. The best results are obtained with concurrent administration of IV contrast, although an oral contrast agent may be helpful in very thin individuals or those with prior surgical history (such as gastric bypass).

Signs and Symptoms

Intestinal Obstruction

- Moderate to severe abdominal pain
- Tender, distended abdomen
- Erythematous, tense, exquisitely tender palpable mass or hernia
- Foul-smelling vomit that may contain bile or appear similar to feces
- Diarrhea
- Bad breath
- Fever
- Shock
- Tachycardia
- Altered mental status
- Cool, clammy skin
- Hypotension
- Hyperactive, high-pitched bowel sounds initially

- Eventual cessation of bowel sounds

Differential Diagnosis

Intestinal Obstruction

- Diverticulitis
- Cholecystitis
- Endometriosis
- Foreign body
- Gastroenteritis
- Inflammatory bowel disease
- Pancreatitis
- Appendicitis
- Urinary tract infection
- Pyelonephritis
- Pelvic inflammatory disease
- Ovarian torsion
- Cholangitis

Transport Management

Intestinal Obstruction

- Stabilize the ABCs.
- Provide fluid resuscitation.
- Provide supplemental oxygen, if needed.
- Continuously monitor the ECG.
- Designate the patient as NPO.
- Place an NG tube.
- Consider antibiotics.

Management

After addressing any life threats related to the patient’s airway, breathing, or cardiac functioning, initial treatment focuses on fluid and electrolyte resuscitation, antiemetics, and analgesia. Avoid promotility agents, which may increase the patient’s discomfort and risk of perforation. Administer isotonic fluid boluses as needed to maintain adequate perfusion. Provide supplemental oxygen through either a nonrebreathing mask or a nasal cannula, if the patient is hypoxemic. Monitor the patient’s ECG continuously for signs of arrhythmias secondary to electrolyte imbalances.

Patients with a suspected intestinal obstruction should be placed on NPO restrictions, and an NG tube should be inserted to relieve distention proximal to the blockage, especially if the patient has ongoing vomiting. This tube may or may not be placed by the CCTP depending on regional protocols. The degree and severity of obstruction determines whether patients will require surgical management. Nonoperative management focuses on bowel rest, decompression, and fluid replacement. Patients with chronic intestinal obstruction, significant bowel dysfunction, or large resection may receive total parenteral nutrition to help them maintain adequate nutrition. Emergency surgery is required in patients with a strangulated bowel. Surgical treatment techniques are directed toward reducing the obstruction through laparoscopic lysis of adhesions or circumventing the obstruction by a bowel resection, particularly if the tissue has become necrotic. Specific treatment for ileus is aimed at correcting electrolyte disturbance.

Nasogastric Tube Insertion

The following equipment is needed to place an NG tube:

- NG tube
- 50-mL irrigation syringe
- Water-soluble lubricant
- Adhesive tape
- Saline for irrigation

- Emesis basin
- Gloves
- Stethoscope
- Low-powered suction unit

Indications for NG tube placement are as follows:

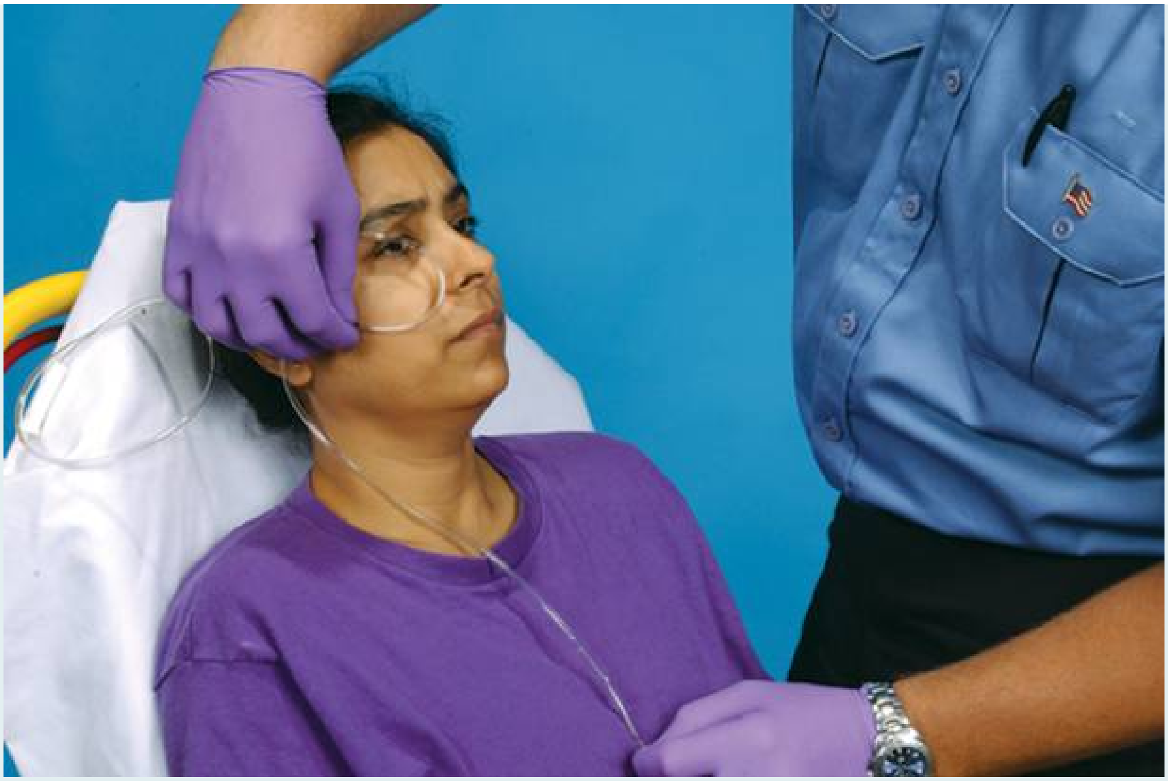
- Evacuation of stomach contents
- Dilution or lavage of poisons in the stomach
- Removal of blood in patients with GI hemorrhage

Contraindications to NG tube placement include severe facial trauma, croup, and epiglottitis. Potential complications of NG tube placement include improper positioning of the tube, which may take two forms: (1) turbinate insertion, causing bleeding and pain, or (2) tracheal insertion, causing the patient to cough and choke. If the tube cannot be advanced to its predetermined length, then it has most likely become curled in the patient's mouth, throat, or esophagus.

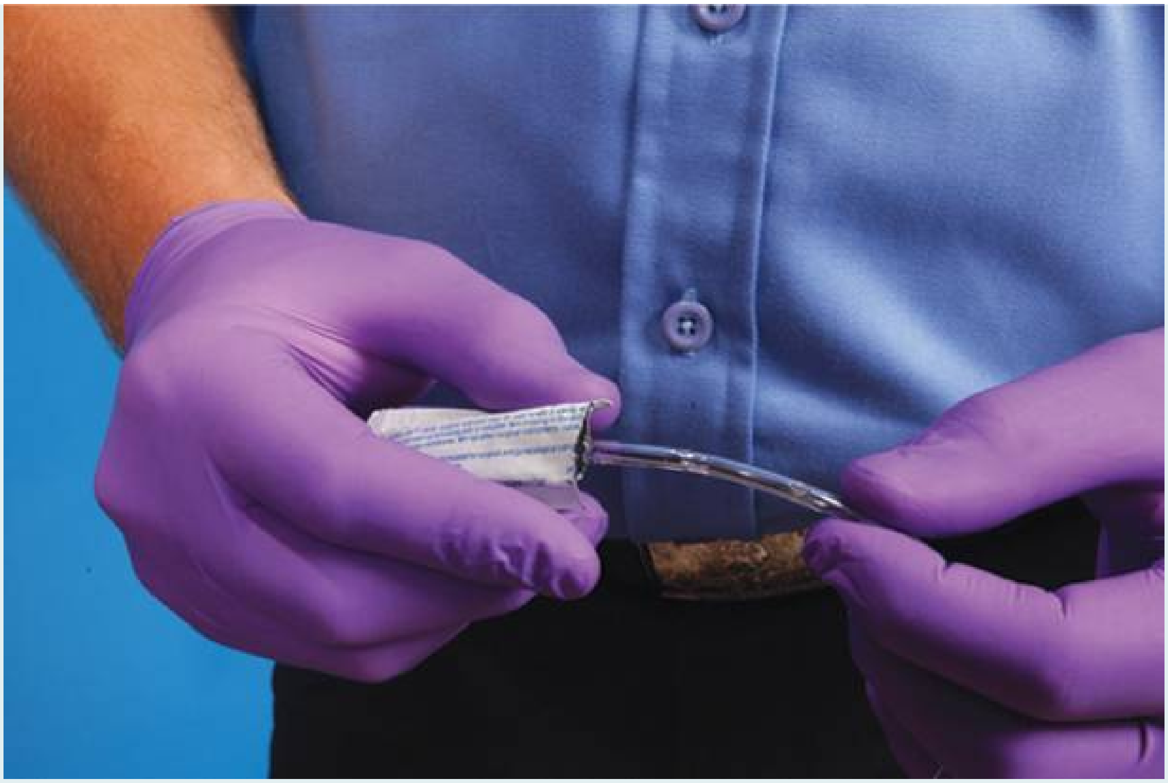
Skill Drill 17-1 shows the steps for NG tube placement, which are summarized here:

SKILL DRILL 17-1 Inserting a Nasogastric Tube in a Conscious Patient

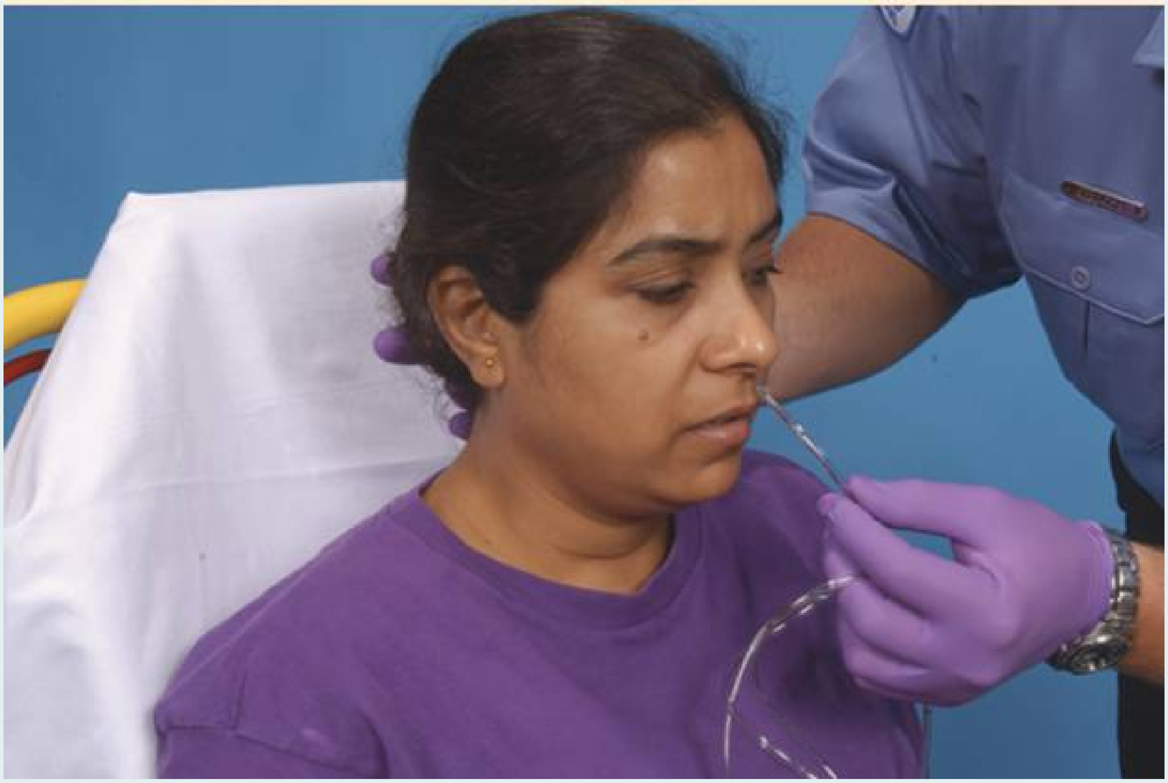
Step 1
Explain the procedure to the patient. Ensure that the patient’s head is in a neutral position and suppress the gag reflex with a topical anesthetic spray.



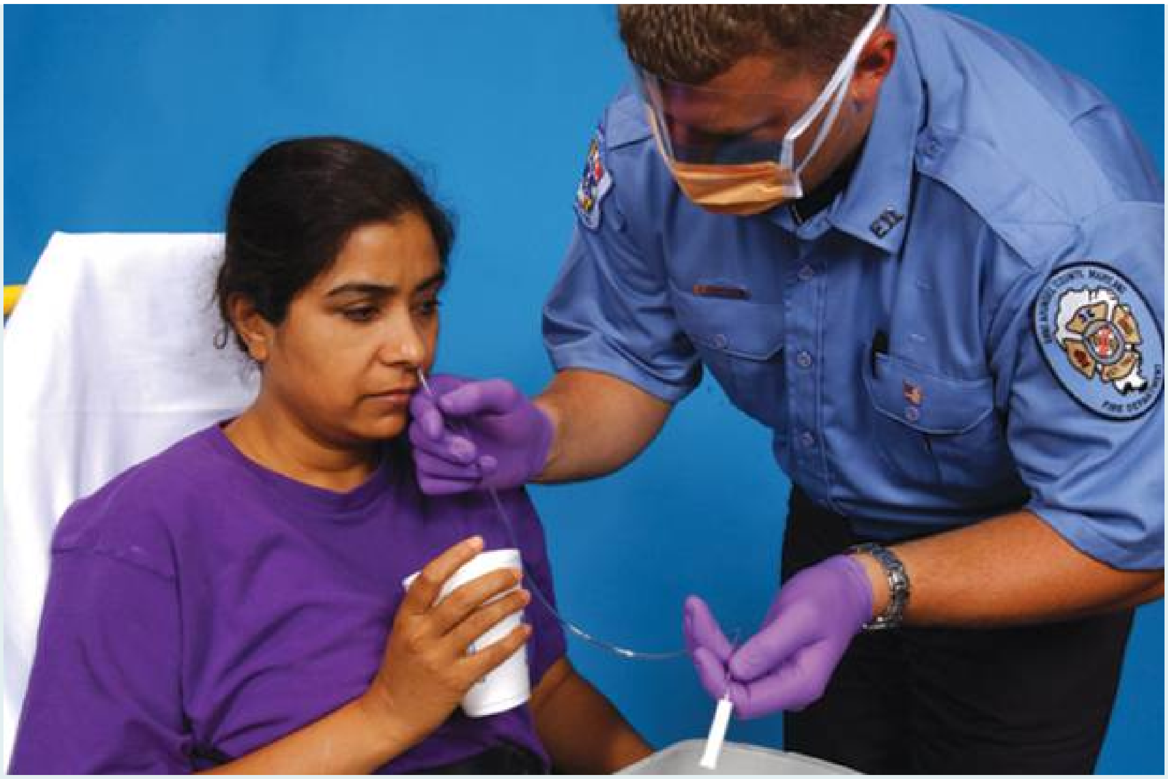
Step 2
Measure the tube for the correct depth of insertion (nose to ear to xiphoid process). Mark the correct length on the tube with adhesive tape.



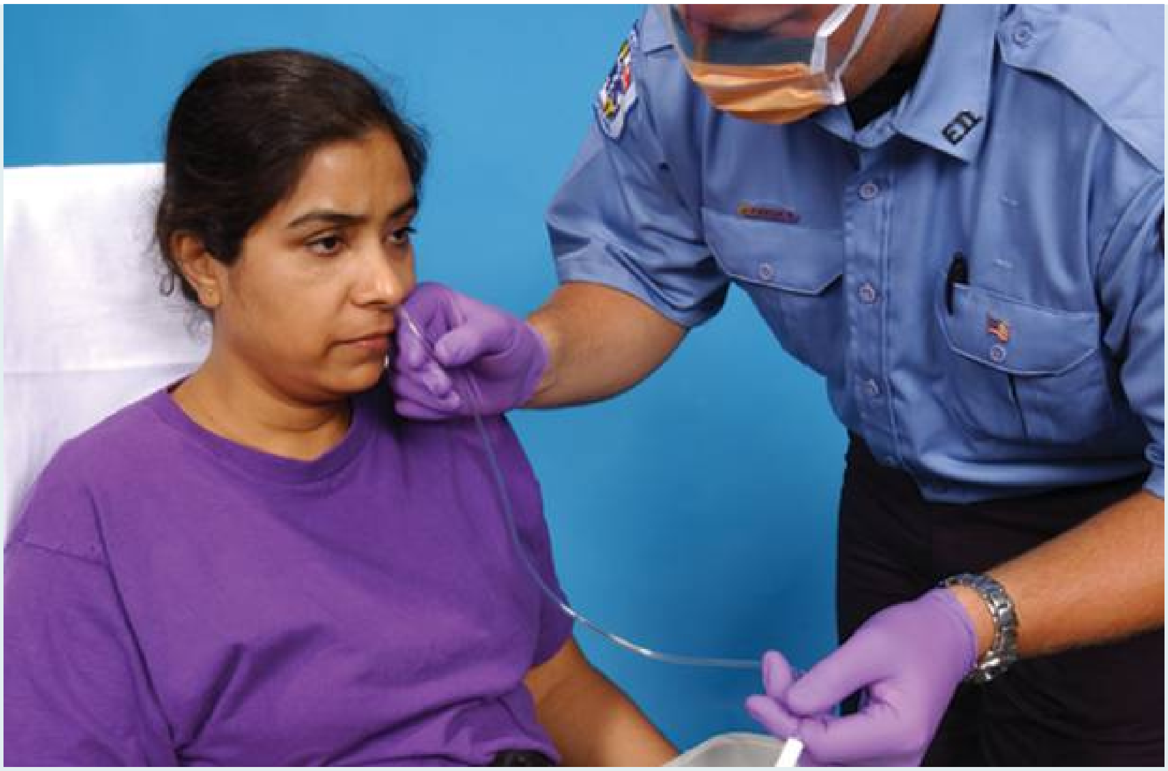
Step 3
Lubricate the tube with a water-soluble gel.



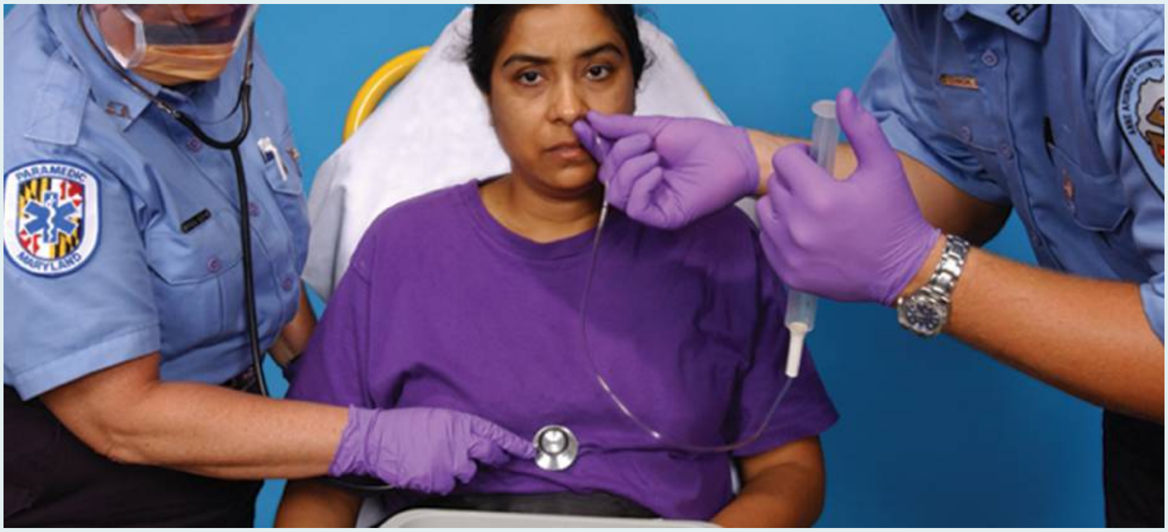
Step 4
Advance the tube gently along the nasal floor.



Step 5
Encourage the patient to swallow or drink to facilitate passage of the tube.



Step 6
Advance the tube into the stomach (to the predetermined point).



Step 7
Confirm proper placement: auscultate over the epigastrium while injecting 30 to 50 mL of air into the tube, and/or observe for gastric contents in the tube. There should be no reflux around the tube.

Step 8
Apply suction (at a low setting) to the tube to aspirate the gastric contents and secure the tube in place.

© Jones & Bartlett Learning.

1. Take standard precautions.
2. Assemble your equipment.
3. Explain the procedure to the patient and oxygenate the patient if necessary. Position the patient in the sitting position. Ensure that the patient's head is in a neutral position and suppress the gag reflex with a topical anesthetic spray, if available **Step 1**.
4. Examine the patient's nose for deformity or obstruction; determine the best side for insertion.
5. If the medication is available and the patient does not have severe hypertension, you may use a topical alpha agonist to constrict the blood vessels in the nares and potentially minimize epistaxis.
6. Measure the tube's insertion, following the anatomic path it will take, from the patient's nose to the earlobe, then down to the xyphoid process.
7. Note the marking on the tube at the nose; this will be the insertion depth **Step 2**.

8. Lubricate 6 to 8 inches (15 to 20 cm) of the tube with a water-soluble gel **Step 3**.
9. Ask the patient to flex their neck, as if attempting to touch the chin to the chest. Gently place your nondominant hand on top of the patient's head to help them maintain this position during insertion.
10. Most NG tubes will have a slight curve from the packaging; use this to your advantage when inserting the tube. With your dominant hand, insert the tube into one nostril. Gently advance the tube toward the posterior nasopharynx **Step 4**. If you feel significant resistance within one nostril, you may pull the tube out and attempt to insert it in the other nostril.
11. When you feel the tube at the nasopharyngeal junction, rotate it 180° inward toward the other nostril if you encounter resistance.
12. Gently advance the tube until it enters the oropharynx, then instruct the patient to swallow **Step 5**. It may help to let the patient know to swallow once they feel the tube touch the back of the throat.
13. Pass the tube to the predetermined point (nose to xiphoid) **Step 6**. Do not force the tube if you encounter resistance. If the patient is choking or coughing excessively, the tube may be in the trachea; in such a case, you should remove the tube and try again. Note that it is not uncommon for patients to vomit during placement of an NG tube. If this happens, pull out the tube to avoid causing aspiration.
14. Check placement of the tube in two ways: auscultate over the epigastrium while injecting about 20 to 30 mL (no more than 50 mL) of air into the tube and/or observe for gastric contents in the tube. There should be no reflux around the tube **Step 7**.
15. Apply suction (at a low setting) to the tube to aspirate the gastric contents and secure the tube in place **Step 8**.

Orogastric Tube Insertion

Use of an OG tube is reserved for patients in whom the airway has been secured. The following equipment is needed to place an OG tube:

- OG tube
- 50-mL irrigation syringe
- Water-soluble lubricant
- Adhesive tape
- Saline for irrigation
- Emesis basin
- Gloves
- Stethoscope
- Low-powered suction unit

Indications for OG tube placement are as follows:

- Decompression of the stomach after intubation
- Pressure of the stomach on the diaphragm

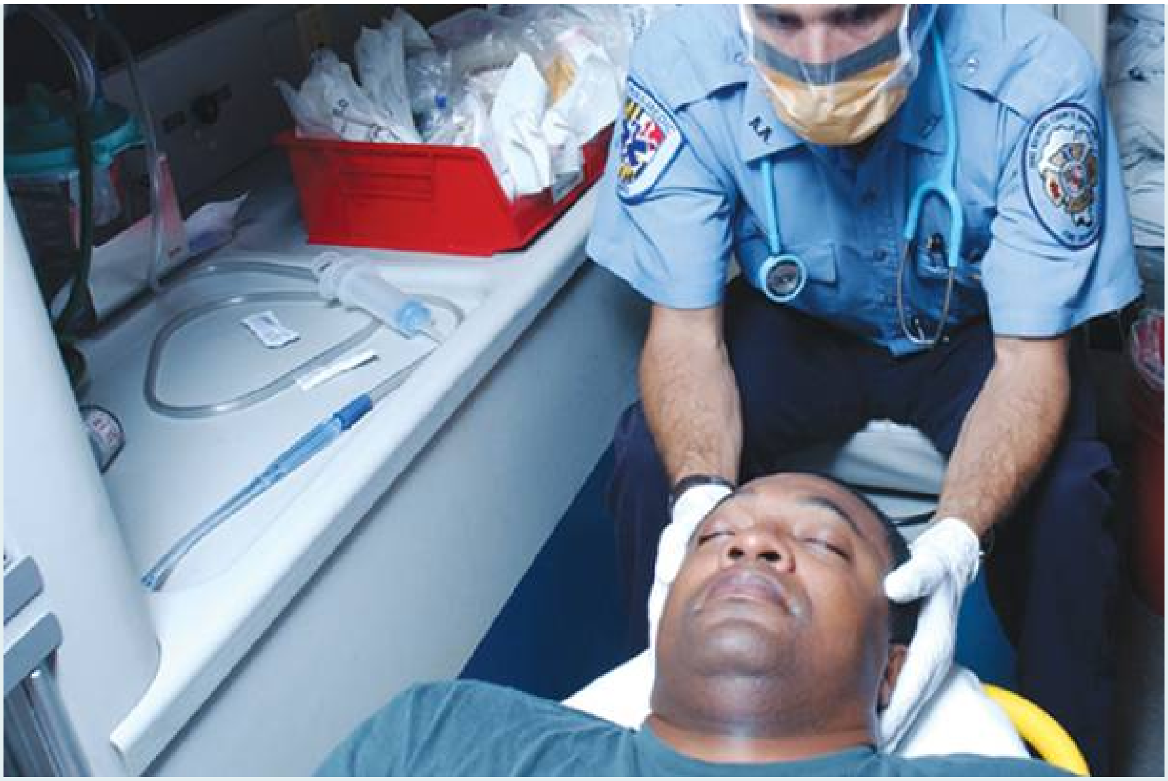
Contraindications to OG tube placement include the following conditions:

- Concern for esophageal tear or rupture
- Severe facial trauma
- Esophageal obstruction

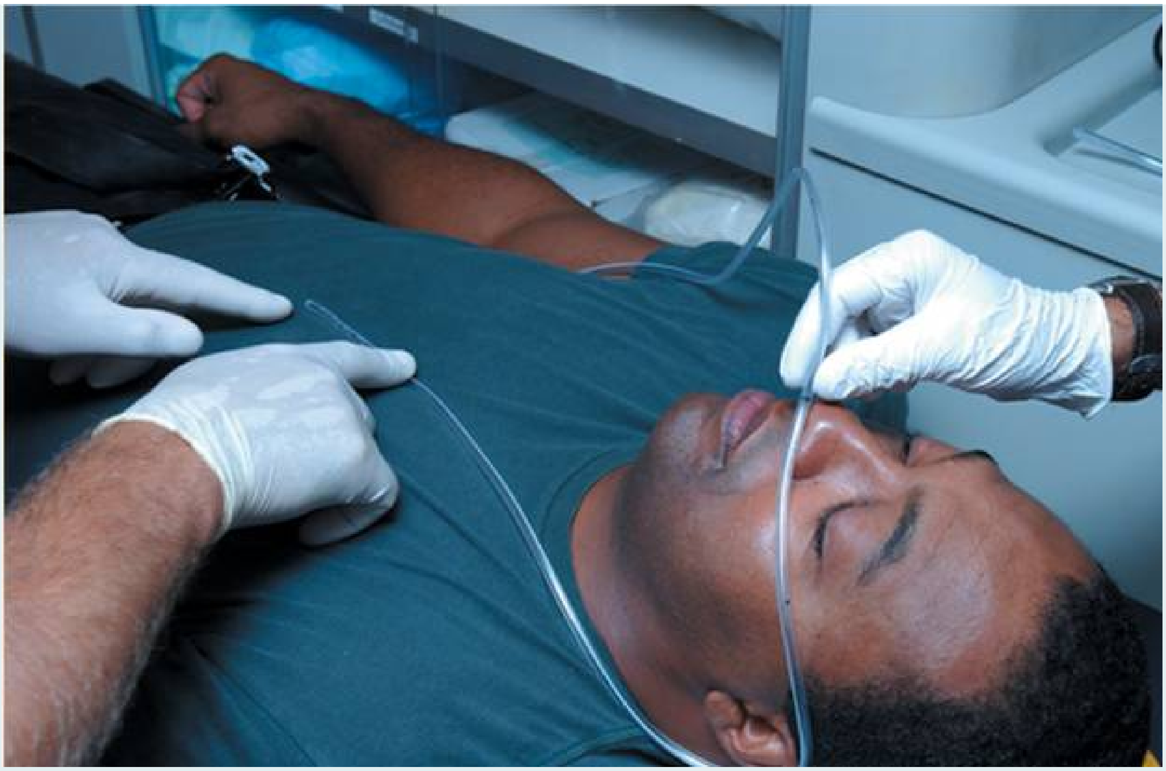
Complications include the patient biting the tube.

Skill Drill 17-2 shows the steps for OG tube placement, which are summarized here:

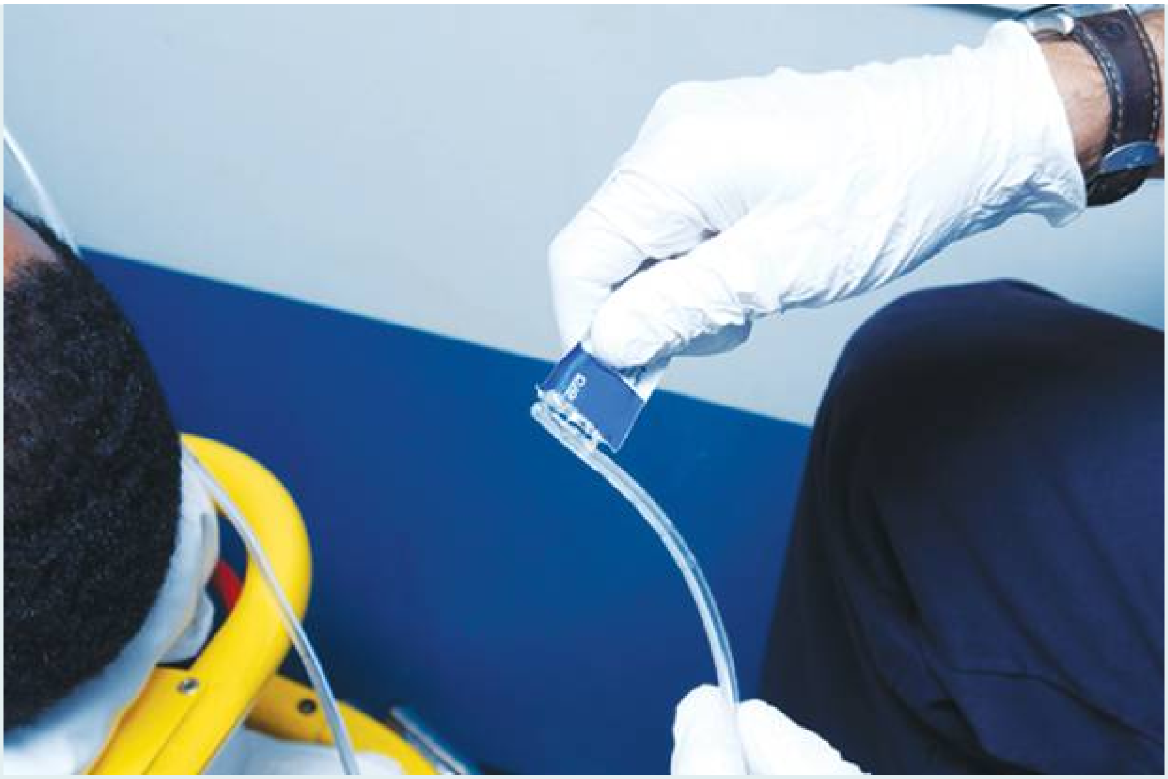
SKILL DRILL 17-2 Orogastric Tube Insertion



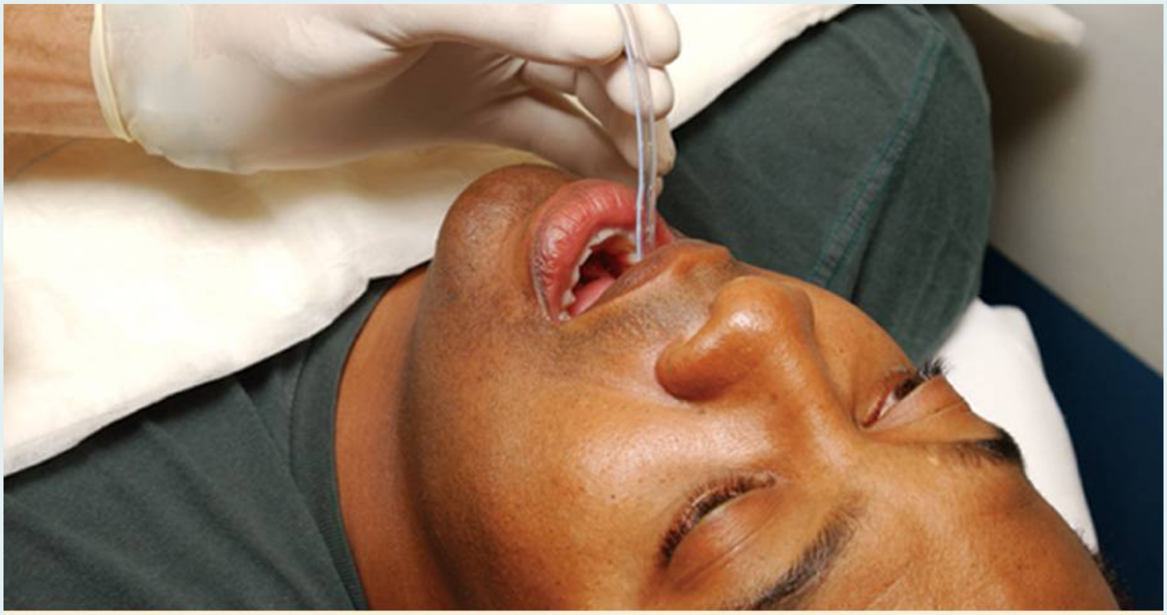
Step 1
Position the patient’s head in a neutral or flexed position.



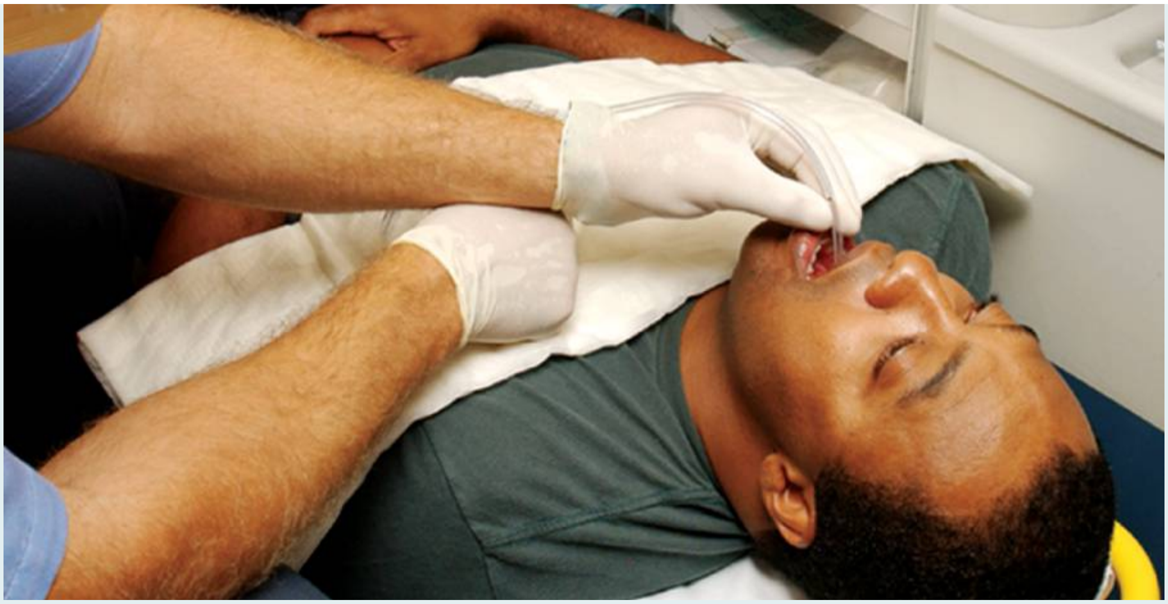
Step 2
Measure the tube for the correct depth of insertion (mouth to ear to xiphoid process).



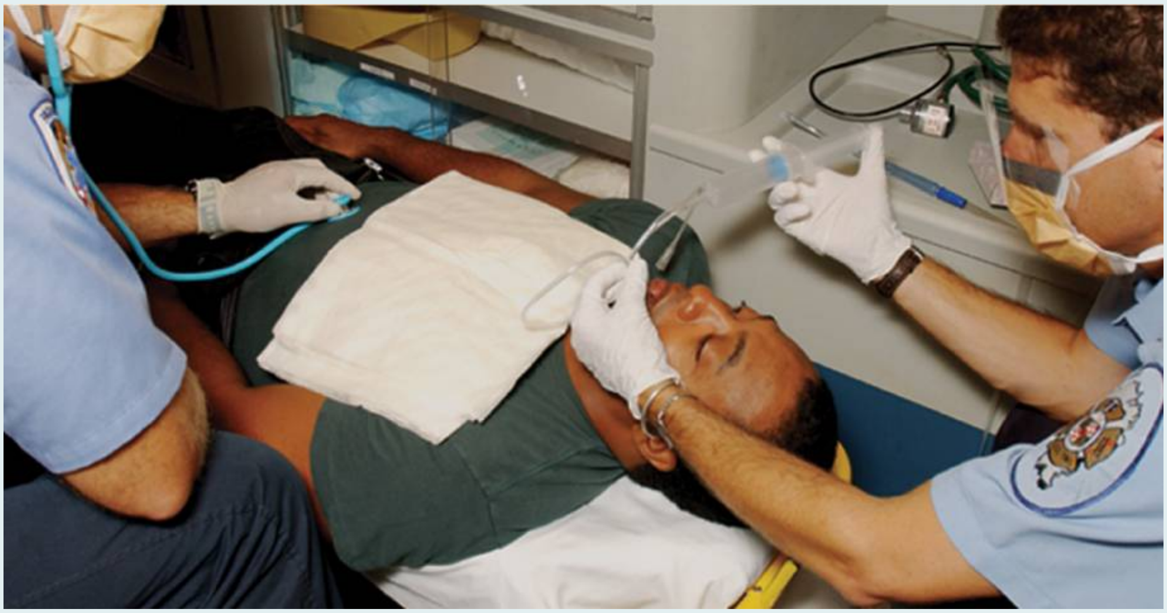
Step 3
Lubricate the tube with a water-soluble gel.



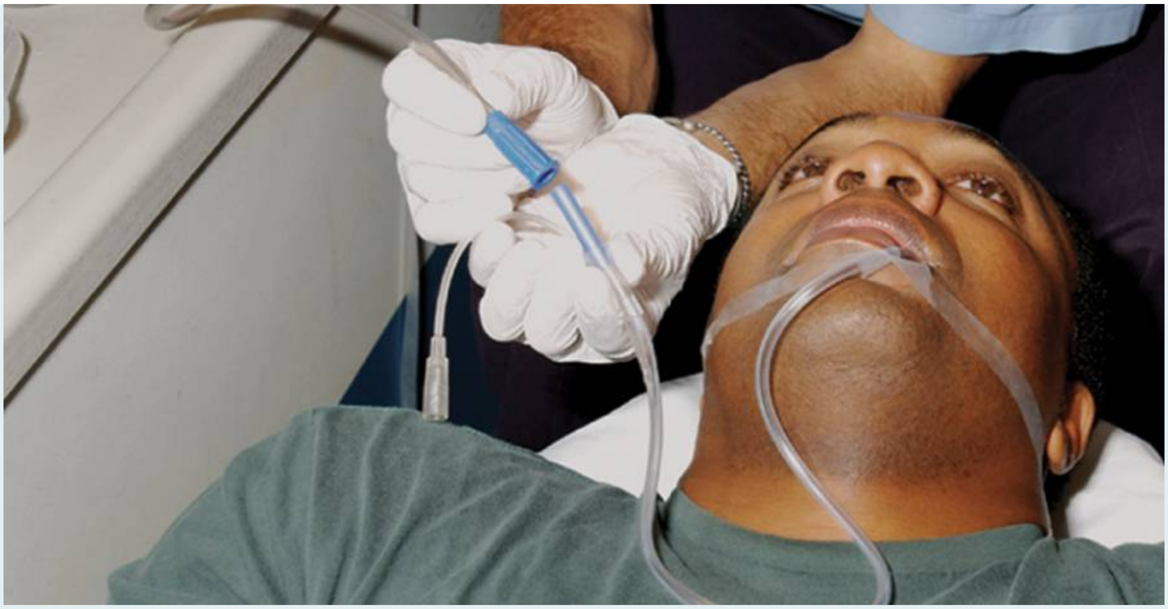
Step 4
Introduce the tube at the midline and advance it gently into the oropharynx.



Step 5
Advance the tube into the stomach.



Step 6
Confirm proper placement: auscultate over the epigastrium while injecting 30 to 50 mL of air and/or observe for gastric contents in the tube. There should be no reflux around the tube.



Step 7
Apply suction to the tube to aspirate the stomach contents and secure the tube in place.

© Jones & Bartlett Learning.

1. Position the patient’s head in a neutral or flexed position **Step 1**.
2. Measure the tube for the correct depth of insertion (mouth to ear to xiphoid process) **Step 2**.
3. Lubricate the tube with a water-soluble gel **Step 3**.
4. Grasp the patient’s mandible using your nondominant hand, pinching with your thumb in the mouth behind the lower teeth and your index finger outside the mouth under the chin to pull the oral tissues out of the way for insertion. Introduce the tube at the midline and advance it gently into the oropharynx **Step 4**.
5. Advance the tube into the stomach **Step 5**.
6. Confirm proper placement: auscultate over the epigastrium while injecting 30 to 50 mL of air and/or observe for gastric contents in the tube. There should be no reflux around the tube **Step 6**.
7. Apply suction to the tube to aspirate the stomach contents and secure the tube in place **Step 7**.

An NG or OG tube may already be in place when the CCTP first encounters the patient, particularly during interfacility transports. In such cases, it is important to ensure that the tube remains properly positioned throughout the transport and to be alert for any potential complications that may arise.

Aspiration is always a concern for patients with an NG or OG tube, whether the tube has been inserted for suction or for feeding. If a patient appears to be in distress with a tube in place, first attempt to ensure the device's proper placement by injecting a small air bolus into the tube while auscultating the epigastrium. If the patient continues to gag or is vomiting, suctioning and removal of the tube may be necessary. The tube can then be reinserted if this procedure is permitted by the CCTP's regional protocols and if the patient's condition allows.

In-Flight Considerations for Intestinal Obstructions

Air transport should be postponed or avoided for any patient with a bowel obstruction if possible. The changes in gas pressure that occur during flight will distend the obstructed bowel, leading to significant pain and possible perforation. If air transport is unavoidable, measures should be taken to provide for air escape proximal to the obstruction, which may accomplished with NG tube placement.

Liver Disease

Considering the amount of vasculature that passes through the liver, it is easy to imagine the far-reaching implications that any injury to this organ could cause. In general, an insult to the liver is either infectious or noninfectious. If the problem resolves within 6 months without any permanent function deficit, it is termed acute. When symptoms persist longer, chronic liver disease has developed. Regardless of the cause, most cases of chronic liver disease have a common ending: cirrhosis.

Epidemiology and Pathophysiology

Types of Liver Disease

Hepatitis, an inflammation of the liver, is the physiologic result of any liver disease. The World Health Organization estimates that viral infection with hepatitis types B and C affects 1 in 3 people worldwide, with 90% of hepatitis-associated fatalities stemming from these infections. Unlike hepatitis A and E, which are typically contracted via the fecal-oral route, hepatitis B, C, and D are transmitted via high-risk sexual behavior or through blood products and are often comorbid with other conditions (eg, human immunodeficiency virus [HIV] infection). Fortunately, hepatitis B can be prevented via vaccination, which has significantly reduced the prevalence of this disease in high-income countries. The remaining 10% of hepatitis cases result from excessive alcohol consumption, autoimmune disorders, toxins, and drugs. Infection by **hepatitis C virus** is especially prominent when the disease becomes a chronic condition, with this infection evolving into chronic hepatitis in 80% of affected people. Hepatitis C accounts for 30% to 45% of all liver transplantations in Europe and the United States.

Fulminant hepatic failure is the result of a sudden significant insult to the liver and is associated with mortality rates ranging from 50% to 90%. The leading causes of fulminant hepatic failure in the

United States are acetaminophen toxicity (46%), idiosyncratic drug reactions (12%), and hepatitis B (7%). This condition is characterized by the acute development of encephalopathy and impaired synthetic function (INR ≥1.5) in a patient without cirrhosis or preexisting liver disease.

Nonalcoholic fatty liver disease (NAFLD), the accumulation of fat in the liver in which alcohol consumption is not believed to be a contributing factor, is the most common liver disorder in Western industrialized countries. Its prevalence is on the rise given its risk factors: central obesity, type 2 diabetes mellitus, dyslipidemia, and metabolic syndrome. Although most patients with NAFLD are asymptomatic, in a subset of patients, the disease can progress to cirrhosis.

Cirrhosis is characterized by irreversible structural changes to the liver that impair its functioning. Once the disease is advanced, the only cure is liver transplantation. The leading cause of cirrhosis in high-income countries is chronic viral hepatitis (hepatitis B or C), followed by alcoholic liver disease, hemochromatosis, and NAFLD. Other causes are responsible for only 5% of cases **TABLE 17-7**. For example, hemochromatosis is a genetic disorder in which increased intestinal iron absorption results in iron overload and accumulation in hepatic tissue.

TABLE 17-7 Causes of Hepatitis and Cirrhosis

Condition	Cause
Hepatitis	Viral Alcohol abuse Autoimmune disorders Toxins Drugs

Condition	Cause
Cirrhosis	Hepatitis C virus Alcoholic liver disease Nonalcoholic fatty liver disease Hepatitis B virus Hemochromatosis Idiopathic

Course of Liver Disease

Inflammation of liver tissue results in damage to a variety of functional cells, including hepatocytes and Kupffer cells. As cells are destroyed, the basic acinar framework involved in blood detoxification and bile production becomes disarranged. Liver sinusoids and bile drainage canals are inflamed, creating an increased resistance to portal blood flow and bile passage. The increased portal resistance to blood flow can progress to portal hypertension, which has significant effects on the body **TABLE 17-8**. Splenomegaly can result from the initial backup of blood, decreasing the effectiveness of the spleen's metabolic processes. Collateral circulation in the mesentery increases as blood attempts to find a low-resistance route to the inferior vena cava, thereby increasing the patient's risk for esophageal or gastric varices. Abdominal **ascites** **FIGURE 17-32** develops as hepatic synthesis of proteins such as albumin decreases and portal hypertension worsens, leading to third spacing of fluid.

TABLE 17-8 Effects of Portal Hypertension

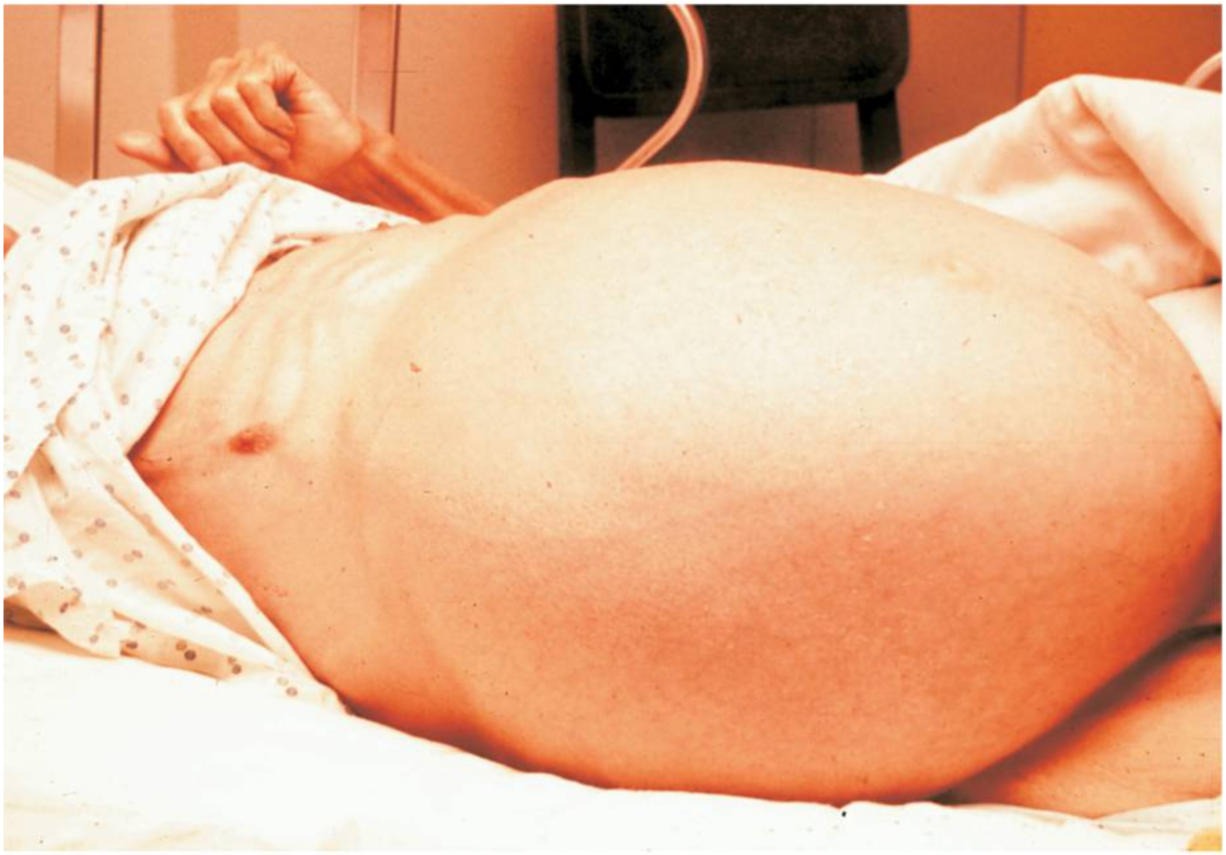

FIGURE 17-32 Marked ascites in a patient with advanced cirrhosis.

Courtesy of Leonard V. Crowley, MD.

Over time, **bilirubin**, which is conjugated and made water-soluble by hepatocytes and excreted via bile, begins to build up in the blood, resulting in jaundice. Pale feces are formed as bilirubin levels decrease in the GI tract. Urine darkens as excess bilirubin is excreted through the renal system.

The lack of proper nitrogen fixation by damaged hepatocytes can lead to an increased concentration of ammonia in the blood. Normally, ammonia is converted to urea by the liver, with urea then being excreted by the kidneys. Placement of an intrahepatic portal shunt in patients with varices tends to increase ammonia levels. Hyperammonemia is thought to be one of the toxic metabolites responsible for **hepatic encephalopathy**, although the overall mechanism is poorly understood. The cognitive deficits associated with hepatic encephalopathy fall on a spectrum, from subclinical changes in concentration to disorientation, somnolence, and ultimately, coma.

In alcoholic liver disease, the liver cells are distended from fat accumulation, disrupting their ability to perform their normal functions. Daily ingestion of more than 1 to 3 ounces (40 to 80 g) of ethanol results in excessive nicotinamide adenine dinucleotide (NADH) production from ethanol oxidation in the liver. Elevated hepatocyte NADH concentrations stimulate triglyceride synthesis; these triglycerides are stored within the cell once produced. The continued fat accumulation over time will result in an enlarged and jaundiced liver.

Cirrhosis develops once hepatocyte damage and destruction become widespread enough to cause local areas of necrotic tissue, such that liver cells attempt to regenerate themselves. During this process, fibroblasts deposit collagen at a disproportionately high rate throughout the extracellular matrix. The increase in inflammation and fibrotic tissue distorts the anatomy of the liver, further impairing its function. This permanent disruption of the liver’s structure, in turn, leads to further inflammation and portal hypertension.

Assessment

Signs and Symptoms

General malaise and fatigue are the most prominent symptoms of early acute hepatitis, due to impaired metabolism and synthesis functions. Portal hypertension results in a series of problems, including ascites and weight gain from abdominal fluid retention, which leads to significant abdominal distention characterized by a “fluid wave.” A combination of decreased hepatic synthesis of coagulation factors and collateral blood flow can create dangerous bleeding, particularly in the GI tract. Chronic shortness of breath can occur not only from impaired diaphragmatic expansion secondary to hepatomegaly, splenomegaly, and ascites, but also from cirrhotic cardiomyopathy (present in as many as 50% of patients with cirrhosis). A neurohormonal cascade caused by portal hypertension and mediated by nitric oxide and prostaglandins results in splanchnic and systemic vasodilation, which decreases cardiac afterload and leads to the loss of peripheral vascular resistance, causing hypotension and tachycardia, often resulting in orthostatic symptoms.

Spontaneous bacterial peritonitis, caused by infection of ascitic fluid, presents with generalized abdominal tenderness and fever. Paracentesis is required for its diagnosis.

Hair loss and gynecomastia are commonly observed as a result of improper hormone metabolism.

Hepatorenal syndrome is characterized by renal injury and renal failure in patients with cirrhosis. In this syndrome, decreased cardiac output and decreased systemic vascular resistance result in a cycle of worsening renal perfusion and renal vasoconstriction. Hepatorenal syndrome may be associated with spontaneous bacterial peritonitis in 25% of cases, a combination that carries a poor prognosis.

Laboratory Data and Imaging

Liver function is assessed by evaluating the presence of the liver’s synthesized products as well as the absence of its cellular enzymes in the blood. Tests for liver function and markers of injury are not identical, however. By the time most lab values become abnormal and symptoms emerge, 60% to 80% of the hepatocytes have already been destroyed.

Albumin is a protein synthesized by the liver that assists in maintenance of osmotic fluid balance in the body. Decreased production of albumin results in the peripheral edema, ascites, and pulmonary edema observed in patients with liver failure. Elevated serum levels of bilirubin signal the presence of hepatocyte insufficiency and are a reliable indicator of the severity of liver damage. A prolonged PT and INR are the result of decreased vitamin K–dependent clotting factor synthesis by the liver.

The Model for End-Stage Liver Disease (MELD) score is a validated score that predicts mortality in patients with liver disease **TABLE 17-9**. It incorporates serum sodium, bilirubin, creatinine, and INR levels. This score is often used to determine candidacy for liver transplantation.

TABLE 17-9 Criteria Used to Determine MELD Score

Dialysis at least twice in the last week (yes or no)

© Jones & Bartlett Learning.

Release of enzymes specific to hepatocytes into the bloodstream can be detected through laboratory testing and is useful as a marker of the existence and progression of liver disease. These enzymes include aspartate aminotransferase (AST), alanine aminotransferase (ALT), and gamma-glutamyltransferase (GGTP or GGT). Elevated serum levels of any of these three enzymes can suggest hepatic insult, with increases in ALT being the most specific to the liver. For example, AST may be elevated from nonhepatic causes, in cases of hemolysis or myopathy. Elevated GGT and bilirubin out of proportion with AST and ALT suggests cholestasis secondary to a biliary obstruction, particularly in conjunction with elevated alkaline phosphatase (AP). A ratio of AST:ALT greater than 2 is strongly suggestive of alcoholic liver disease.

In patients presenting with an altered mental status, a blood glucose test can reveal hypoglycemia from decreased glucose metabolism and glycogen storage secondary to hepatocyte injury. Elevated serum ammonia concentrations from decreased nitrogen fixation in the damaged liver can result in hepatic encephalopathy. Increased levels of blood urea nitrogen (BUN) and serum creatinine indicate impaired renal function and may suggest hepatorenal syndrome.

TABLE 17-10 emphasizes the many metabolic and synthetic functions that are disrupted in liver dysfunction. Although no imaging studies are necessary to diagnose hepatitis, they can prove valuable in differentiating hepatitis from similarly presenting diseases. Cirrhosis, particularly if advanced, may be visualized across various imaging modalities (CT, magnetic resonance imaging [MRI], ultrasonography). Ascites is often identified as free fluid in the abdomen **FIGURE 17-33**.

TABLE 17-10 Normal Versus Abnormal Laboratory Values in Liver Disease

Test	Normal	Abnormal
Albumin	3.5–5.0 g/dL	↓
Bilirubin, serum (direct, conjugated)	0.1–0.3 mg/dL	↑
Bilirubin, total	0.3–1.2 mg/dL	↑
Prothrombin time	10–13 s	↑
Alkaline phosphatase	30–120 U/L	↑

Test	Normal	Abnormal
Serum ammonia	10–80 µg/dL	↑
Blood glucose	70–110 mg/dL	↓
Blood urea nitrogen	8–23 mg/dL	↑
Creatinine, serum	0.6–1.2 mg/dL	↑
Liver Enzymes		
Aspartate aminotransferase	10–30 U/L	↑
Alanine aminotransferase	10–40 U/L	↑
Gamma-glutamyltransferase	2–30 U/L	↑

Abbreviations: ↑, above normal values; ↓, below normal values

Management

Treatment of hepatitis focuses on primary prevention (eg, public health and sanitation measures, vaccination programs) and prevention of further injury in an attempt to halt the progression to cirrhosis. In patients with infectious hepatitis, antiviral and interferon drugs are administered to suppress the viral load. Many of these drugs are used in the treatment of HIV infection as well. Pharmacologic treatment of hepatitis is an active topic of research, and usage of specific medications will vary between institutions.

Care for patients with fulminant hepatic failure and end-stage cirrhosis is largely supportive, mainly concentrating on preventing and correcting any complications. In more severe cases of liver disease, neurologic function and arousal may be diminished, requiring airway management. Efforts to prevent encephalopathy focus on decreasing GI absorption of ammonia or ammonia-producing bacteria with lactulose or rifaximin, respectively. Third spacing secondary to hypoalbuminemia can cause hypotension and is treated with fluid resuscitation. Severe hypotension and hepatorenal syndrome may require vasopressor therapy, along with administration of albumin. ECG monitoring enables the CCTP to observe the patient for arrhythmias from electrolyte imbalances, especially hypokalemia. Patients should also be monitored for evidence of GI bleeding, renal failure, and encephalopathy. Avoidance of alcohol and hepatotoxic medications is essential. In many cases, dosages of common medications must be reduced in anticipation of decreased hepatic metabolism.

Prevention of ascites through a low-sodium diet, fluid restriction, and diuretics is often necessary in patients with cirrhosis, with an eye toward maintaining BP. **Paracentesis**, "tapping" of the abdomen with a needle, can be used to aspirate ascitic fluid from the abdomen as a therapeutic modality, because accumulation of this fluid can approach several liters per day. This procedure is also performed, albeit by collecting only a small quantity of fluid, to diagnose spontaneous bacterial peritonitis, which requires aggressive antimicrobial therapy.

There is no cure for hepatitis or its resultant cirrhosis other than liver transplantation. Liver transplantations have a fairly high success rate, although patients with hepatitis C commonly have graft infection and as many as 30% will have cirrhosis again within 5 years. Unfortunately, as with other organs, there is vastly greater demand for liver transplants than there is supply. In addition, individuals with cirrhotic liver disease are at increased risk of developing hepatocellular carcinoma.

Signs and Symptoms

Liver Disease

- Jaundice

- Dark urine
- Clay-colored feces
- General malaise
- Fever and chills
- Ascites
- Weight gain
- Easy bleeding
- Melena, hematochezia
- Shortness of breath
- Hypotension
- Tachycardia
- Hair loss
- Cognitive disorders
- Spider angiomas
- Hypoglycemia

Differential Diagnosis

Liver Disease

- Acute hepatitis
- Cholestasis
- Acute hepatic failure
- Chronic hepatitis
- Cirrhosis
- Hepatomegaly
- Liver mass or cancer
- Jaundice (icterus)
- Spontaneous bacterial peritonitis

Transport Management

Liver Disease

- Manage the airway.
- Provide vasopressors and fluid resuscitation as needed.

- Monitor the ECG.
- Monitor for GI bleeding, renal failure, and encephalopathy.
- Avoid medications that are metabolized by the liver.

Biliary Tract Obstructions

Blockage of the biliary system at any point will result in a backup of bile and possibly, depending on the location of the obstruction, pancreatic enzymes. These digestive juices accumulate first in the tracts, and then in the organs from which they originated. The damage caused by this type of obstruction is twofold. Distal to the obstruction, normal digestive processes of the GI system are disrupted, while proximally, the accessory organs and ducts become distended and inflamed.

Epidemiology and Pathophysiology

Most often, the biliary tract system is obstructed by a migrating gallstone. Gallstones in the gallbladder, a condition termed **cholelithiasis**, affect approximately 10% of Americans each year **FIGURE 17-34**. They can form one of two ways: through accumulation of excess cholesterol in the bile (cholesterol stones) or through accumulation of excess bilirubin and calcium salts in the bile (pigment stones). Both etiologies result in the crystallization of bile into stones, which may range in size from small grains to the size of a golf ball. Cholesterol stones account for the majority of gallstone cases in the United States, with the remainder accounted for by pigment and mixed stones. Notably, patients with cirrhosis are at higher risk for pigment stones.

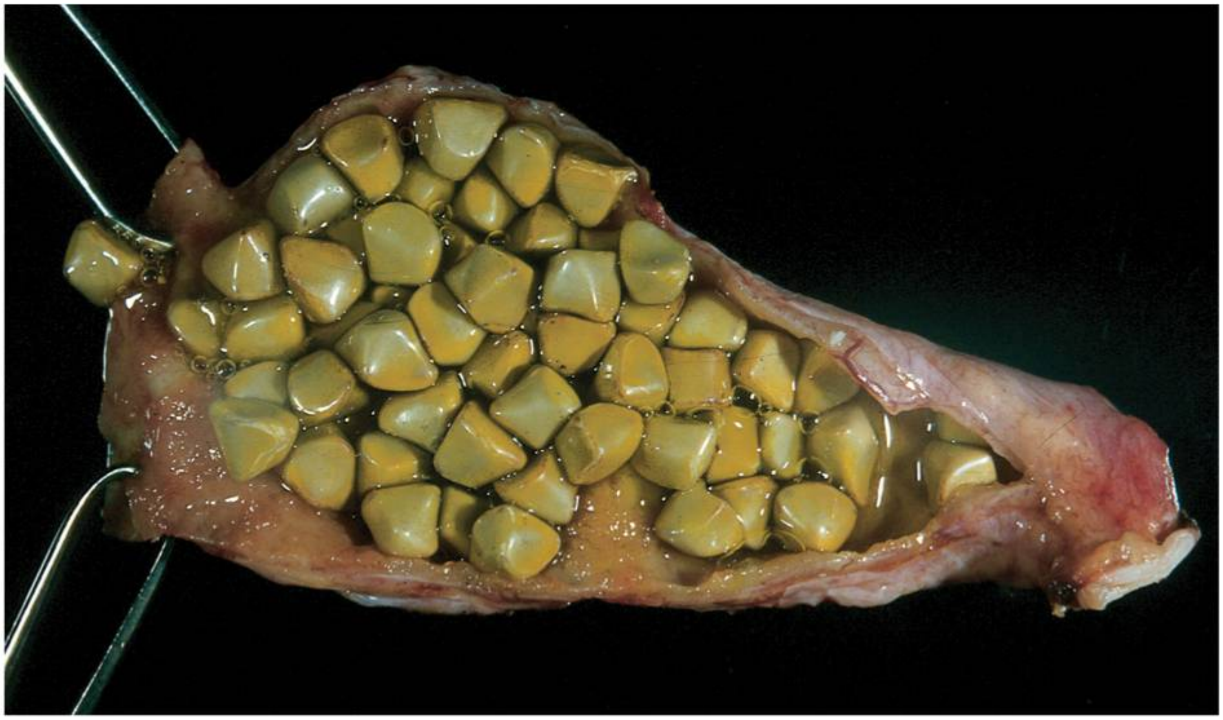

FIGURE 17-34 Open gallbladder filled with gallstones composed of cholesterol.

Courtesy of Leonard V. Crowley, MD.

Inside the gallbladder, stones that block the outflow of bile may cause distention and inflammation of the gallbladder itself, known as **cholecystitis**. When the stone becomes impacted inside the biliary ducts, the condition is termed **choledocholithiasis**. The stone may begin to travel into the cystic duct at any time, lacerating the inner walls as it moves. Frequently, it will lodge in either the cystic duct or the distal common bile duct. If the stone lodges in the common bile duct and fully obstructs the lumen, both bile and pancreatic juice will be unable to pass into the duodenum. As pancreatic enzymes accumulate proximal to the obstruction, they will begin to digest the tissues of both the ducts and the pancreas. This autodigestion leads to **gallstone pancreatitis**, a condition responsible for almost one-half of all cases of pancreatitis. As enzymes and bile leak through the compromised duct lining, peritonitis can occur and eventually lead to a systemic inflammatory response and shock.

Assessment

Signs and Symptoms

Cholecystitis causes colicky pain in the right upper quadrant of the abdomen. In some people, this pain can be localized more in the epigastrium and may mimic heartburn. Cholecystitis pain tends to emerge following ingestion of high-fat foods because fatty chyme stimulates gallbladder contraction. Due to the pain, a patient with this condition will exhibit a positive **Murphy sign**, or sudden arrest of inspiration when constant pressure is applied to the right upper quadrant.

Patients with choledocholithiasis have blockage of biliary outflow not only from the gallbladder, but also from the liver. Obstructive jaundice soon follows in these patients, who are at higher risk of developing a rapidly progressive infection called ascending **cholangitis**. This process is typically characterized by fever, jaundice, and right upper quadrant pain, which are collectively known as **Charcot triad**. Nausea and vomiting frequently accompany Charcot triad. As the condition progresses, these individuals develop altered mental status and shock.

Laboratory Data and Imaging

Bilirubin, a product of heme breakdown, may be elevated for a variety of reasons, ranging from hemolysis (unconjugated bilirubin) to intrahepatic cholestasis or cholelithiasis (conjugated bilirubin). A good framework for remembering how bilirubin becomes elevated is to consider whether it is accumulating before or after hepatic processing (conjugation). The effects of biliary obstruction can be observed through elevations of serum values indicating blocked secretions from the gallbladder and pancreas. Serum bilirubin levels increase, along with serum amylase and lipase, if pancreatic obstruction is also occurring. AP and GGT levels will be elevated. Over time, PT will increase as vitamin K absorption decreases owing to a lack of bile in the GI tract. If infection is present, such as in cholangitis, white blood cell levels and inflammatory markers will increase as well.

Transabdominal ultrasonography is a useful first test for evaluating patients with upper abdominal pain due to its low cost, lack of ionizing radiation, and extremely high sensitivity for cholelithiasis when a stone is visualized and the patient exhibits the Murphy sign. CT is often used as an alternative to ultrasonography, as it is also highly sensitive for cholecystitis and can be used to identify other pathologies at the same time. In addition to providing for the direct visualization of stones, ultrasonography can detect distention proximal to the obstruction, especially in the common bile duct. The presence of a dilated common bile duct is suggestive of a stone migrating beyond the gallbladder and obstructing the biliary tract more distally (choledocholithiasis). This finding may change the management from a cholecystectomy to an endoscopic retrograde cholangiopancreatography. Some patients may undergo endoscopic ultrasonography in an attempt to visualize impacted stones.

Endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTC) are two methods of cholangiography that have excellent accuracy in detecting choledocholithiasis. They are both diagnostic and therapeutic. Both involve injection of contrast into the biliary duct system to observe the obstruction. PTC is typically performed if ERCP is unsuccessful. Endoscopists are able to extract obstructing stones while using these techniques; however, these procedures are not used as an initial diagnostic strategy given the risk of complications such as perforation or pancreatitis. An alternative to ERCP, magnetic resonance cholangiopancreatography (MRCP), is noninvasive and permits visualization of stones anywhere in the biliary system. Cholescintigraphy is another modality that involves injection of radioactive dye and subsequent evaluation for cholelithiasis of the cystic duct by noting the progress (or lack thereof) of the dye into the gallbladder.

Management

Immediate treatment of gallstone disease involves pain management once general treatment has been provided. Because evidence has suggested that opioids can increase pressure at the sphincter of Oddi, NSAIDs are the treatment of choice. Providers may escalate pain relief treatment to opioids in patients with contraindications to NSAIDs and in those who do not obtain adequate relief from NSAIDs.

Definitive treatment occurs at the hospital and focuses on removal of the stone or obstruction (if it is a tumor or other structural abnormality). ERCP is frequently used to remove the stone after fulfilling its diagnostic role. **Lithotripsy** can break apart larger stones through external vibrations, facilitating their subsequent removal by ERCP or percutaneous transhepatic cholangiography. A sphincterotomy is often performed to allow the stones to pass into the duodenum, where they can be caught with a basket or catheter. Cholecystectomy will generally be performed in patients with cholecystitis or to prevent recurrence of choledocholithiasis.

Signs and Symptoms

Biliary Tract Obstruction

- Charcot triad
  - Fever
  - Jaundice
  - Right upper quadrant pain
- Nausea and vomiting
- Clay-colored feces
- Murphy sign: exquisitely tender right upper quadrant

Differential Diagnosis

Biliary Tract Obstruction

- Appendicitis
- Cholecystitis
- Cholangitis
- Gastritis
- Peptic ulcer disease
- Hepatitis
- Inflammatory bowel disease

- Pancreatitis
- Biliary stricture
- Choledocholithiasis
- Pancreatic tumor
- Choledochal cyst

Transport Management

Biliary Tract Obstruction

- Provide oxygen as required.
- Place an IV line.
- Monitor the ECG.
- Provide analgesia.

Pancreatic Disease

Epidemiology and Pathophysiology

Inflammation of the pancreas, known as **pancreatitis**, can lead to significant impairment of GI physiology depending on its level of severity and etiology. The most common causes of pancreatitis are gallstones (40% to 70%) and alcohol abuse (25% to 35%), with the remainder of cases resulting from idiosyncratic drug reactions, ERCP, tumors, hypertriglyceridemia, hypercalcemia, and congenital defects **TABLE 17-11**. Most cases are mild, self-resolving in 3 to 4 days with a very low mortality. Pancreatic necrosis occurs in approximately 15% of patients, likely due to dysregulated caustic secretions. Approximately 20% of patients will eventually present with **systemic inflammatory response syndrome (SIRS)** and organ dysfunction, marking a shift to severe acute pancreatitis, which has a mortality rate of approximately 10%.

Systemic inflammatory response syndrome

Abbreviation: ERCP, endoscopic retrograde cholangiopancreatography
© Jones & Bartlett Learning.

Chronic pancreatitis is characterized by the presence of irreversible anatomic changes to the pancreas, along with some degree of function loss. Alcohol use disorder and smoking are major risk factors for this condition, although the exact pathological mechanisms are not completely understood. Pancreatitis is more likely to develop in men than in women, and idiopathic chronic pancreatitis accounts for 10% to 30% of all cases.

The inflammatory process in pancreatitis evolves in response to autodigestion of the pancreatic tissue **FIGURE 17-35**. Pancreatic enzymes are normally produced as inactive precursors, which then become activated in the GI lumen. When these enzymes become prematurely activated inside either the pancreas or the ducts that drain the secretions, they immediately begin digesting the surrounding tissues. Because of the retroperitoneal location of the pancreas, the activated enzymes can easily spread throughout the peritoneum as well as to other retroperitoneal organs. Once digestion of the pancreatic blood vessels begins, hemorrhaging occurs. As the disease progresses, tissue necrosis will occur. In addition to forming local fluid and necrotic collections, the resulting necrotic tissue is susceptible to bacterial infection, such that spontaneous infections of the pancreas or peritoneum frequently occur.

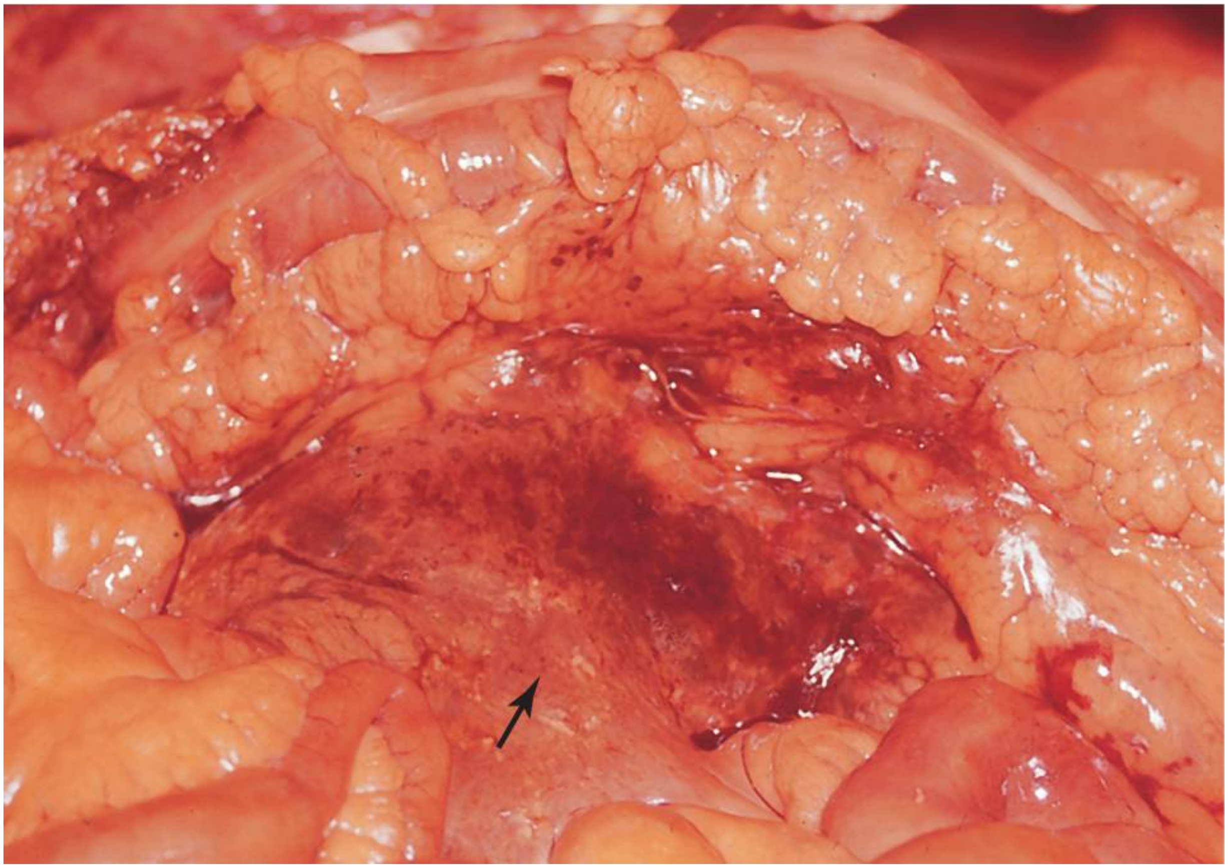

FIGURE 17-35 Acute pancreatitis. The transverse colon (upper part of the photograph) has been elevated to reveal the pancreas (arrow), which is inflamed and contains large areas of hemorrhage.

Courtesy of Leonard V. Crowley, MD.

Pancreatic pseudocysts are walled-off aggregates of cellular debris and extracellular pancreatic enzymes that sometimes form more than 4 weeks after the onset of acute pancreatitis. The cytokine cascade that ensues following pancreatic inflammation and digestive enzyme dysregulation manifests clinically as SIRS. This condition puts patients at risk for failure of one or more organs. Pulmonary complications may include arterial hypoxemia, atelectasis, pleural effusions, pneumonia, and acute respiratory distress syndrome. Fluid shifts and enzyme-induced vasodilation can cause hemodynamic instability and shock. The resultant decrease in organ perfusion can lead to acute renal failure. Diffuse intravascular coagulation can develop, further exacerbating organ dysfunction and shock.

Assessment

Signs and Symptoms

Severe upper abdominal pain is the primary symptom of pancreatitis. This pain may radiate throughout the abdomen and to the back depending on the level of pancreatic involvement. Patients will have abdominal guarding, with rigidity if peritonitis has developed. Nausea and vomiting are common. Fever will be present secondary to the body's immune response against the infectious complications of pancreatitis. Depending on the severity of pancreatitis, patients may be tachycardic, hypotensive, and/or hypoxemic. Discoloration of the low back and flank, known as Turner sign, and periumbilical discoloration, known as Cullen sign, are both rare and nonspecific findings of the retroperitoneal hemorrhage that may occur in severe pancreatitis. If biliary tract obstruction is the cause of the pancreatitis, the patient may exhibit jaundice.

Laboratory Data and Imaging

As the pancreatic cells are destroyed or the walls of ducts are digested, pancreatic-specific enzymes are released into the bloodstream. Serum lipase and amylase levels are the most sensitive indicators; they are frequently elevated to more than three times their normal levels in acute pancreatitis **TABLE 17-12**. Serum lipase has a higher specificity and levels remain higher for longer than amylase, making it the lab test of choice for pancreatitis. Although elevated levels of these two enzymes support a diagnosis of pancreatitis, higher levels of amylase can result from several other conditions as well.

TABLE 17-12 **Normal Versus Abnormal Laboratory Values for Pancreatitis**

Test	Normal	Abnormal
Amylase, serum	27–131 U/L	↑

Test	Normal	Abnormal
Lipase, serum	31–186 U/L	↑
Aspartate aminotransferase	10–30 U/L	↑
Alanine aminotransferase	10–40 U/L	↑
Gamma-glutamyltransferase	2–30 U/L	↑
Leukocytes (white blood cells)	4,500–11,000/μL	↑

Abbreviation: ↑, above normal values

© Jones & Bartlett Learning.

Liver function testing for ALT/AST, AP, GGT, and serum bilirubin can help rule out other causes of abdominal pain and may indicate a biliary tract origin of disease. An elevated leukocyte count indicates the presence of infection, inflammation, or both.

A CT scan with contrast can visualize pancreatic necrosis, peripancreatic abnormalities, abscesses, and the overall size of the pancreas. It has 90% specificity and is invaluable for determining disease severity. For the detection of gallstones in the bile duct, MRCP has a 90% accuracy rate. ERCP is an alternative to MRCP in patients with pancreatitis with a suspected biliary origin. In addition to supporting a diagnosis, ERCP can be used to simultaneously treat the patient if sphincterotomy and gallstone removal are necessary.

Visualization of the pancreas by abdominal ultrasonography is often obstructed by intestinal gas and adipose tissue; hence, this imaging modality performs poorly in identifying pancreatitis. When combined with endoscopy, however, it becomes a useful bedside procedure that can assist in the diagnosis of both pancreatitis and gallstones.

Management

General treatment of pancreatitis includes supportive care such as supplemental oxygen administration, analgesia, and ECG monitoring. Large-bore IV access is recommended, as fluid replacement is a priority in patients with hypotension and tachycardia. Isotonic crystalloid boluses of 20 mL/kg are recommended, with careful attention to urinary output (>0.5 to 1 mL/kg/h).

All patients with pancreatitis should be placed on NPO restrictions to prevent increased stimulation of pancreatic enzyme synthesis and secretion. In severe cases, nasojejunal tube feeding may be required. Pain management is necessary to avoid additional hemodynamic instability, and may take the form of IV opioids or IV patient-controlled analgesia devices.

Once the patient has entered the hospital, specific treatment of acute pancreatitis focuses on preventing complications and decreasing pancreatic workload. Prophylactic antibiotic administration is not recommended in patients with acute pancreatitis.

Signs and Symptoms

Pancreatitis

- Upper abdominal pain
- Tenderness and guarding of the abdomen
- Tachycardia
- Nausea, vomiting
- Fever
- Turner sign (discoloration of the low back and flank)
- Cullen sign (periumbilical discoloration)
- Jaundice
- Hemodynamic instability
- Shock

Differential Diagnosis

Pancreatitis

- Cholecystitis
- Cholangitis
- Gastritis

- Hepatitis
- Bowel obstruction
- Pancreatic cancer

Transport Management

Pancreatitis

- Administer supplemental oxygen if needed.
- Place an IV line.
- Monitor the ECG.
- Replace fluids in patients with hypovolemia.
- Monitor fluid output.
- Provide analgesia.

Urinary System Conditions

Conditions affecting the urinary system include renal failure, urinary tract infections, nephrolithiasis, testicular torsion, ovarian torsion, penile fracture, ruptured ovarian cysts, and priapism. This section discusses all of these conditions, except ovarian torsion and ovarian cysts, which are discussed in Chapter 22, *Obstetric and Gynecologic Emergencies*.

Kidney Injury

Epidemiology and Pathophysiology

The nephron, the structural and functional unit of the kidney, requires a consistent gradient of fluid flowing across its membranes to function optimally. Significant decreases in renal perfusion pressure disrupt the elimination of waste from the bloodstream by lowering the glomerular filtration rate. Furthermore, the tissues of the kidney are inherently sensitive to hypoperfusion and hypoxia. An acute decrease in glomerular filtration in a patient without preexisting renal dysfunction is termed **acute kidney injury (AKI)**. Most instances of AKI are sudden and usually reversible, and they are accompanied by a rise in serum sodium, creatinine, BUN, and other metabolic waste products. Hospitalized patients are commonly found to have some level of AKI, and this condition is especially common in patients treated in the intensive care unit. Disproportionately higher mortality rates are observed in patients with AKI in the intensive care unit compared with the general patient population. As with most disease processes, AKI exists on a spectrum of severity, with mild cases often being managed in the outpatient setting. The downstream effects of severe AKI, such as volume overload and electrolyte disturbance, tend to exacerbate the challenges of caring for a critically ill patient.

AKI is classified in terms of its location as prerenal, intrarenal, or postrenal. **TABLE 17-13** summarizes the causes and types of AKI.

TABLE 17-13 Causes and Types of Acute Kidney Injury

Type	Cause
Prerenal	Hypovolemia Dehydration Congestive heart failure Hepatorenal syndrome Third spacing Systemic inflammatory response syndrome Shock of any etiology Medications
Intrarenal	Acute tubular necrosis Interstitial nephritis Glomerulonephritis Medications
Postrenal	Renal calculi Blood clots Tumors Prostate obstruction Malfunctioning urinary catheter

© Jones & Bartlett Learning.

Prerenal AKI is the most common type, implicated in as many as two-thirds of cases. This condition is associated with many reversible causes and, if treated promptly and appropriately, can be corrected in as many as 90% of cases. Hypovolemia and intravascular volume depletion secondary to dehydration or blood loss often cause prerenal AKI, as does hepatorenal syndrome (in patients with cirrhosis). SIRS and shock states decrease renal perfusion and are almost always associated with AKI. Conversely, increased venous congestion and hypotension from congestive heart failure will also reduce the gradient of pressure, and thus perfusion, across the nephrons. A variety of medications, including angiotensin-converting enzyme (ACE) inhibitors and diuretics, can decrease renal perfusion through both intrinsic kidney injury (intrarenal AKI) and excess volume depletion.

One of the earliest signs of prerenal AKI is oliguria, a reduction in urine volume to less than 400 mL/d. The body's attempt to conserve water results in a decreased GFR, which in turn translates to a decrease in fluid volume entering the reabsorption tubules. The kidneys attempt to increase renal perfusion pressure by increasing solute (eg, sodium) reabsorption, which draws water back into the systemic circulation. In patients with severe hypoperfusion, the body's compensatory mechanisms for maintaining BP prioritize perfusion of the heart and brain, thereby worsening the situation for the kidneys. Any vasoconstrictive effort (via vasopressors) will further decrease renal perfusion. Eventually, the decreased renal perfusion will result in tissue ischemia, injury, and necrosis. When the tubules become necrotic, they lose their ability to perform ion exchange, which prevents proper urine formation. Inflammation and extensive shedding of dead tissue will further decrease the flow rate.

In contrast to the process just described, in situations where cardiac dysfunction results in renal hypoperfusion, vasopressor medications will actually improve renal perfusion and overall kidney function. This is sometimes referred to as cardiorenal syndrome.

Intrarenal, or intrinsic, AKI is classified as a structural injury to the kidney itself. **Acute tubular necrosis**, the most common cause of intrarenal AKI, is usually a result of renal ischemia or the presence of a toxin. Over time, a prolonged insult, such as untreated prerenal AKI, may also transition to cellular damage and acute tubular necrosis. Interstitial nephritis commonly results from adverse reactions to medications, such as antibiotics, NSAIDs, and diuretics. Contrast-induced nephropathy has been an area of intense controversy and research. Although once thought to be nephrotoxic, modern contrast dyes have not been shown to cause clinically meaningful kidney injury.

In glomerulonephritis (another cause of intrarenal AKI), glomerular tissue becomes inflamed secondary to an immune response. Glomerulonephritis is a collective term covering approximately 20 glomerular conditions, with rapidly progressive glomerulonephritis being a severe form that impairs renal function. It is characterized by hematuria, initially on a microscopic level but progressing to visible quantities of blood in the urine and accompanied by proteinuria and hypertension. Postinfectious causes are frequently implicated in glomerulonephritis, especially group A beta-hemolytic *Streptococcus* infection following pharyngitis. Other precipitators of glomerulonephritis include immunoglobulin A nephropathy and systemic lupus erythematosus.

Postrenal AKI occurs when urine flow distal to the nephrons becomes obstructed. The least frequently observed of the three types of AKI, this condition is associated with ureteral or urethral blockage by renal calculi, blood clots, or lumen-penetrating tumors. It is also seen in prostatic hypertrophy and can occur as a result of a malfunctioning urinary catheter. Anuria (absence of any urine output) is typically a result of obstruction at the urethra or the bladder, as both ureters would require simultaneous blockage to cease all urine flow. Large kidney stones tend to obstruct in the distal ureter (near the ureterovesical junction) and can cause backup of urine in the blocked kidney. This kind of total obstruction leads to severe pain, disrupts the kidney's normal architecture (termed hydronephrosis), and sometimes induces urosepsis.

A gradual decrease in renal function over a long time is known as **chronic kidney disease (CKD)**. The hallmark of CKD is an irreversible destruction of nephrons brought about by the continuous effects of several disease processes, including diabetes mellitus, hypertension, and autoimmune disorders. Over time, CKD progresses to **end-stage renal disease (ESRD)**, at which point dialysis is needed to replace renal function. Patients may receive dialysis via different modalities, each with its own risks and benefits. By far the most common approach is intermittent hemodialysis (IHD) **FIGURE 17-36**. These therapies are discussed later in this chapter, in the management section.

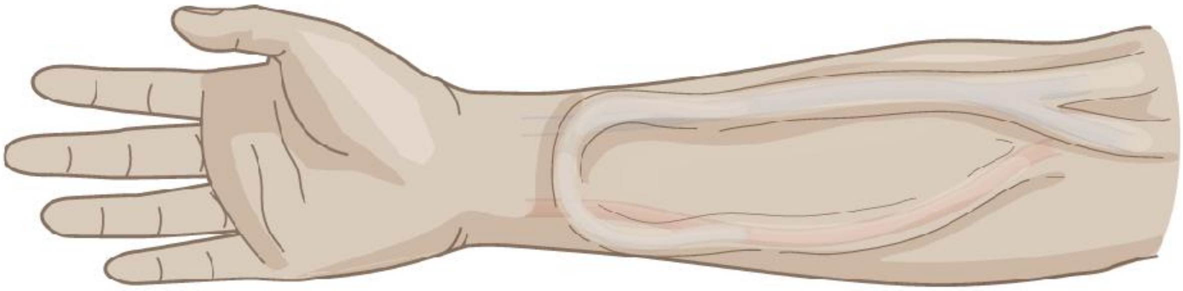

FIGURE 17-36 An arteriovenous fistula used for intermittent hemodialysis.

© Jones & Bartlett Learning.

Assessment

The patient's medical history and family history are important components of the assessment for AKI. A family history of renal disease indicates a predisposition to AKI when a precursor disease of AKI is present. The incidence of AKI is increased in patients with diabetes, hypertension, congestive heart failure, or lupus. The incidence increases greatly with age as well. Taking into context the patient's environment (eg, a house with no air conditioning during a heat wave), medication list (eg, multiple antihypertensives and diuretics), and any recent illness will help facilitate accurate management of AKI. When caring for an individual with ESRD who is receiving IHD, the CCTP must confirm the days on which the patient is typically scheduled for dialysis as well as the last time the patient had a session (and whether it was a full session).

Signs and Symptoms

Signs of AKI include abnormalities in urine production. Oliguria is the most common abnormality, although an increase in urine output can occur if the nephrons cannot effectively concentrate the urine. Lack of urine production is suggestive of anuric renal failure or an obstruction. In the latter case, patients may have significant suprapubic discomfort as bladder distention worsens. Patients may have radiation of pain to the flanks and nausea as well.

Given that dehydration is often a precipitating factor for AKI, patients commonly present with dizziness, poor skin turgor, thirst, flat neck veins, dry mucous membranes, tachycardia, and orthostatic BP changes. If third spacing and fluid retention are the cause of the AKI, the patient may exhibit peripheral edema or ascites. Low back pain, suprapubic pain, and fever may be present in patients with AKI caused by urinary tract infection. With intrarenal AKI, patients may develop peripheral edema from fluid buildup from a variety of factors, mainly due to decreased urine production, inappropriate solute and protein losses, and electrolyte dysregulation. Ongoing volume overload without appropriate urinary output can lead to pulmonary edema and congestive heart failure. Accumulation of uremic toxins ultimately results in encephalopathy, while hyperkalemia can lead to fatal dysrhythmias.

Many complications of AKI overlap with CKD, and sometimes dysfunction develops more rapidly and dramatically because of already-impaired kidneys. Patients with ESRD who are completely dependent on dialysis can present with profound metabolic dysregulation because their homeostasis depends on external support. When patients miss dialysis or have a superimposed illness (eg, worsened fluid overload from heart failure), the downstream effects can overcome their body’s buffer systems. These individuals can present with severe hyperkalemia and dysrhythmias, metabolic acidosis, and fluid overload. The retention of urea and other metabolic waste in the blood leads to **uremia**, a condition characterized by nausea, vomiting, fatigue, anorexia, weight loss, pruritus, and altered mental status. Elimination of uric acid through the skin in sweat causes the “uremic frost” phenomenon, which is characterized by white dust on the skin.

Laboratory Data and Imaging

The retention of wastes in the bloodstream that results from a decreased GFR provides an easy way to monitor for the existence and severity of AKI. When this disease is present, serum creatinine levels will be elevated proportionally to the decrease in GFR. The BUN level is a less reliable indicator of GFR, however, because it may be altered by numerous other metabolic functions unrelated to renal physiology. Nevertheless, it will be elevated in patients with AKI. The combination of elevated BUN level and serum creatinine is known as **azotemia**.

Urinalysis is critical for differentiating between the various types of AKI. Patients with prerenal AKI exhibit increased osmolality, specific gravity, and BUN-to-creatinine levels, along with a decreased fractional excretion of sodium and urine sodium concentration. Acute tubular necrosis is associated with nearly the opposite set of findings: Urine osmolality is decreased, with an increased urine sodium concentration and fractional excretion of sodium. **TABLE 17-14** summarizes renal laboratory values for patients with AKI.

TABLE 17-14 Normal Versus Abnormal Laboratory Values in Patients With Acute Kidney Injury

Test	Normal	Abnormal
BUN	8–23 μg/dL	↑
Creatinine, serum	0.6–1.2 mg/dL	↑
Urinalysis		
• Osmolality	275–295 mOsm/kg	↑ Prerenal
• Specific gravity	1.003–1.030	↑ Prerenal; ↓ Intrinsic
• BUN:creatinine	10:1	↑ Prerenal; ↓ Intrinsic
• Fractional excretion of sodium	1%	↓ Prerenal; ↑ Intrinsic
• Urine sodium excretion (over 24 h)	43–217 mEq/24 h	↓ Prerenal; ↑ Intrinsic

Abbreviations: ↑, above normal values; ↓, below normal values; BUN, blood urea nitrogen
© Jones & Bartlett Learning.

Renal ultrasonography is the gold standard for assessing suspected postrenal AKI. This imaging modality allows for rapid visualization of hydronephrosis and bladder distention. CT can visualize and measure renal calculi, tumors, and secondary signs of inflammation (eg, perinephric fat stranding).

When they have CKD and ESRD, patients may live in a persistently anemic state due to decreased renal erythropoietin synthesis. Hyperparathyroidism can evolve from decreased renal vitamin D metabolism, causing osteoporosis and skeletal abnormalities. Although some patients may become anuric, others may exhibit polyuria as a result of the diseased nephrons' inability to concentrate urine efficiently, a phenomenon known as isosthenuria. Metabolic acidosis frequently occurs in patients with CKD from a combination of acid retention and bicarbonate wasting.

Management

Initial treatment of the patient with AKI involves maintaining the ABCs and a BP sufficient to provide for adequate perfusion of organs. Data suggest that a MAP greater than 60 mm Hg is sufficient to maintain renal perfusion and minimize AKI from hypotension.

Once these basics are ensured, management focuses on increasing the GFR. This management goal must be factored into the choice of all treatment modalities, but particularly medication administration and fluid resuscitation. Administration of crystalloid fluid is indicated in dehydrated patients to treat oliguria, although the CCTP must be careful to avoid volume overload. Care must be taken when administering fluids in patients with prerenal AKI and congestive heart failure, as these patients may require inotropic medication to improve cardiac output and may be harmed by large volumes of crystalloid fluid. Diuretic administration is warranted in patients with signs of frank volume overload from congestive heart failure, as this treatment can reduce venous congestion and increase renal perfusion pressure and GFR. Serum electrolyte levels, especially potassium, must be monitored closely to avoid complications from hyperkalemia. Patients who develop hyperkalemia with interval widening on ECG require immediate temporizing measures (eg, calcium gluconate, insulin, dextrose) and emergent dialysis.

Renal replacement therapy (RRT) is a frequently used treatment for AKI that has resulted in significant physiologic disruption (eg, acidosis, volume overload, hyperkalemia) and has not responded to less-invasive therapies. The modality of choice remains controversial, but options include IHD, continuous venovenous hemofiltration, and peritoneal dialysis.

IHD is the most commonly used method for hemodynamically stable patients in both inpatient and outpatient settings. It involves the use of a dialysis machine, filter, extensive water supply, and tubing. The patient’s blood is filtered by diffusion through an external semipermeable membrane and then returned to the body. Access to the patient’s circulation can be obtained in different ways depending on the duration for which dialysis is required. A central venous catheter (CVC) is placed into either the internal jugular vein or the femoral vein for short-term access. The catheter size should allow blood flow rates of up to 300 mL/min. Subclavian access can be used but is less preferred as it can result in vessel stenosis and subsequent issues with placement of permanent AV fistulas. For long-term IHD, AV fistula is the preferred method of access: It provides for increased blood flow, superior long-term patency, and decreased likelihood of thrombosis or infection. To form an AV fistula, a vascular surgeon anastomoses an artery and a vein, most commonly in the patient’s nondominant forearm. The typical patient receiving IHD is treated two to three times per week in 4-hour sessions. To avoid damaging an AV fistula, the fistula extremity should not be used for BP measurements, blood draws, or venous access.

The major indication for continuous renal replacement therapy (CRRT) instead of IHD is hemodynamic instability, which is often seen in critically ill patients. Four CRRT options are typically available, all of which require a dual-lumen hemodialysis catheter connected to a venovenous circuit using an extracorporeal pump to facilitate flow of blood through a filter. No single therapy always provides better outcomes; instead, the selection of the CRRT approach depends on hospital personnel's expertise and availability, the intended goals for removal of solutes and/or fluid volume, and acid–base control. CRRT can be run continuously or intermittently (6- to 12-hour cycles). As yet, no clear consensus statements have been published to aid in selection of therapy for patients requiring CRRT.

The most common types of CRRT include continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), continuous venovenous hemodiafiltration (CVVHDF), and slow continuous ultrafiltration (SCUF). CVVH removes solutes entirely by convection, using a high ultrafiltration rate (20 to 25 mL/kg/h), such that administering replacement fluid (usually crystalloid) is necessary to avoid hypovolemia. CVVHD adds dialysate fluid to the circuit, at flow rates of 20 to 25 mL/kg/h, and removes solutes primarily by diffusion. Ultrafiltration rates are low, typically ranging from 2 to 8 mL/min, which limits net fluid removal as well as the need for fluid replacement. CVVHDF combines convection and diffusion, uses dialysis fluid, and necessitates administration of replacement fluid to limit the net volume removed. SCUF, which is typically used for isolated volume overload, uses neither dialysate nor replacement fluid and has minimal ability to remove solutes; however, it can remove up to 8 L of fluid per day.

CRRT equipment is bulky **FIGURE 17-37**, sensitive to movement, and has power and temperature requirements that are often not compatible with transport vehicles. If a patient is leaving the ICU for a short time, blood from the CRRT machine can be returned to the patient and the machine can continuously recycle the IV fluids present until the patient returns. Alternatively, the machine can recycle the flow by using the patient's blood already in the circuit. For travel to another facility, CRRT will need to be discontinued prior to transport.

The CCTP who is caring for a patient undergoing CRRT should take the following considerations into account:

- **Access.** When connecting, disconnecting, or transferring CRRT or IHD from a temporary catheter, access must be preserved. Each port should be flushed with normal saline, clamped, and capped. Prior to clamping and capping, many institutions instill an anticoagulant locking solution such as 4% sodium citrate to maintain patency. Sodium citrate has several clinical advantages over concentrated heparin solution (the fluid previously used for this purpose) and is less costly. When a locking solution is not available, a temporary dialysis catheter should be periodically flushed with saline to maintain patency. Bleeding can occur at the insertion site of dialysis catheters. Should such bleeding occur during transport, the CCTP should control it with direct pressure to the site and apply a pressure or hemostatic dressing, if necessary.
- **Infection.** Large catheters are used to provide the venous access necessary for dialysis, and the presence of these devices increases patients' risk of contracting a central line–associated bloodstream infection. The CCTP should inspect IHD catheter sites to ensure the dressing is secure, clean, dry, and intact. The patient and all nearby providers should wear masks whenever such a catheter is accessed. Meticulous attention must be paid to aseptic technique.
- **Thermoregulation.** CRRT is an extracorporeal circuit, transporting the patient's blood volume external to the body for filtration. To maintain normothermia, blood heaters are used on all extracorporeal circuits. The CCTP should monitor the patient for hypothermia and compensate for lowering of the patient's

body temperature by covering the patient with additional blankets or adjusting the cabin temperature.

- **Anticoagulation.** CRRT filter life may be prolonged with either systemic or regional anticoagulation. Citrate infused regionally, to facilitate anticoagulation in only the CRRT circuit, and heparin infused systemically are the two most common CRRT anticoagulation practices. When discontinuing CRRT before transport, the CCTP should determine whether the patient will still need any regional or systemic anticoagulation.
- **Volume status.** The process of initiating and discontinuing CRRT pulls and returns approximately 150 mL of blood to/from an average adult patient. Although this may seem like a small amount of fluid, the CCTP may observe significant changes in fluid volume status, particularly in hemodynamically unstable patients. Volume replacement may be necessary.
- **Laboratory abnormalities.** CRRT can remove significant quantities of small solutes and provide dramatic correction of acid–base derangements. If equipped to do so, the CCTP should monitor lab values periodically during transport, especially when CRRT is discontinued prior to the trip.

Peritoneal dialysis (PD) is infrequently initiated acutely in the hospital setting, although it can be continued in patients with CKD managed with PD in the outpatient setting. This technique involves the insertion of a rubber catheter into the abdomen and the use of the peritoneum as a semipermeable membrane. A dextrose solution is injected into the peritoneal space; from there, it moves across the membrane while wastes move in the opposite direction, thereby effecting their removal from the body. The most common complication of this form of dialysis is an increased risk of peritonitis and infection.

At times, the CCTP may encounter patients receiving dialysis who require IV access or even discontinuation of ongoing dialysis as a result of complications during transport. Patients with CKD who are on dialysis typically have poor peripheral vasculature and obtaining access may be extremely difficult. It is important to ensure that patent venous access is available prior to initiating transport. A fistula, shunt, or AV graft should never be routinely used for vascular access. An extremity with a fistula should not be used to obtain a BP reading, draw blood, obtain peripheral IV access, or obtain finger-stick blood glucose specimens. If other forms of venous access are lost during transport and the patient's condition deteriorates into extremis (a grave condition) or the patient experiences cardiopulmonary arrest, the CCTP may consider using a fistula only as a last resort. The likelihood of infection or damage to the fistula is so significant that intraosseous or central venous access (such as internal/external jugular access) should always be attempted before resorting to the use of a fistula.

Complications often arise during dialysis as well. Some of these complications can be treated during dialysis, whereas others may become so severe that dialysis must be discontinued. The most common complication is hypotension, which can usually be treated with small (100- to 250-mL) fluid boluses. Severe episodes of hypotension may necessitate that dialysis be stopped during treatment. Muscle cramping is another frequent complication and is often associated with rapid volume removal from the patient. Cramps can also be treated with small fluid boluses.

Maintenance doses of many drugs for patients on dialysis may need to be reduced, although the loading doses of drugs typically administered in the prehospital setting rarely need to be changed. Other medications, such as meperidine, NSAIDs, and oral antidiabetic agents, should be avoided in these patients. The list of medications whose dosages need to be reduced in patients on dialysis is extensive (refer to a publication on the specific topic for a complete list).

Signs and Symptoms

Acute Kidney Injury

- Dizziness
- Poor skin turgor

- Thirst
- Flat neck veins
- Dry mucous membranes
- Weight loss
- Orthostatic BP changes
- Fever
- Edema
- Ascites
- Low back pain

Differential Diagnosis

Acute Kidney Injury

- CKD
- Pyelonephritis
- Obstructing renal stone
- Glomerulonephritis
- Acute tubular necrosis
- Congestive heart failure

Transport Management

Kidney Injury

- Ensure and maintain the ABCs.
- Obtain IV access.
- Monitor the ECG.
- Maintain perfusing BP through IV fluids or vasopressor medications.
- Closely monitor serum electrolyte levels.
- Monitor the dialysis machinery (if in place) for potential complications.

Urinary Tract Infections

Bacterial flora that live symbiotically in the GI system can cause considerable damage when they are introduced into the urinary system. A urinary tract infection (UTI) develops as bacteria manage to travel up the urethra. Incidence of UTIs is significantly higher in females, owing to the shorter urethral distance needed to reach the female bladder. More than 20% of females will experience a UTI at some point in their lives. Patients with urinary retention from an obstruction or nervous system disruption are predisposed to UTIs, because regular urine flow normally prevents bacterial overgrowth and cleanses the tracts of pathogens. Patients with bladder catheters are also at a high risk for infection, as the foreign material facilitates bacterial migration.

Lower UTIs include infections of the urethra and urinary bladder, known as urethritis and cystitis, respectively. Migration of the pathogen to the ureters and kidneys results in an ascending infection called **pyelonephritis**, which can progress to urosepsis if not treated promptly. Infection can also spread into the prostate, causing prostatitis, which requires a prolonged course of antibiotics.

As many as 90% of UTIs are caused by *Escherichia coli* bacteria, which are normal inhabitants of the GI tract. The antimicrobial culprits vary in patients with frequent catheterization or chronic indwelling catheters (eg, *Enterococcus*, *Klebsiella*), and the rate of antibiotic resistance among these organisms continues to rise. Inflammation secondary to the infection causes bladder irritability, resulting in urinary frequency and urgency, as well as a burning pain exacerbated by urination, at times accompanied by foul-smelling urine. Pyelonephritis symptoms are more significant and include fever, chills, low back and flank pain, and nausea (with or without vomiting). Sexually transmitted infections such as gonorrhea and chlamydia may cause symptoms mimicking UTI and may be associated with urinary discharge.

The majority of both lower and upper UTIs are treated successfully with antibiotics. On occasion, surgery may be required to remove an intrarenal or perinephric abscess that forms during pyelonephritis. In more severe cases of pyelonephritis, IV antibiotics may be required, and the CCTP may have to manage their administration during interfacility transports.

Nephrolithiasis

Renal calculi, commonly referred to as kidney stones, result from mineral buildup in the renal pelvis. Most often the calculi consist of calcium-based compounds, although occasionally they are composed of struvite or uric acid. The lifetime risk of renal calculi is approximately 10%, with males being twice as likely as females to experience this condition. Family or personal history of calculi should increase suspicion for this diagnosis.

Most renal calculi pass through the urinary tract and are excreted without significant complications, although they certainly can produce excruciating pain during their travels. The crystals can cause epithelial injury, bleeding, pain, and infection. A small percentage of calculi become lodged in the lumen of either the ureter or the urethra. As the blockage worsens, these stones can cause life-threatening AKI and infections secondary to the backup of urine in the kidneys. Abnormal reflux of urine into the kidneys causes widening of renal calices and disruption of normal architecture, also known as hydronephrosis.

The classic presentation of **nephrolithiasis** is colicky flank pain, which may be accompanied by nausea, vomiting, and radiation of pain into the groin. Although abdominal pain may be present, these patients usually do not demonstrate a tender abdomen during palpation. Some patients may have tenderness with percussion of the costovertebral angle of the affected side. Gross hematuria is seen in only one-third of cases. Risk factors for poor outcomes include diabetes, history of renal transplant or single kidney, and urinary tract infection.

Ultrasonography is the optimal diagnostic test, as it is used to evaluate for hydronephrosis in the context of an increased pretest probability of renal calculi, while avoiding radiation. Noncontrast CT is another effective diagnostic modality; it can localize and measure a stone, as well as other pathology that may mimic the symptoms of renal calculi (eg, aortic pathology).

Toradol has excellent analgesic and antispasmodic effect in patients with this condition, with opioids being a reasonable option for breakthrough pain. Antiemetics and medical expulsive therapy with alpha-1 antagonists are often provided as well.

Testicular Torsion

Normally, the tunica vaginalis secures the testes inside the scrotum, preventing any excessive movement or rotation. In approximately 12% of the male population, this attachment is misaligned, allowing some degree of free testicular movement. These patients are susceptible to **testicular torsion**, a condition in which one or both testes rotate to the point of occluding their blood supply **FIGURE 17-38**. Trauma to the groin and vigorous exercise are common etiologies for torsion. A rotation of 720°—that is, two full rotations of the testicle around the axis of the testicular artery and vein—is required to fully tamponade the vessel and cause a resultant buildup of waste products within the testes and scrotal swelling. This condition is a true urologic emergency and must be addressed within 6 hours of symptom onset to maintain viability. Indeed, torsion is extremely painful, and manual detorsion followed by emergent surgical intervention may be required to salvage the testis and avoid necrosis. The CCTP must be able to recognize the symptoms and initiate rapid transport to an appropriate facility or notify the receiving facility of suspicions upon arrival. Analgesia should be administered to patients with this condition.

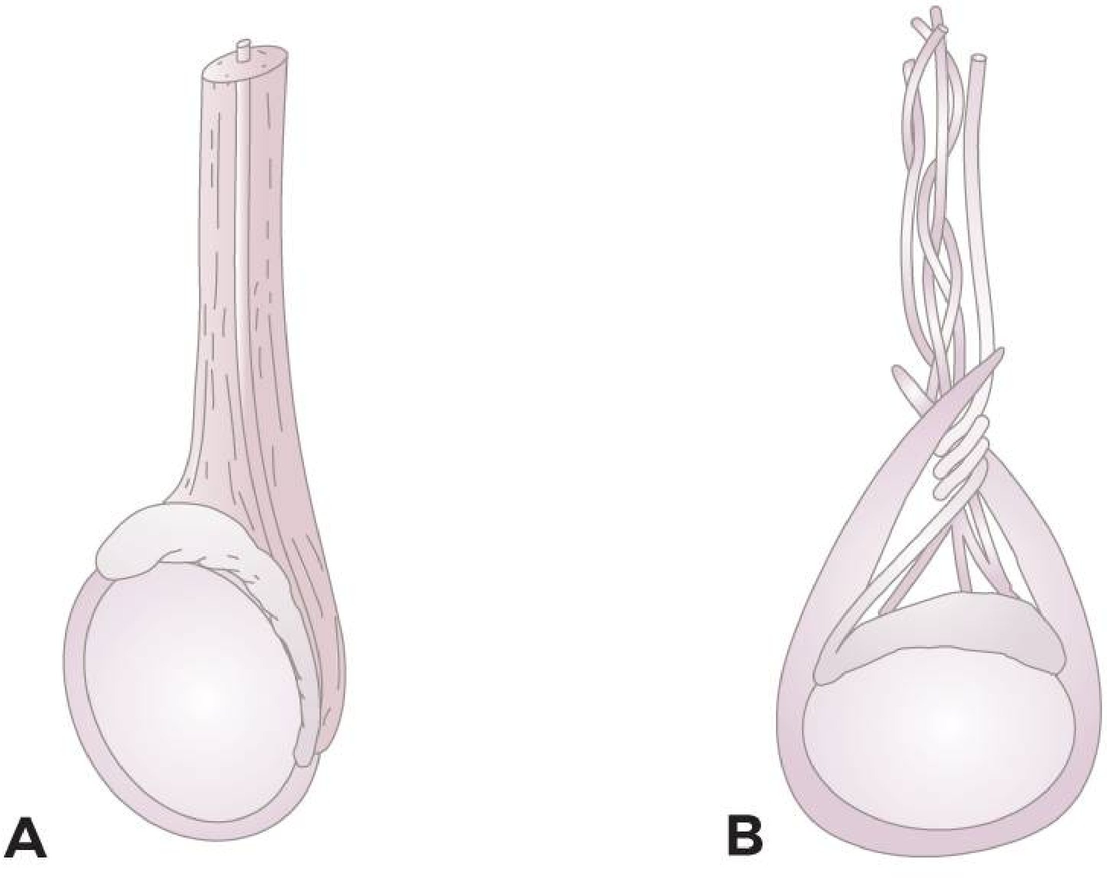

FIGURE 17-38 A. The normal testicle. **B.** Testicular torsion.

© Jones & Bartlett Learning.

Description

Patients with testicular torsion will occasionally present with nausea, vomiting, and pain. Pain may be localized to the scrotum or quite vague, radiating anywhere from the flank to the lower abdomen. In addition to nausea or vomiting, the presence of an enlarged, indurated, or high-riding testicle and an absent cremaster reflex suggest torsion. This condition is most often seen in adolescent males, with most cases occurring in males younger than 30 years.

Penile Injuries

Priapism is a penile erection lasting longer than 2 to 4 hours in the absence of sexual stimulation. This condition can be painful and damaging to tissues in the immediate area.

The two major classifications of priapism are arterial high-flow (non-ischemic) and low-flow (ischemic) priapism. High-flow priapism is rare and typically occurs secondary to traumatic or iatrogenic penile (or perineal) injury that causes excessive arterial flow and persistent erection. Spinal cord transection is commonly cited as a precursor to high-flow priapism, although it resolves spontaneously and rarely requires treatment. Low-flow priapism, which involves impaired relaxation of cavernosal smooth muscle, is the more painful of the two conditions. It is idiopathic in most cases, but is prevalent in patients with sickle cell disease or taking certain medications. Drugs that place men at risk for this condition include a number of prescription pharmaceuticals, including psychotropic medications, calcium channel blockers, and oral erectile dysfunction agents. Intracavernosal injection of drugs such as papaverine, phentolamine, and prostaglandin E_1 for erectile dysfunction are commonly implicated as well. Rarely, cases of priapism may be associated with use of the more popular selective cyclic guanosine 3′, 5′-monophosphate inhibitors such as sildenafil citrate (Viagra).

Initial treatment is application of a cold pack, followed by intracavernosal aspiration and administration of a sympathomimetic drug (eg, phenylephrine). The CCTP will rarely encounter a patient with priapism but must be prepared to treat it as a urologic emergency, with the major complication being subsequent impotence.

Some males may seek care in the aftermath of blunt injury to the penis while erect, usually during sexual intercourse. Rupture of the engorged vascular spaces within the penis results in **penile fracture**. Cold compresses should be applied to the area of injury. As with other urologic trauma, the CCTP should avoid inserting a urinary catheter if there is blood at the meatus or suspicion of urethral injury.

Maintenance Tubes

A variety of tubes may be encountered or placed by the CCTP while caring for a patient with a GI or GU condition. The following sections focus on two major types of these devices: feeding tubes and drainage tubes **TABLE 17-15**.

TABLE 17-15 | **Gastrointestinal/Genitourinary Maintenance Tubes**

Type of Tube	Examples
Feeding tube	Nasogastric or Dobhoff tube Percutaneous endoscopic gastrostomy (PEG) tube Jejunostomy tube (J tube) Percutaneous endoscopic gastro-jejunal (PEG-J) tube Total parenteral nutrition
Drainage tube	Straight catheter Indwelling urinary catheter Suprapubic tube External condom catheter Colostomy Ileostomy Ileoanal anastomosis Kock pouch Ileal conduit urostomy Colon conduit urostomy Jackson-Pratt drain Hemovac drain Davol drain T tube

© Jones & Bartlett Learning.

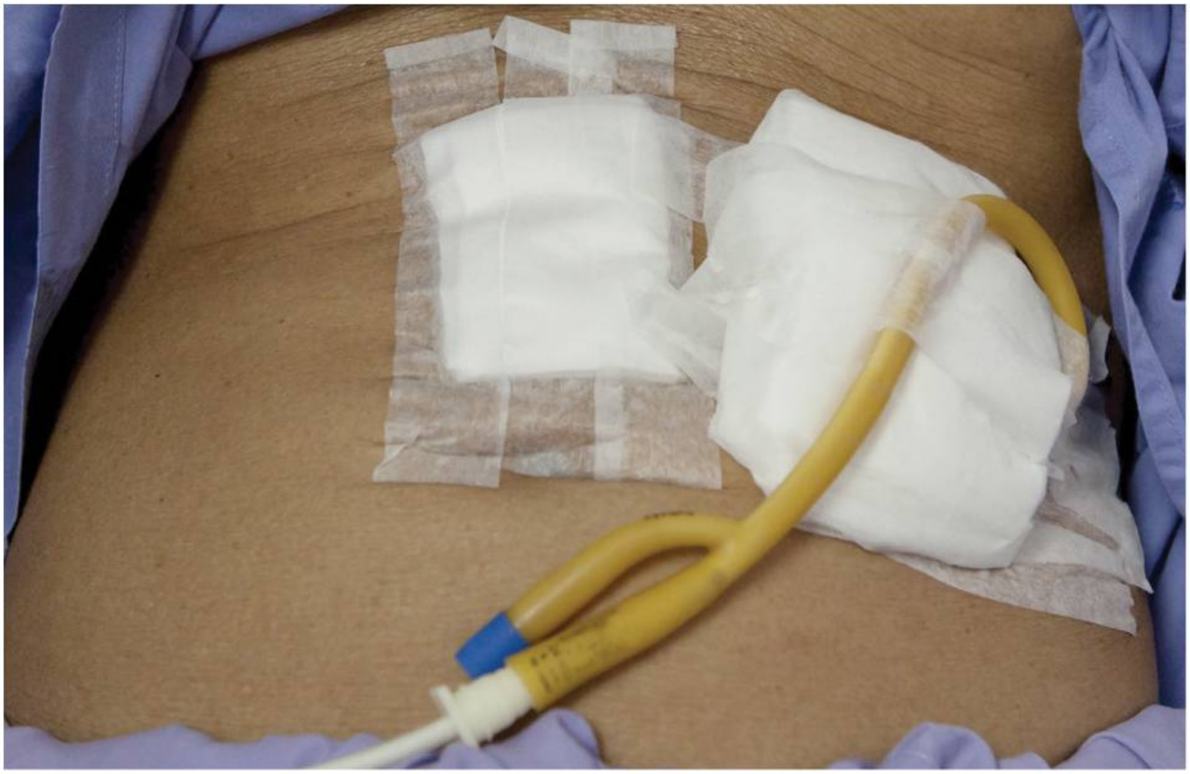
Feeding Tubes

Proper nutrition is necessary for life, wound healing, and recovery, and must be provided enterally to patients who are extensively incapacitated by either disability or sedation. Unless total parenteral nutrition is required as a result of damage to or resection of the alimentary tract, use of the body's digestive organs is the best way to effect nutrient absorption. Enteral nutrition, commonly called tube feeding, can be administered in steps, depending on its expected duration.

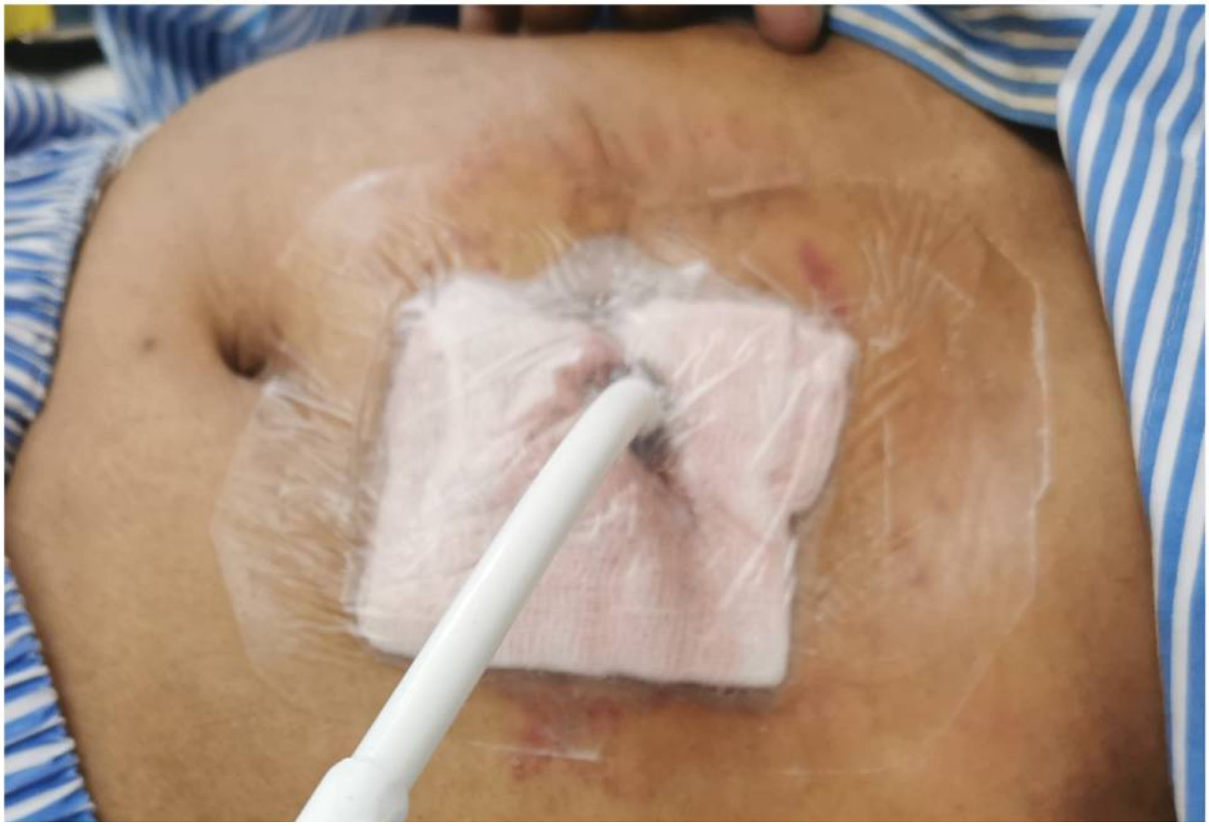
Enteral Nutrition

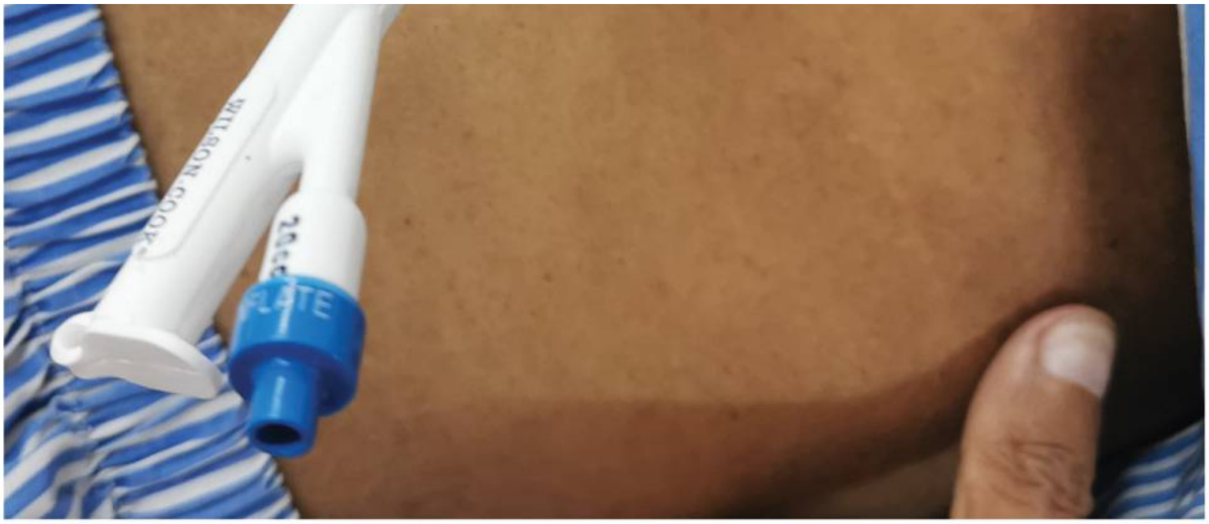
Perhaps the largest obstacle to food intake in the incapacitated patient is the inability to swallow safely and effectively. This can be circumvented by placement of a simple NG tube, which can be used to administer food into the stomach or to remove food. These minimally invasive tubes are often inserted through the nasal orifice, with the assistance of the patient, in preparation for a short-term event during which temporary enteral feeding is required.

For longer-term situations, a gastrostomy tube (G tube) can be inserted. This type of tube is also referred to as a **percutaneous endoscopic gastrostomy (PEG) tube** because of the insertion technique used for its placement. PEG tubes are placed through a small, surgically created opening from the stomach, through the peritoneum, to the abdominal wall **FIGURE 17-39A**.



A





B

FIGURE 17-39 A. A percutaneous endoscopic gastrostomy (PEG) tube placed in the patient's stomach. **B.** A jejunostomy (J) tube placed in the patient's jejunum.

A: © stockphoto mania/Shutterstock; **B:** © Casa nayafana/Shutterstock.

Description Description

Alternatively, a **jejunostomy tube (J tube)** can be introduced directly into the jejunum through a comparable technique, known as a percutaneous endoscopic jejunostomy **FIGURE 17-39B**. J tubes possess an advantage over their PEG counterparts: Aspiration risk is much lower with J tubes because food is administered distal to the pyloric sphincter. Unfortunately, J tubes are also associated with a higher insertion complication rate because the small intestinal wall is less stable than the thicker stomach lining, which serves to anchor a PEG tube more securely.

A newer procedure known as a PEG-J tube lessens this risk while providing the benefit of decreased aspiration. During this procedure, a PEG tube is first placed through the abdominal wall, then advanced through the lumen to the duodenum and into the jejunum.

Liquid nutritional products can be administered to the patient through any of these tubes by either a rate-controlled pump or syringe boluses. Proper functioning of the tube is confirmed by a lack of pain or resistance while pushing the syringe upon food administration.

Aspiration is the most common complication from a feeding tube and could potentially develop into a life-threatening situation. To avert this complication, sit the patient upright during feeding or vomiting. Bleeding may occur at the insertion site if the tube is pulled on or traumatically removed. Significant hemorrhage from this situation is unlikely, and bleeding is typically self-limited. A third complication involves infection around the insertion site, which may be observed as a reddening or swelling in the immediate vicinity.

If the feeding tube becomes clogged, a 30- to 50-mL sterile warm water bolus can be used to clear the blockage. If the tube is removed unexpectedly, the site should be covered with an occlusive dressing until it can be properly replaced. Some protocols may allow the CCTP to replace a tube that has been removed or insert a Foley catheter to keep the tract patent. Unmanageable blockage or a removal of the PEG or J tube is not of major concern in the short-term care of the patient, as a brief lapse in feeding can be accounted for later. However, the CCTP should confirm alternative administration routes for time-sensitive medications (such as antiepileptic drugs) that are administered through an enteral tube.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is an alternative feeding method used when the GI tract is not functioning adequately. During TPN, all required nutrients are administered intravenously to the patient. Typically, central access is used for administration to prevent osmotic fluid shifts, although some preparations can be delivered through a peripheral vein. Medications are often added to the TPN solution during its creation, but they should not be introduced once that process is complete. TPN should be used when enteral feeding is not an option because of the significant GI atrophy that occurs with ongoing dormancy of the GI tract. Long-term use of TPN is associated with hypertriglyceridemia, hepatic dysfunction, and an increased risk of sepsis.

Like patients with other types of central venous lines, patients receiving TPN are at high risk for an air embolus and thrombosis. An air embolus is most likely to occur when changing a line or following an unexpected disruption of the line. This situation has a high mortality rate and must be aggressively treated with high-flow oxygen, occlusive dressing placement, and movement of the patient into a Trendelenburg position. Thrombosis is treated by removing the catheter, then administering anticoagulation and thrombolytic therapy. Continuous monitoring for metabolic abnormalities is essential when the patient is receiving TPN, as well as monitoring for electrolyte imbalances, which can easily arise with this feeding method.

Management

When transporting a patient with a feeding tube, contact medical direction if the patient develops pain at insertion site, has vomited, or develops a distended abdomen.

Transport Management

Patients With Feeding Tubes

- Examine the insertion site for signs of infection, such as redness or swelling.
- Assess for pain at the insertion site.
- Assess for any leakage or blockage of the tube.
- Keep the patient in a position of comfort.
- Provide supportive care as required.

Drainage Tubes

The digestive system has equally important input and output functions, and the tubes placed in the critically ill patient must meet both of these needs. Just as various feeding tubes exist to introduce food to the body when the patient cannot independently consume it, so drainage tubes exist to remove waste when it is being retained. Waste products of human metabolism take the form of urine and feces, which are parenterally removed through urinary catheters and ostomies, respectively. In some critically ill patients with large-volume diarrhea, rectal tubes may be placed temporarily for fecal management.

Urinary Catheters

Types of Urinary Catheters

Different methods of urine collection exist, each with its own advantages and disadvantages.

Straight catheters, often called intermittent catheters, are designed for temporary use and may be self-inserted by the patient. They enable the patient to drain residual bladder contents that might otherwise lead to infection. These catheters are associated with less inflammation than catheters intended for longer-term use, but the drainage process must be repeated three or more times per day. Intermittent catheterization is preferred if longer indwelling catheters can be avoided, in an effort to avoid catheter-associated UTIs.

Indwelling urinary catheters, also known as Foley catheters, are used as a more permanent solution for urine retention or incontinence. These may be placed in patients who require close monitoring of urine status, intubated patients, and individuals with wounds that may be soiled by incontinence, for example. These pliable rubber catheters are introduced into the bladder via the urethra. A balloon is inflated with 5 mL of saline inside the bladder to prevent inadvertent removal of the catheter.

Some urinary catheters have a slight bend at the insertion end, called a coudé tip, which allows them to pass around scar tissue or an enlarged prostate. Individuals with a history of difficult catheterization may require this type of catheter. Other patients may have a triple-lumen catheter in place to enable continuous bladder irrigation. This approach is sometimes used to remove or prevent clot formation or accumulation in the bladder, particularly in the aftermath of urologic surgery.

When surgery or trauma makes urethral catheter introduction undesirable, a suprapubic tube may be inserted instead. Patients who require permanent or semipermanent urinary drainage, such as those with neurogenic bladder or severe dementia, will benefit from this approach due to a decreased risk of infection and improved comfort. The urine collection tube is placed directly into the bladder through the abdominal wall by way of a surgically created stoma.

Some patients have the option of using noninvasive urinary devices, including suction-assisted wicks for women and condom catheters for men. Although they are less secure, they are also less susceptible to complications and are a good alternative to diapers.

Each type of urine-collection catheter functions in a similar way, draining into a bag that allows for clean collection, observation, and measurement of urine output. Two types of collection bags are frequently used: a leg bag that straps to the leg underneath clothes, allowing for greater mobility with a discreet presence, and a down-drain bag that hangs on the side of the patient’s bed. Larger down-drain bags are more commonly used in hospitals and nursing homes. The drains function by gravity, so it is important to ensure they are hung below the patient.

Complications of Urinary Catheters

Common complications of urine collection catheters include clogging, infection, pain, leakage, and dislodgement. Clogging can typically be cleared with a small fluid bolus, although persistent obstruction may indicate dislodgement. Dislodgement is the largest concern during transport. Dislodgement and leakage are corrected by replacing the catheter into the bladder; they are often a result of selecting an improper size of catheter. Care must be taken to deflate the internal balloon before performing any adjustment of the catheter.

Management

It would be unlikely for urinary catheter placement to occur during transport, but the procedure is covered here in the event that the CCTP performs it prior to transport. Care should be taken when inserting urinary catheters in patients with recent GU trauma, surgery, or prior history of very difficult placement, as excessive force can cause injury to the urethra and potentially create a false passage.

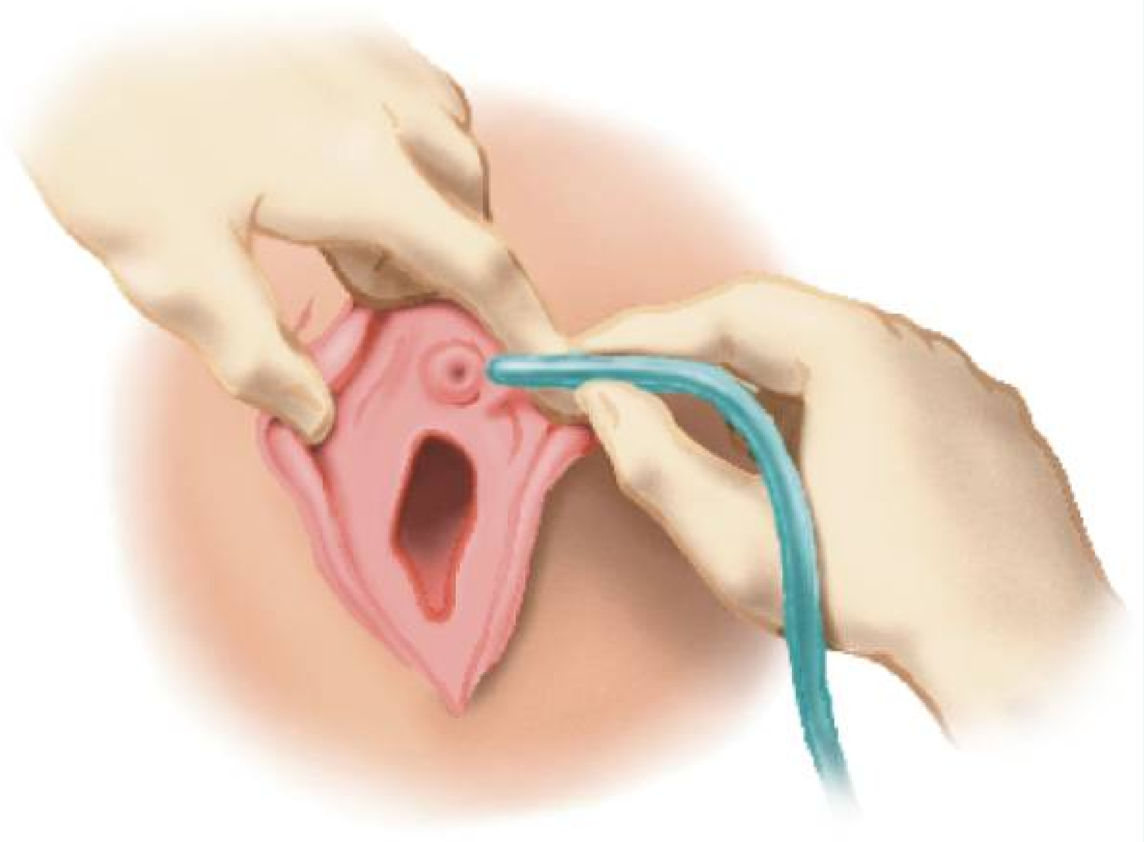
When preparing to place a urinary catheter, gather the following equipment:

- Disposable sterile bladder catheter kit
- Water-soluble lubricant
- Drapes
- Cleansing solution
- Sterile gloves
- Prefilled syringe containing sterile water
- Correct size urinary catheter
- Clamp
- Connecting tubing
- Collecting bag

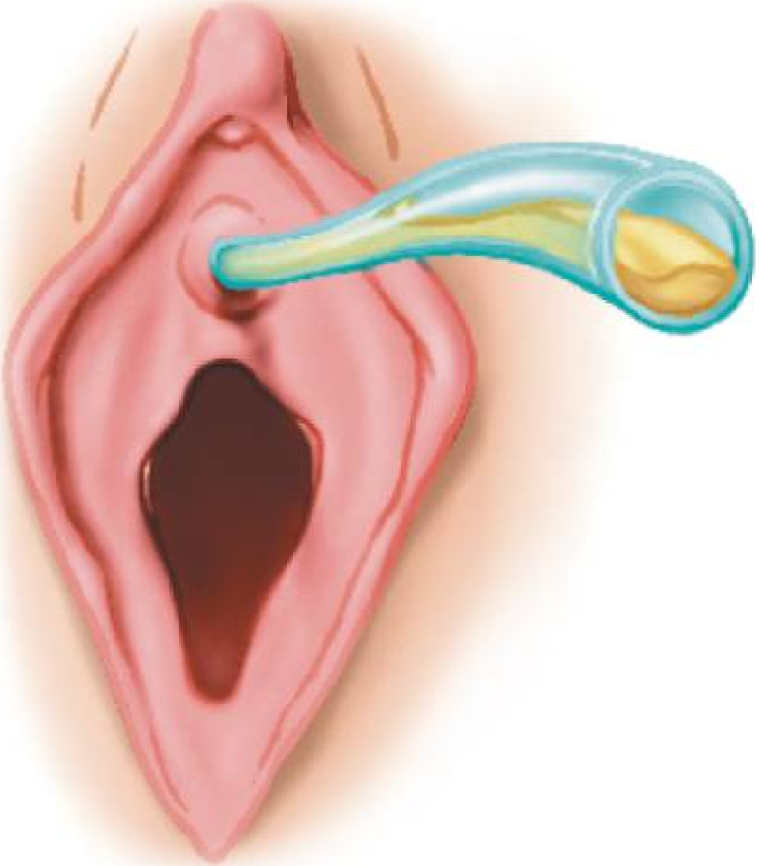
Indications for urinary catheter placement include drainage of the urinary bladder to precisely measure urine output and to aid fluid balance and retention. Contraindications include suspected urethral injury, as evidenced by blood at the urethral meatus (opening) of a trauma patient or significant penile or scrotal hematoma without having excluded urethral injury; postoperative urologic patients; and a history of urethral stricture (narrowing). When transporting a patient with a urinary catheter by air, air medical considerations include ensuring the balloon is filled with water.

The steps to place a female urinary catheter are shown in **Skill Drill 17-3** and summarized here:

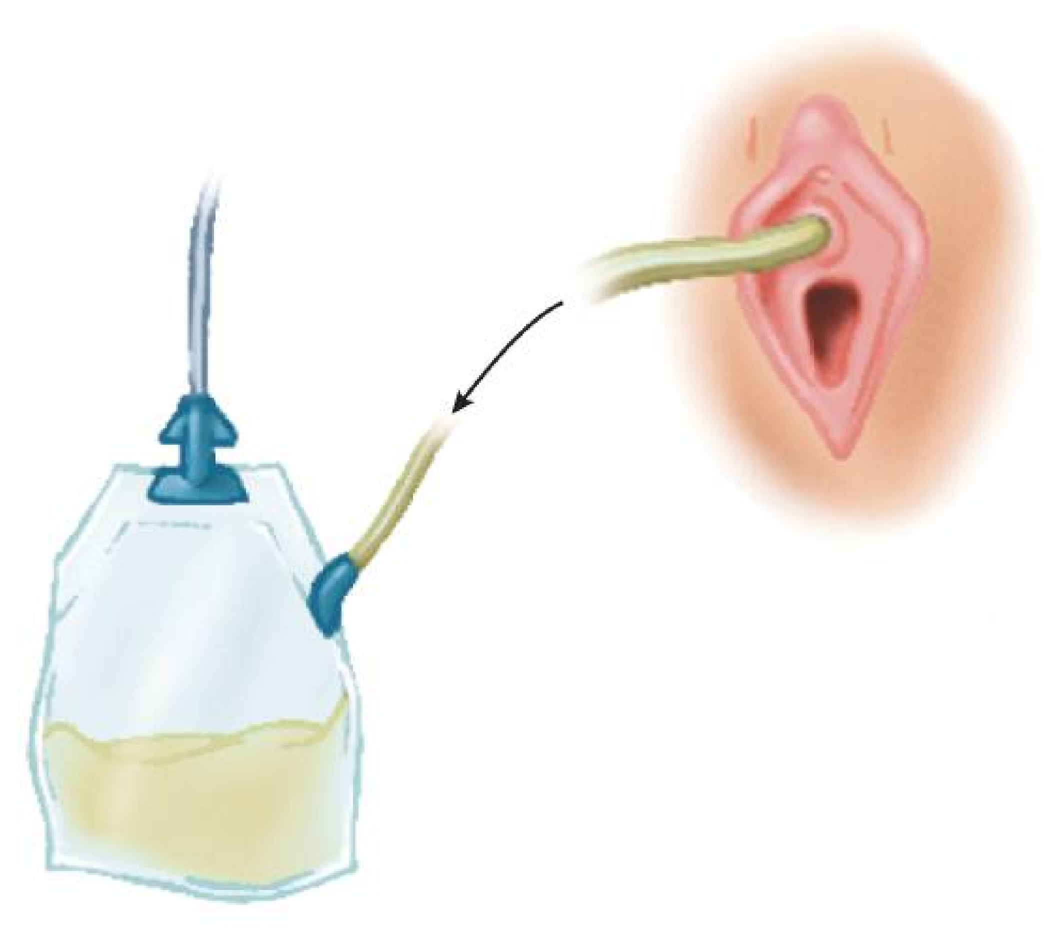
SKILL DRILL 17-3 Placing a Female Urinary Catheter



Step 1
Insert the catheter into the meatus gently until urine flow begins.



Step 2
Fill the fluid retention balloon until it is secure.



Step 3
Connect the open end of the catheter to the drainage tube and collection bag. Secure the catheter to the patient’s leg.

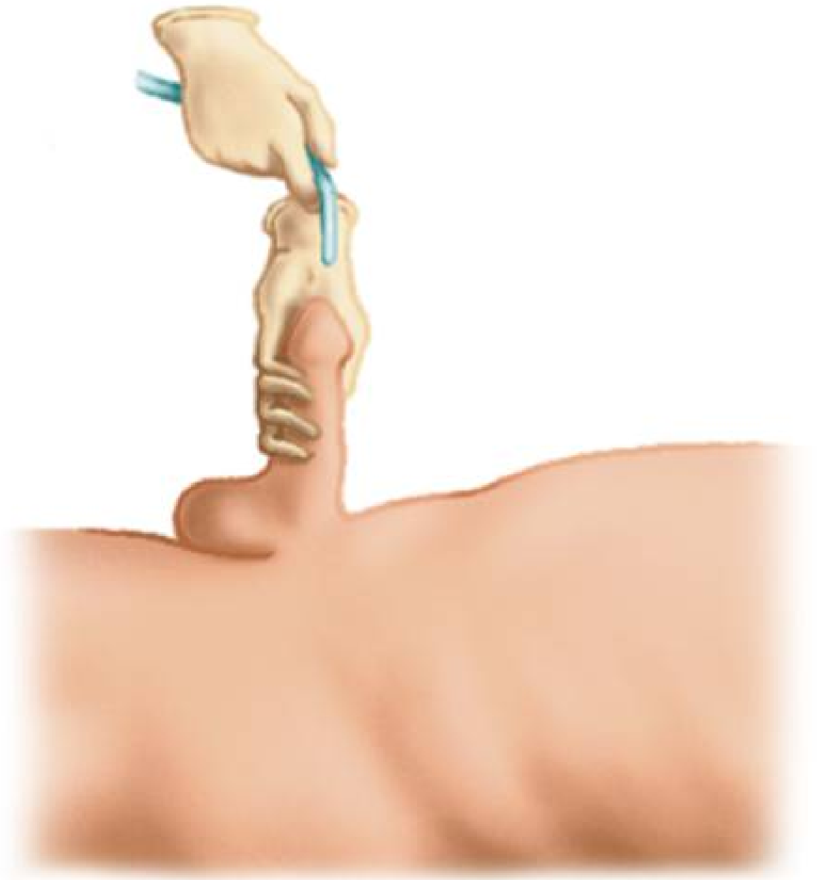
© Jones & Bartlett Learning.

1. Prepare the equipment.
2. Take standard precautions.
3. Place the patient in the supine position, with hips flexed and abducted.
4. Open the kit and prepare the equipment using sterile technique.
5. Test the balloon on the indwelling catheter by injecting it with sterile water or saline.
6. Position the drapes.

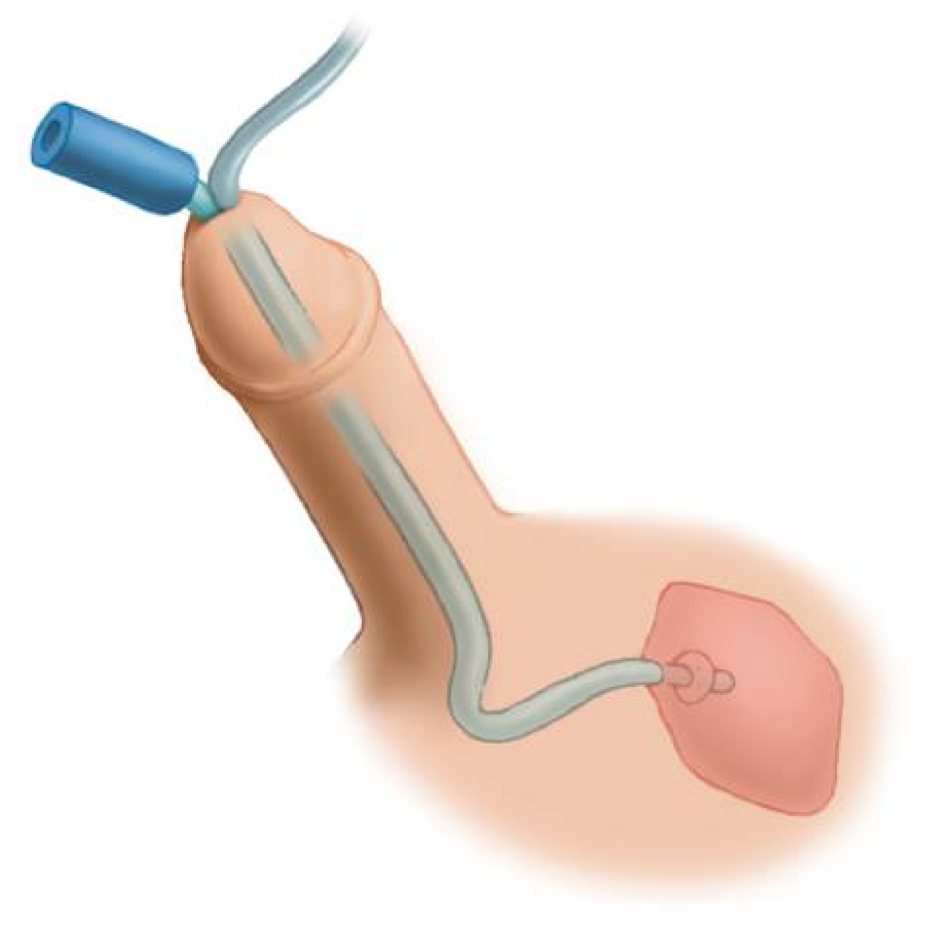
7. Lubricate the catheter.
8. Cleanse the sides of the labia and meatus with a chlorhexidine 2% solution.
9. Insert the catheter into the meatus gently until urine flow begins **Step 1**.
10. Fill the fluid retention balloon until it is secure **Step 2**.
11. Connect the open end of the catheter to the drainage tube and collection bag **Step 3**.
12. Secure the catheter to the patient's leg with tape.

The steps to place a male urinary catheter are shown in **Skill Drill 17-4** and summarized here:

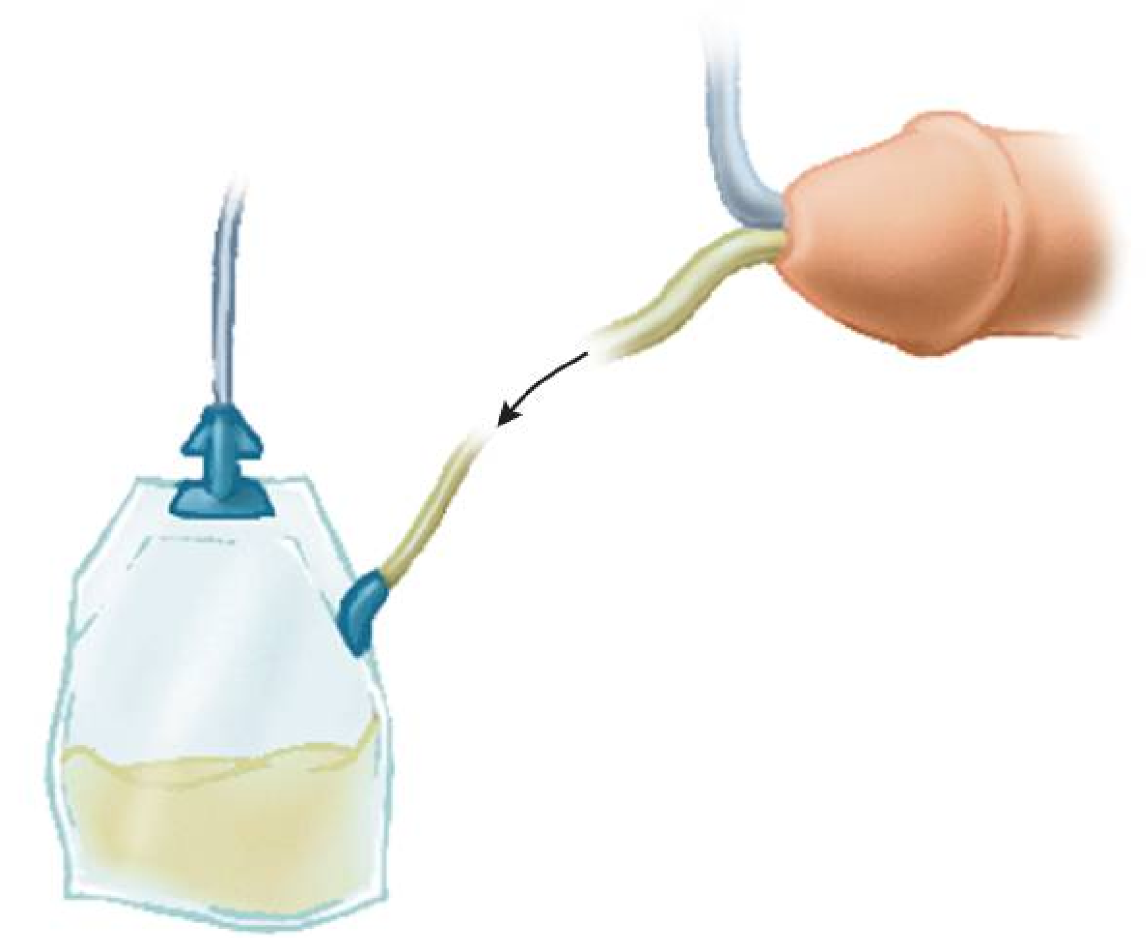
SKILL DRILL 17-4 Placing a Male Urinary Catheter



Step 1
Insert the catheter gently until urine flow begins. Once urine is observed, gently advance the catheter an additional 2 to 3 inches (5 to 8 cm).



Step 2
Fill the fluid retention balloon until it is secure.



Step 3
Connect the open end of the catheter to the drainage tube and collection bag. Secure the catheter to the patient’s leg.

© Jones & Bartlett Learning.

1. Prepare the equipment.
2. Take standard precautions.
3. Place the patient in the supine position.
4. Open the kit and prepare the equipment using a sterile technique.
5. Position the drapes.
6. Lubricate the catheter.
7. Cleanse the penis from head to base, always moving the disinfectant brush in a direction away from the meatus.

8. Insert the catheter gently until urine flow begins. Once urine is observed, gently advance the catheter an additional 2 to 3 inches (5 to 8 cm) **Step 1**.
9. Fill the fluid retention balloon until it is secure **Step 2**.
10. Connect the open end of the catheter to the drainage tube and collection bag **Step 3**.
11. Secure the catheter to the patient's leg with tape.

Transport Management

Patients With Urinary Catheters

- If clogging occurs, clear the catheter with a small fluid bolus.
- If dislodgement or leakage occurs, replace the catheter. A different size of catheter may be needed.

Ostomies

Types of Ostomies

An **ostomy** is a surgically created opening of the GI tract through the abdomen that allows for waste removal. The ostomy may originate in the ileum of the small intestine (ileostomy) or anywhere in the large intestine (colostomy), depending on which segments of the GI tract must be bypassed. Urostomies may be created as well to drain urine directly from the urinary tract when a distal portion must be avoided as a result of disease or trauma. Indications for an ostomy include bowel injury or disease, bladder injury or disease, and congenital anomalies.

Colostomies **FIGURE 17-40** and ileostomies drain intestinal contents out of the GI tract and into a collection bag. The drainage from a colostomy is more solid than that from an ileostomy because the material has progressed farther through the digestive process. The drainage is collected in a bag attached to the opening and strapped to the patient's body. Sometimes a section of small intestine is surgically modified to create an internal collection site called a Kock pouch. In an ileoanal anastomosis, also known as a J pouch, the rectum is preserved, allowing it to function in fecal collection. These methods are beneficial to the patient because they allow less visible collection methods and offer more convenient waste disposal management.

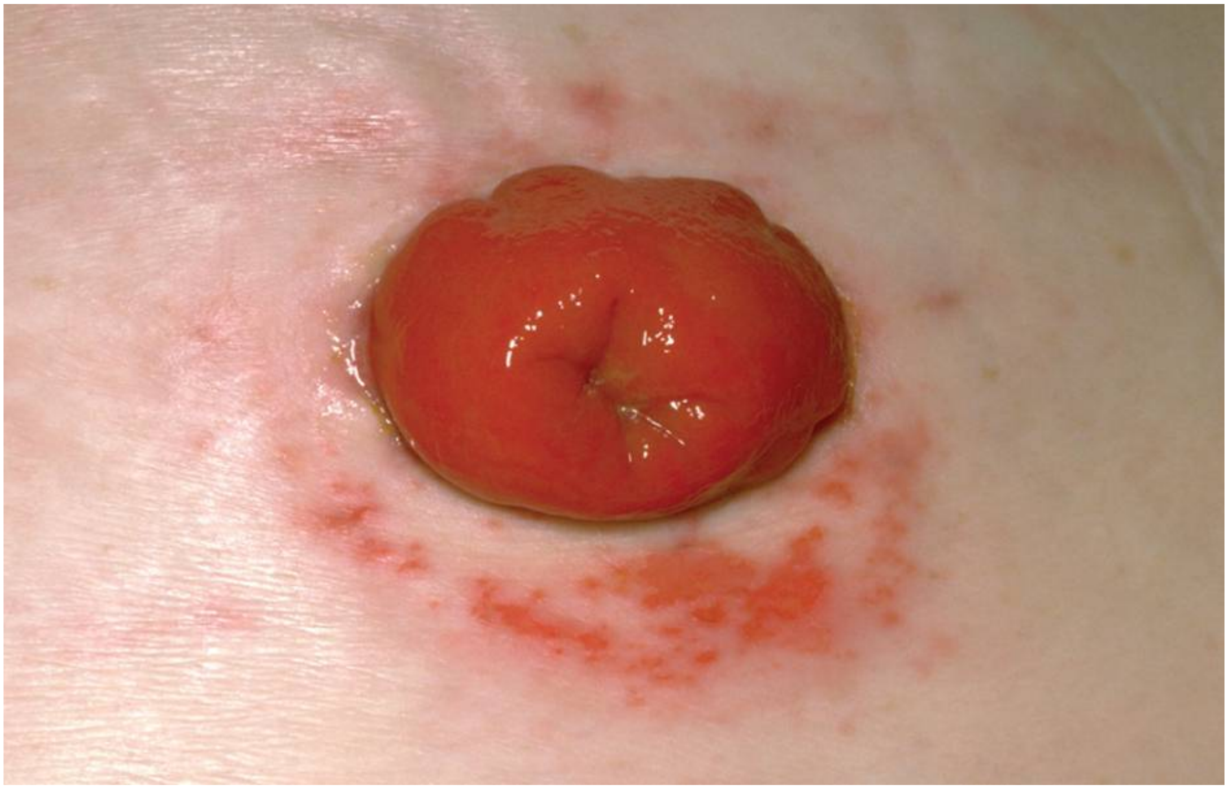


FIGURE 17-40 A colostomy.

© Medical-on-Line/Alamy Stock Photo.

Urostomies divert urine away from the urinary bladder by creating a passageway from the ureter to an abdominal stoma through a piece of ileum or large intestine that is surgically separated from the GI tract. When the ileum is used for this purpose, it is called an ileal conduit; when the large intestine is used, it is called a colon conduit. An external collection pouch is attached to the stoma and secured to the patient's body.

Management

Complications of ostomies include the following possibilities:

- Obstruction
- Constipation (with colostomies)
- Diarrhea
- Dehydration
- Leakage
- Tissue necrosis
- Detachment
- Prolapse
- Infection

The patient with an ostomy should be monitored for signs of tissue necrosis and infection, which, if detected, may warrant treatments ranging from antibiotic therapy to surgical intervention. Normal assessment findings for a patient with an ostomy include a pink, pain-free site that is free of redness or swelling. Detachment or prolapse of intestinal tissue from the abdominal wall may require bleeding control and occlusive dressings as well as surgical reconstruction. When assessing the patient with an ostomy, expose the stoma site and examine it for redness, swelling, or leakage. If any of these signs are found, notify the receiving facility upon arrival. Always ask the patient if the ostomy is functioning normally, without either leakage or obstruction.

An ileostomy pouch needs to be emptied four to six times per day; a colostomy pouch needs to be emptied one or more times per day. Laxatives should not be used by patients with ileostomies, and adequate daily fluid replacement (such as 6 to 8 glasses of water) is a necessity. In addition, the patient should not use soaps that contain baby oil, cold cream, or perfumes.

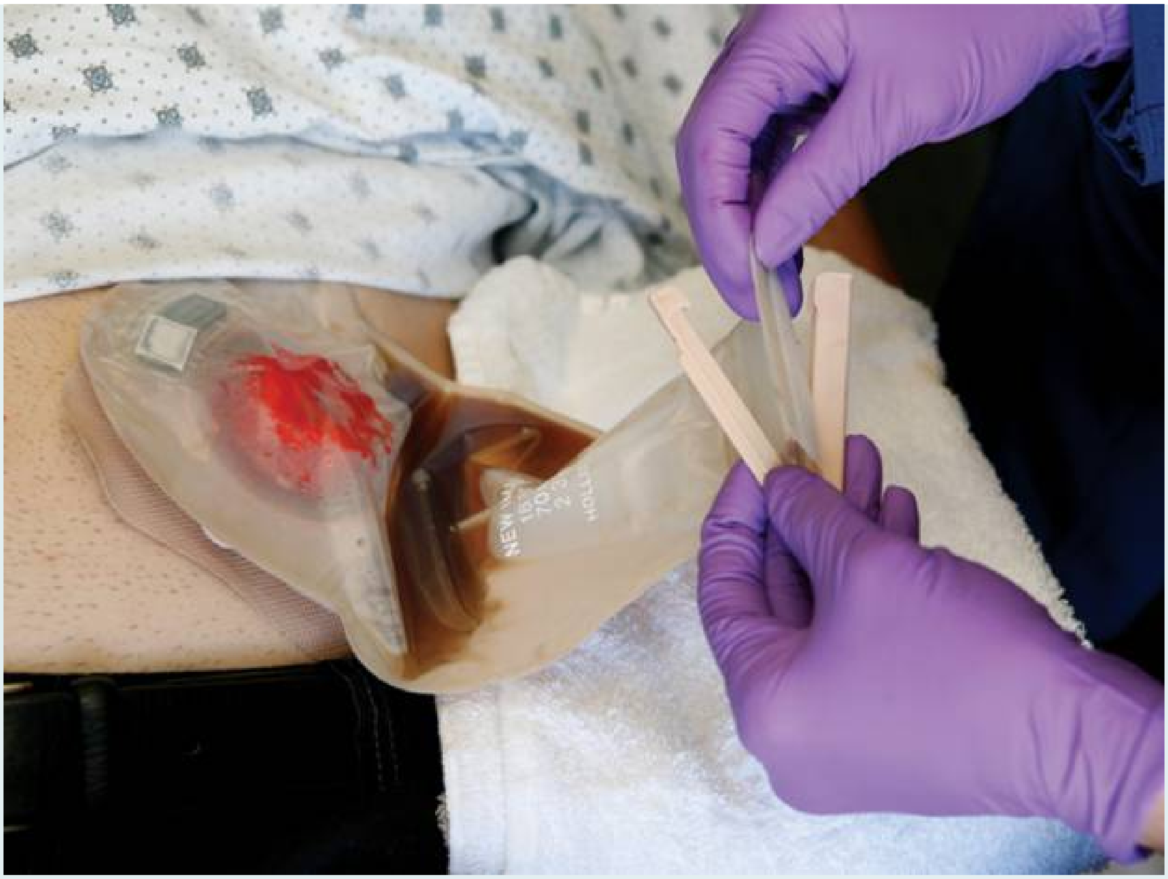
When preparing to empty or replace an ostomy, gather the following equipment:

- Stoma measuring guide or pattern

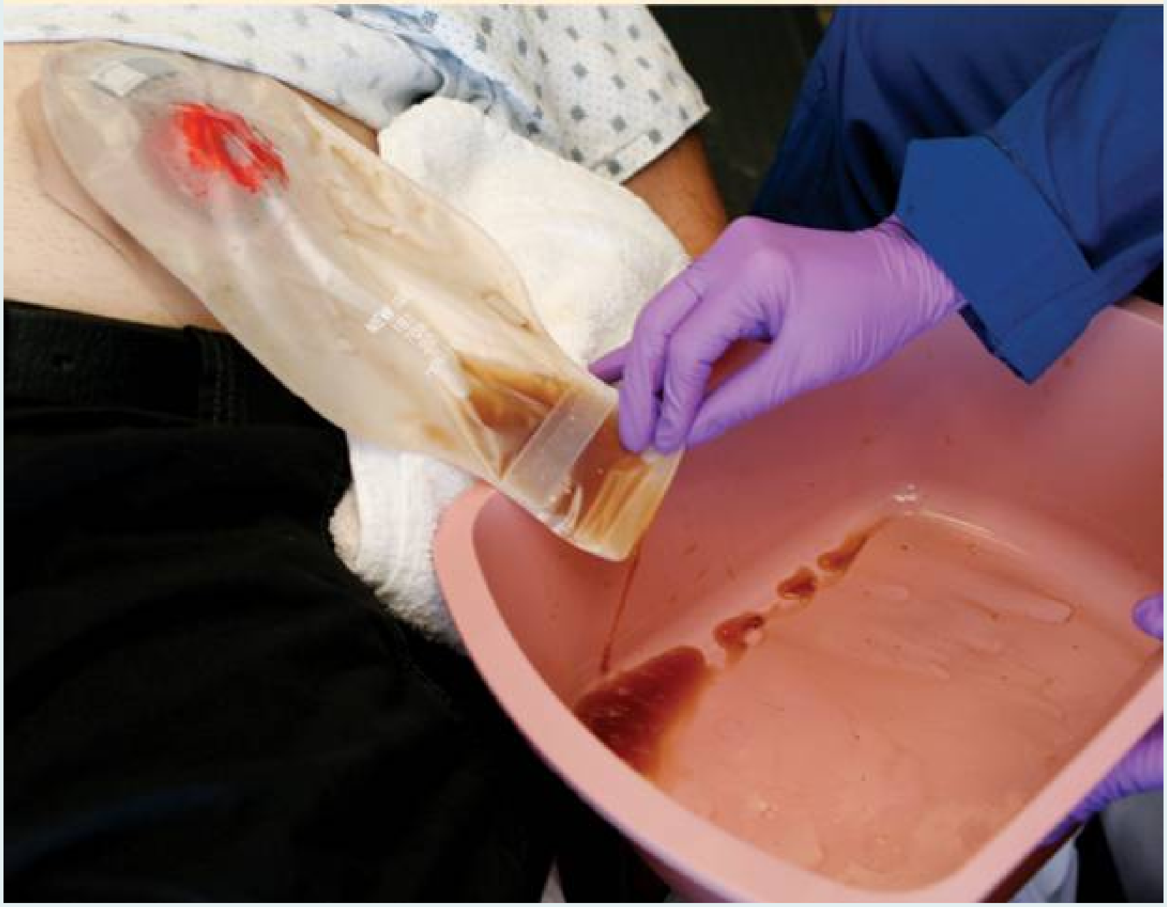
- Scissors
- New pouch
- Soft washcloth
- Soap and water
- Razor for shaving hair on abdomen
- Waste collection container
- Toilet paper
- Rubber ear (bulb)
- Biohazard bag for soiled pouch

Skill Drill 17-5 shows the steps for emptying an ostomy pouch. The pouch should be emptied when it is one-third to one-half full.

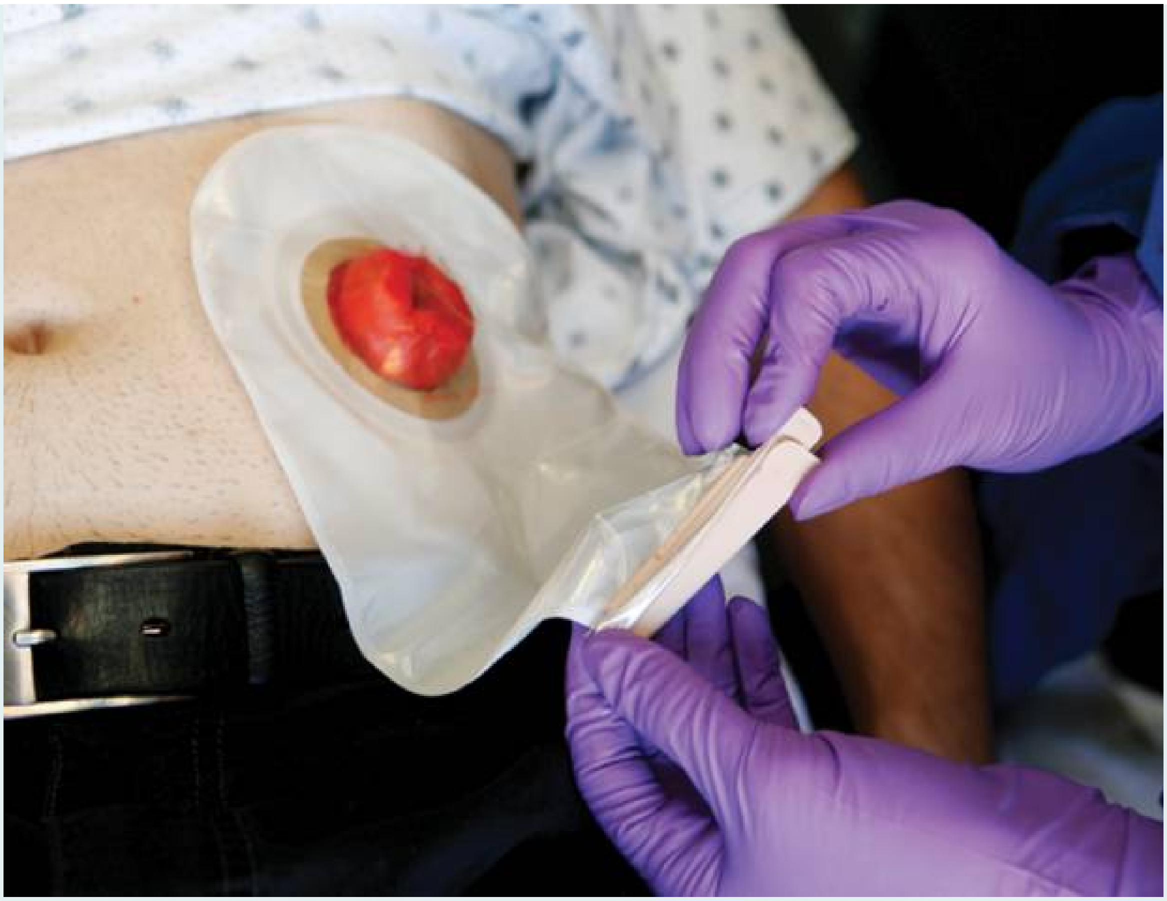
SKILL DRILL 17-5 Emptying an Ostomy Pouch



Step 1
Remove the clamp that keeps the pouch closed.



Step 2
If patient is supine, lift the pouch and position the opening over a waste collection container.



Step 3
Slide your fingers down the outside of the pouch to squeeze the contents out of the pouch. Clean the inside of the pouch opening with a piece of toilet paper. Rinse out the pouch with room-temperature water using a rubber ear (bulb) syringe. Put the clamp back onto the pouch to close it.

© Jones & Bartlett Learning.

1. Remove the clamp that keeps the pouch closed **Step 1**.
2. If the patient is supine, lift the pouch and position the opening over a waste collection container **Step 2**. If possible, have the patient lie on their side with the pouch opening positioned over a waste collection container.
3. Slide your fingers down the outside of the pouch to squeeze the contents out of the pouch.
4. Clean the inside of the pouch opening with a piece of toilet paper.

5. Rinse out the pouch with room-temperature water using a rubber ear (bulb) syringe.
6. Put the clamp back onto the pouch to close it **Step 3**.

Although ostomy pouches typically need to be changed only every few days, the CCTP may be required to change one under certain circumstances. If a leak or rupture of the bag occurs during transport, the pouch must be removed and replaced if the equipment is available. Less-emergent reasons to change a pouch include inflammation, pain, or irritation around the insertion site. In such instances, changing the pouch can typically be delayed until arrival at the receiving facility.

Skill Drill 17-6 shows the steps for replacing an ostomy pouch, which are summarized here:

SKILL DRILL 17-6 Replacing an Ostomy Pouch

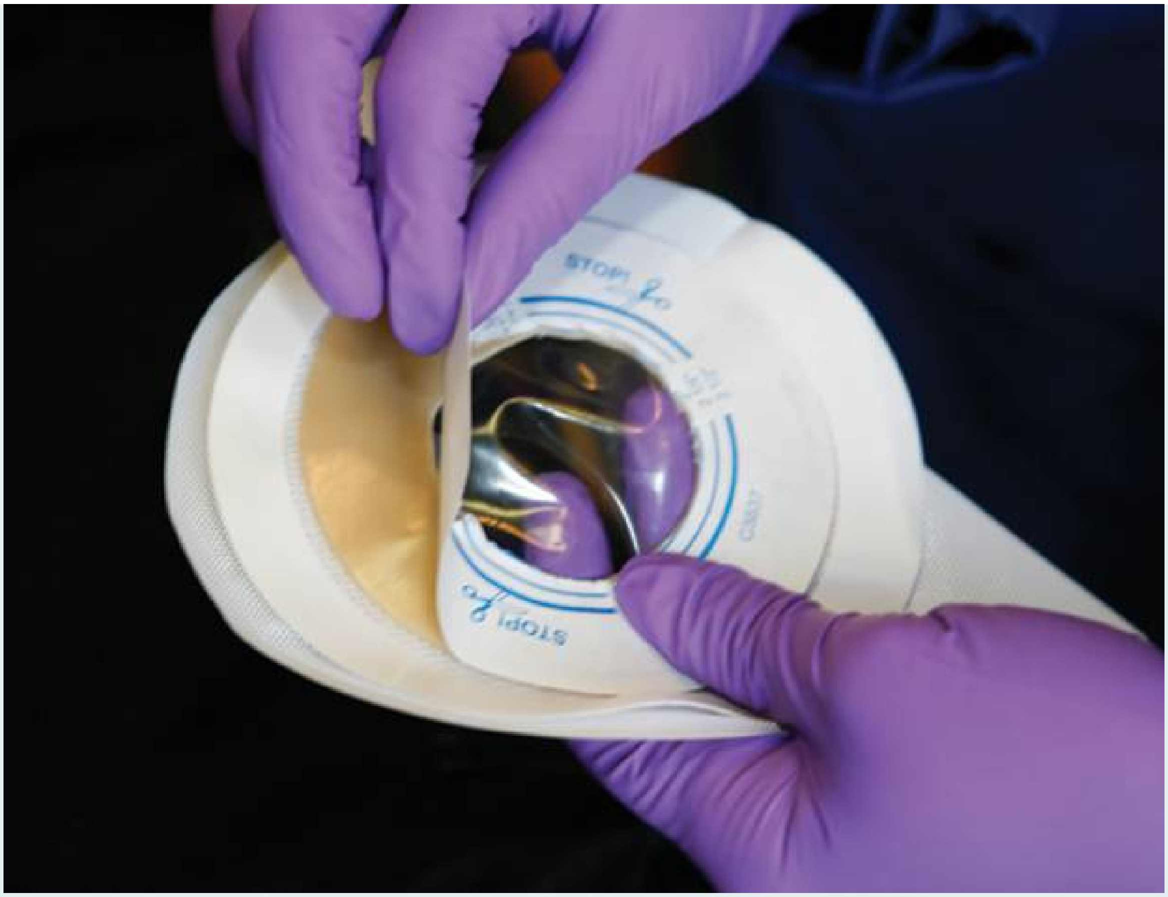
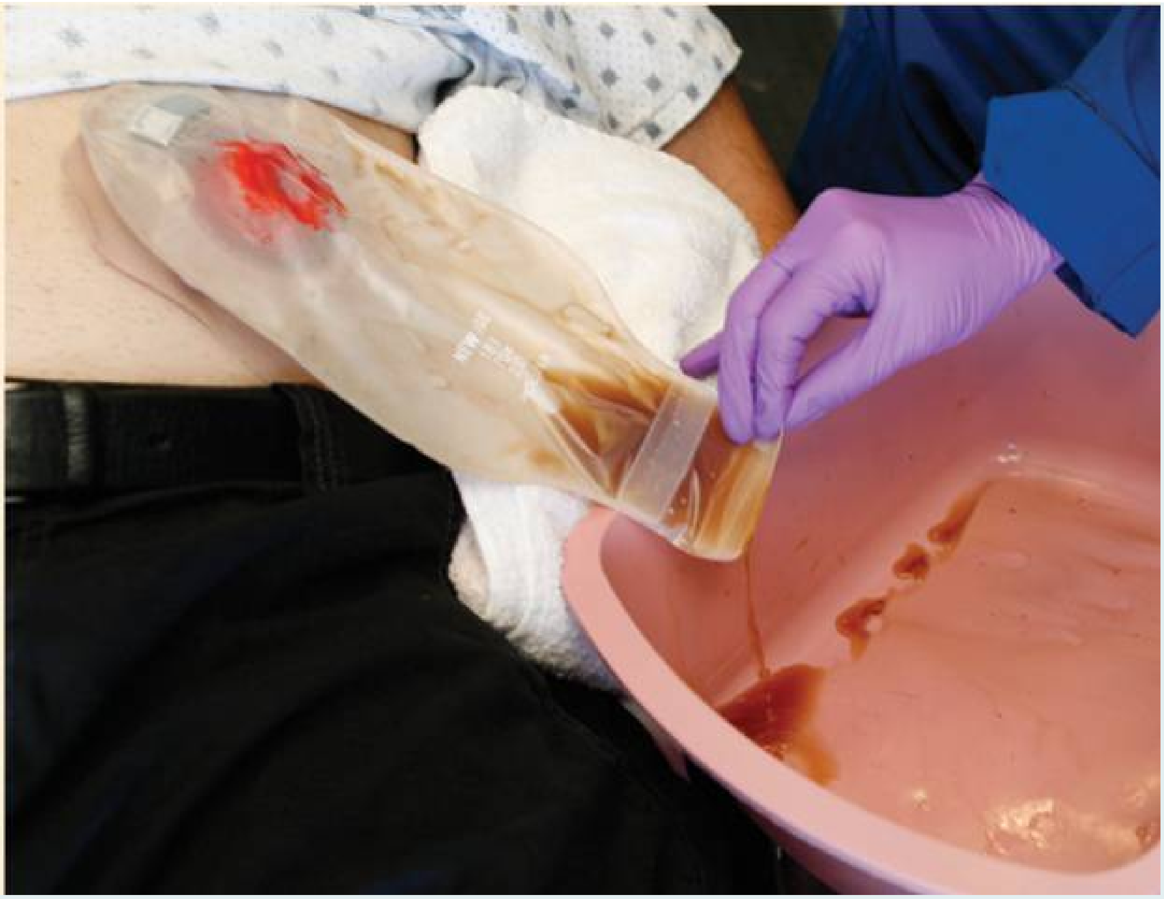
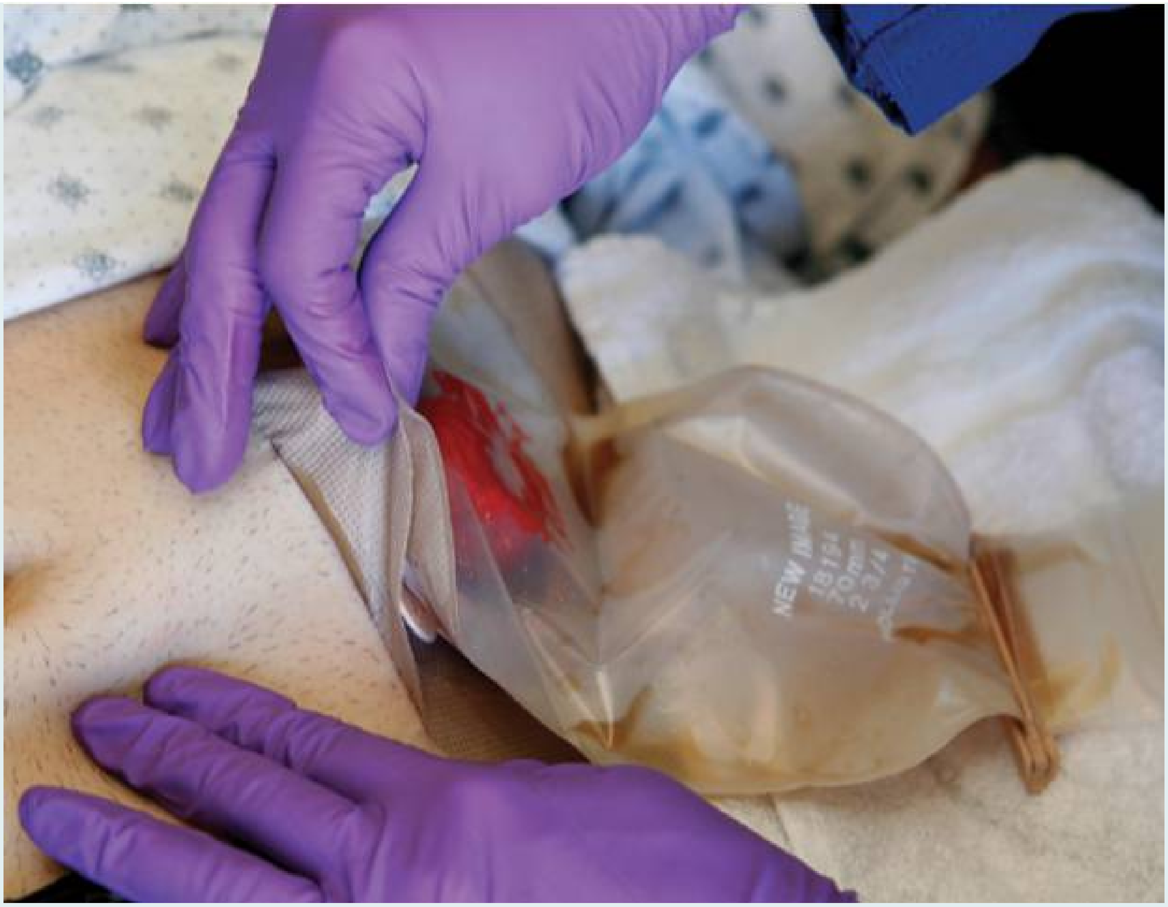
Step 1
Take standard precautions. Using the measuring guide or pattern, trace the correct opening onto the skin barrier of the new pouch, then cut out the opening you traced.



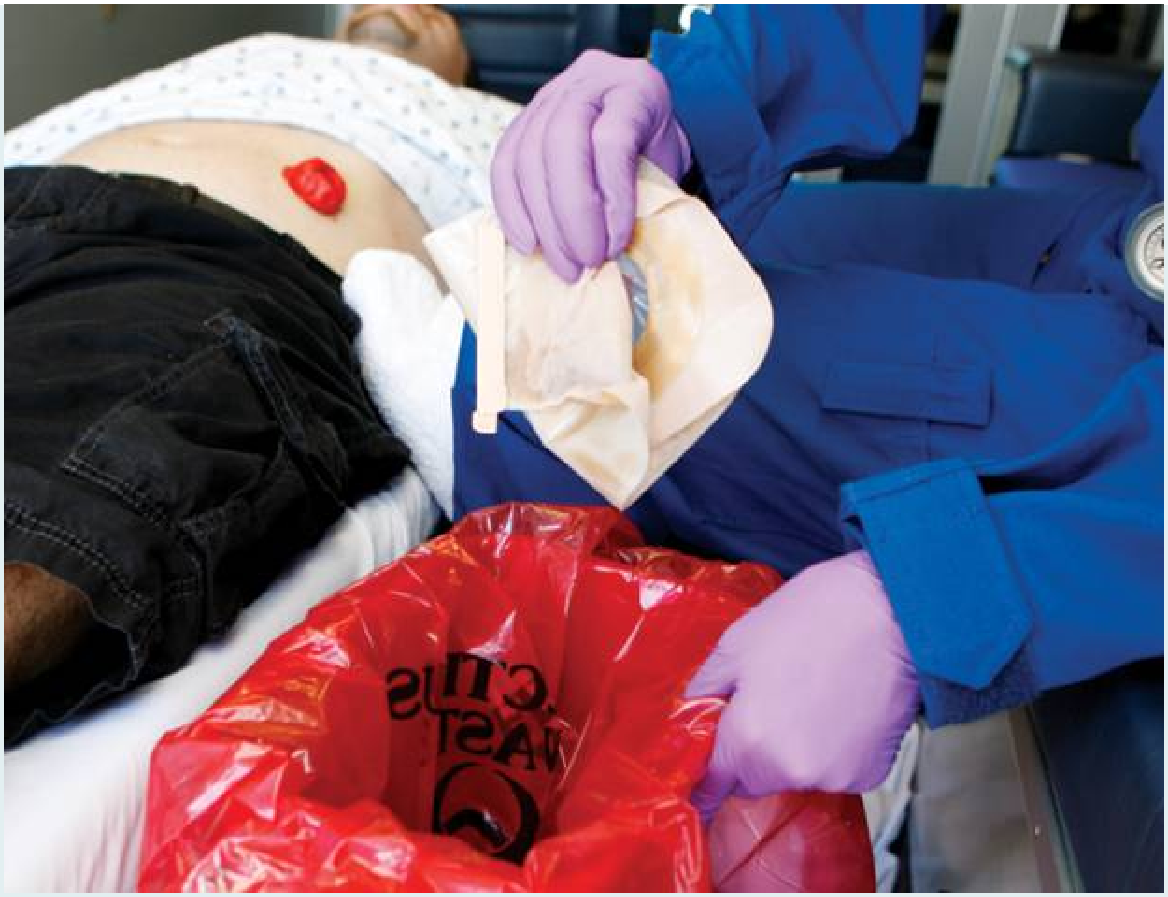
Step 2
Remove the paper backing that covers the adhesive on the skin barrier of the new pouch.



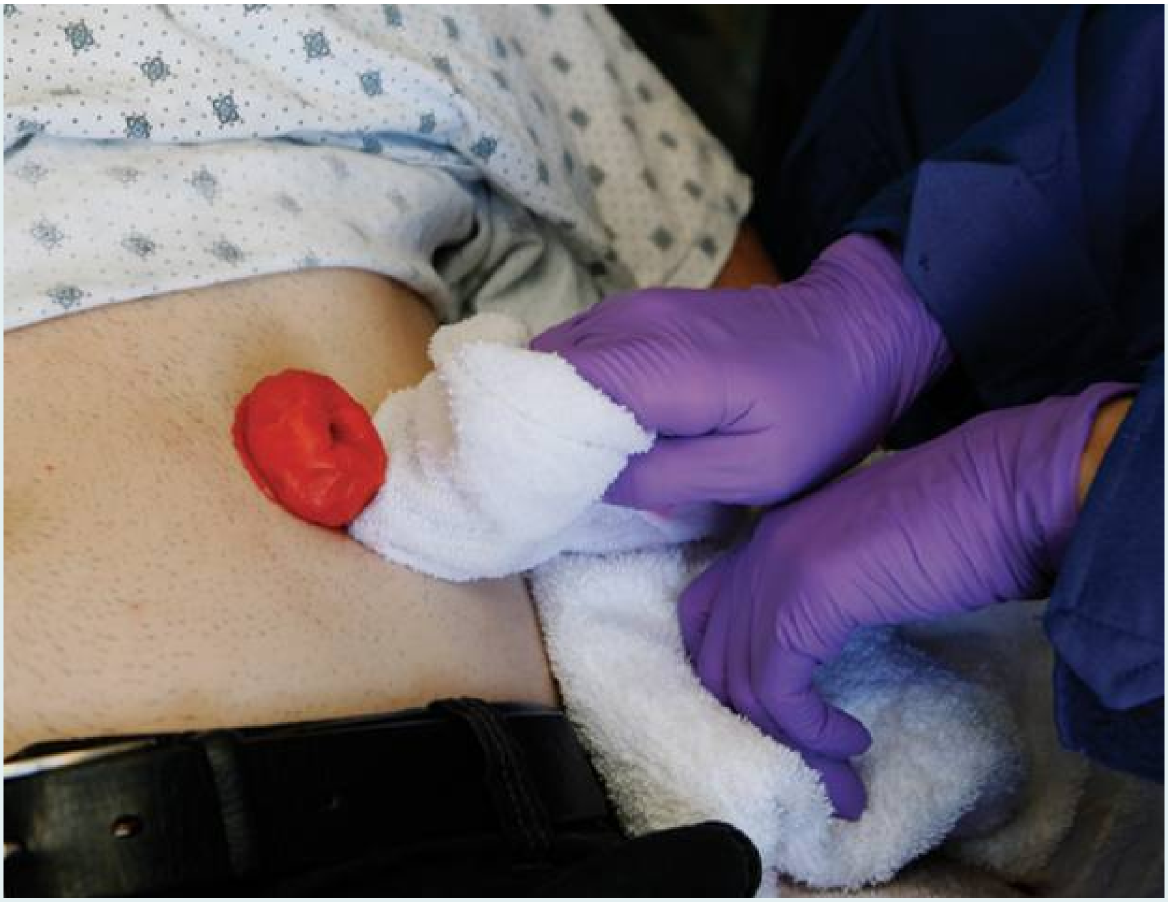
Step 3
Empty the pouch the patient is wearing.



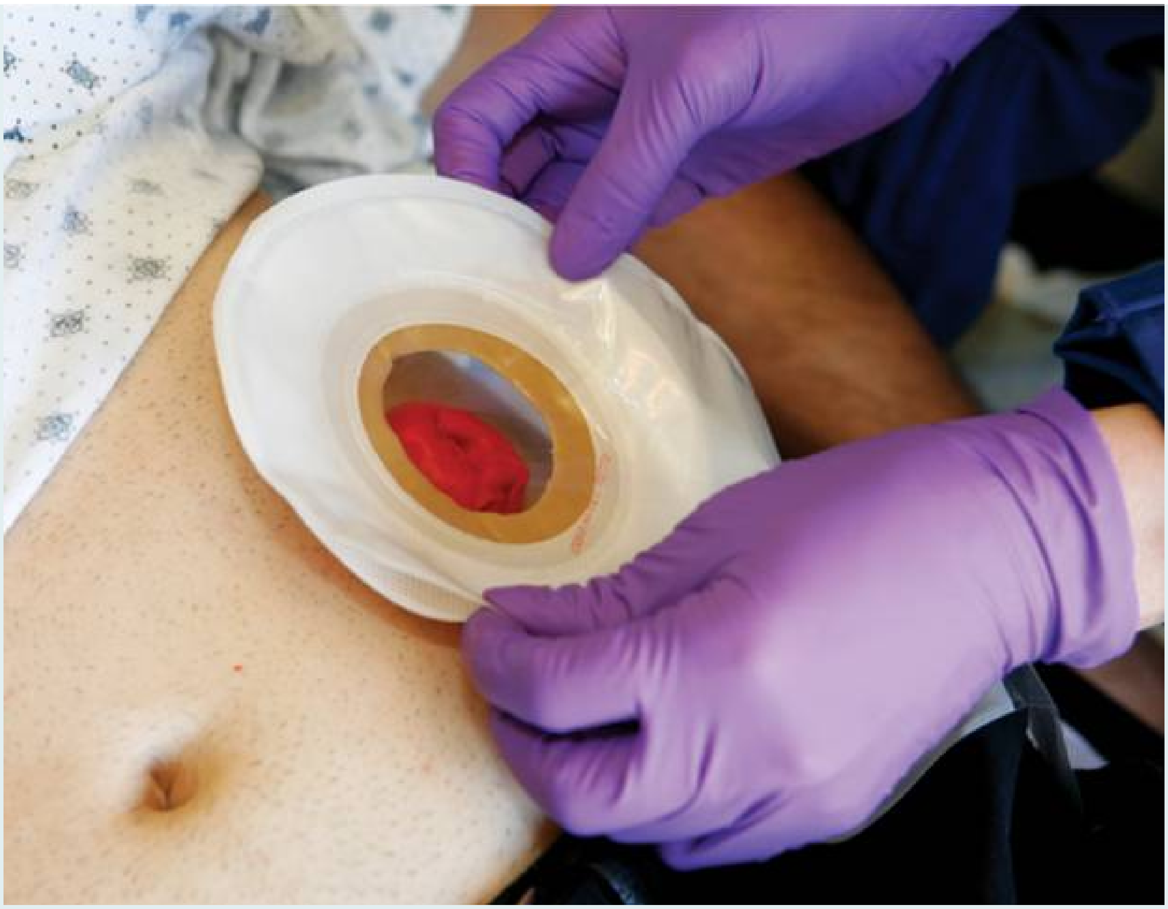
Step 4
Remove the pouch by stabilizing the skin around the pouch with your nondominant hand and peeling off the pouch with the other hand.



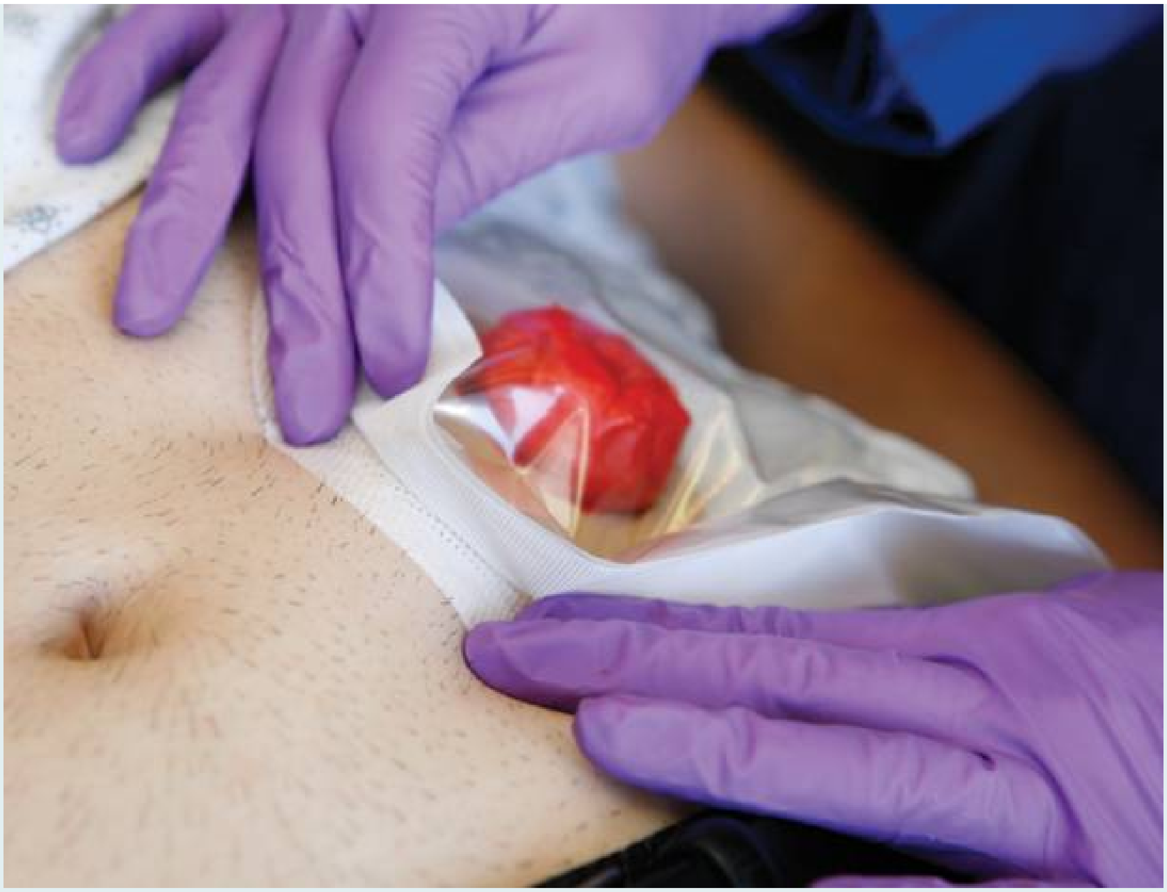
Step 5
Remove the clamp from the old pouch. Dispose of the old pouch by placing it into a biohazard bag.



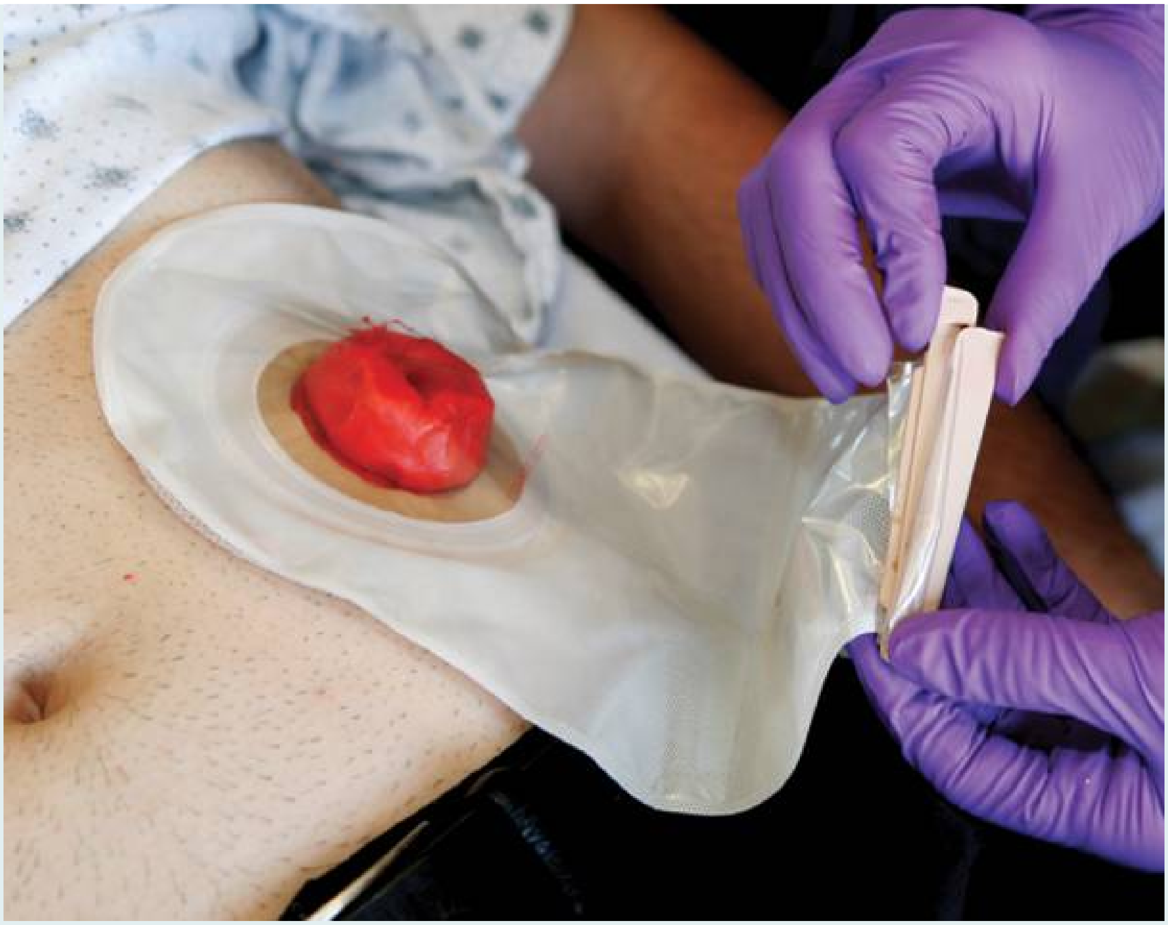
Step 6
Wash thoroughly around the stoma with mild soap and warm water. Rinse and dry the area with a soft cloth.



Step 7
Center the new pouch opening over the stoma.



Step 8
Press the skin barrier wafer onto the abdomen, removing all wrinkles or creases in the wafer.



Step 9
Put the clamp from the old pouch onto the opening of the new pouch.

© Jones & Bartlett Learning.

1. Take standard precautions.
2. Using the measuring guide or pattern, trace the correct opening onto the skin barrier of the new pouch, then cut out the opening you traced **Step 1**.
3. Remove the paper backing that covers the adhesive on the skin barrier of the new pouch **Step 2**.
4. Lay the pouch near you with the adhesive side up.
5. Empty the pouch the patient is wearing (see Skill Drill 17-5) **Step 3**.

6. Remove the pouch by stabilizing the skin around the pouch with your nondominant hand and peeling off the pouch with the other hand **Step 4**.
7. Remove the clamp from the old pouch.
8. Dispose of the old pouch by placing it into a biohazard bag **Step 5**.
9. Wash thoroughly around the stoma with mild soap and warm water **Step 6**.
10. Rinse and dry the area with a soft cloth. A small amount of bleeding may be normal.
11. Center the new pouch opening over the stoma **Step 7**.
12. Press the skin barrier wafer onto the abdomen, removing all wrinkles or creases in the wafer **Step 8**.
13. Put the clamp from the old pouch onto the opening of the new pouch **Step 9**.

Specific Drainage Tubes

After major abdominal surgery, a number of drainage tubes are placed to both assist in and evaluate the recovery process. For example, **Jackson-Pratt drains** are inserted to remove postoperative buildup of fluid and blood in the abdominal cavity **FIGURE 17-41**. Prevention of fluid accumulation in this way greatly decreases the risk of abscess formation and infection. The drain is controlled by the patient, who squeezes a bulb to induce suction. A flexible tube connected to the bulb travels through the surgical incision and into the wound site.

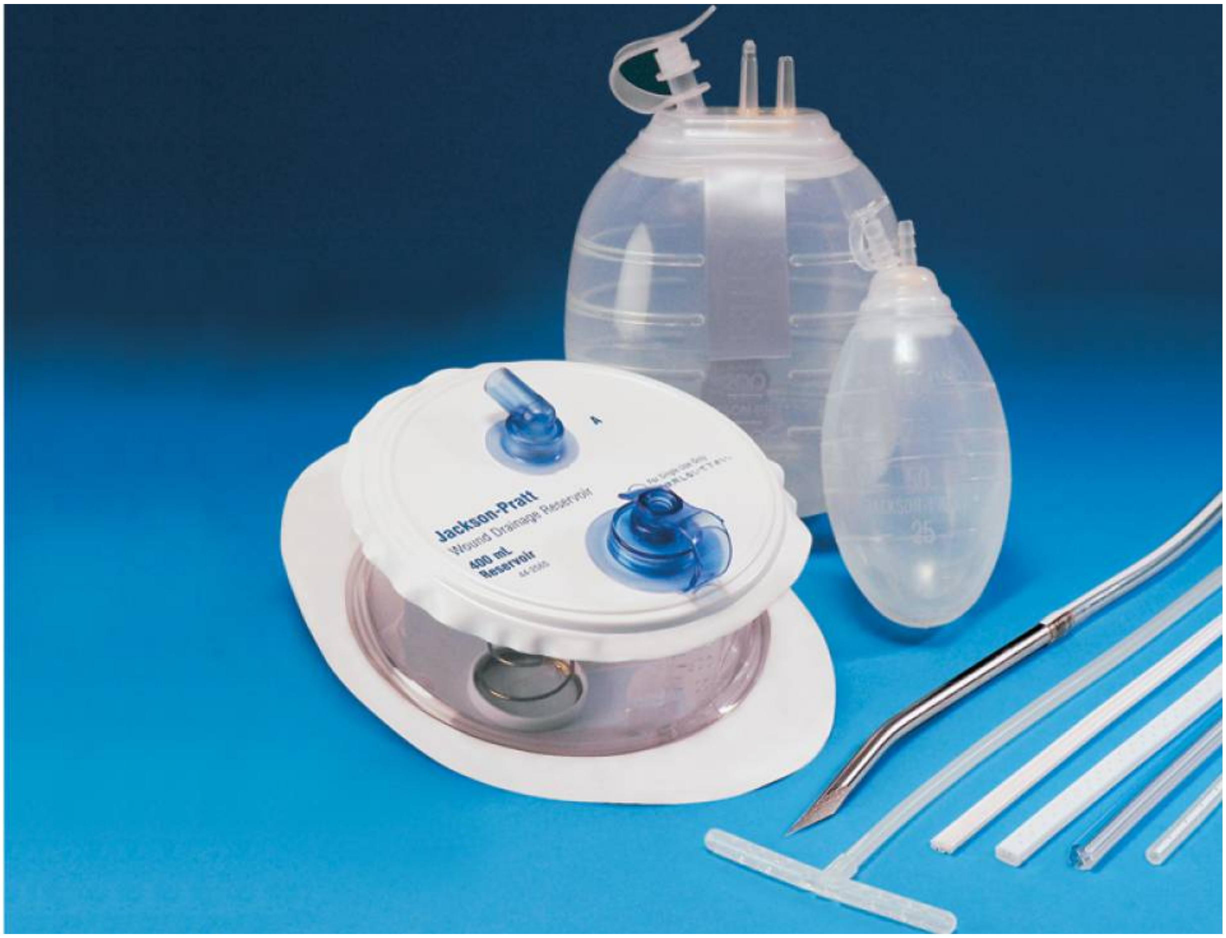


FIGURE 17-41 A Jackson-Pratt drain (in background) and a Hemovac drain (with blue connectors).

Courtesy of Cardinal Health.

Description

Similar surgical drainage tubes include the Hemovac and Davol drains. Both of these draining devices operate similarly to the Jackson-Pratt drain, with the only difference being bulb design.

During liver transplantation surgery, a **T tube** is placed to monitor bile drainage from the gallbladder. After the drainage bag has been removed, the tube may remain in place to facilitate examination of the biliary tract through a T-tube cholangiogram test.

All of these drainage tubes often become obstructed by blood clots, which can usually be cleared by digitally manipulating the tube. Dislodgement can slow the healing process and greatly increase the likelihood of infection, and the drain may need to be replaced through surgical means. Bleeding may occur from the wound site after dislodgement of the tube, and should be controlled. The wound site and sutures should be monitored for any signs of infection or improper healing.

In-Flight Considerations for Maintenance Tubes

In-flight complications need to be considered when patients have any of the numerous drainage systems that include closed bags containing air. Air pressure decreases as altitude increases. Gas volume increases proportionally to the decrease in air pressure, which could lead to distention of drainage devices. Although fixed-wing aircraft typically incorporate pressure-controlling mechanisms, the CCTP should always be prepared for equipment failure and know how to handle this situation. Controlling air pressure on rotor-wing aircraft may be more difficult because the aircraft may change altitude rapidly and often.

Excess air should be vented from any drainage bag such as a colostomy or urostomy prior to flight, in anticipation of changes in air pressure. Further venting may be required during transport, and the CCTP should confirm that the specific device in use can accommodate this manipulation. Similar preparations must be made for Jackson-Pratt and other surgical drainage devices. Be sure to unclamp any feeding or drainage catheters prior to departure and ensure that they remain unclamped for the duration of travel.

Metabolic Regulation of Acid–Base Status

The human body has an amazing ability to adapt to and function in extreme environmental conditions. From the peaks of mountains to great ocean depths, arid deserts, remote arctic locations, and the weightless expanse of space, human activities continue despite the environmental challenges. Yet, even with this incredible adaptability, the human body requires a carefully controlled internal environment for cells to function, organs to perform, and life to continue.

Significant alterations of the body’s oxygen and carbon dioxide levels, electrolyte concentrations, temperature, glucose levels, and acid–base status will impair cell, tissue, and organ function, eventually leading to death. CCTPs must manage any of these alterations resulting from illness, injury, or extrinsic factors to save patients’ lives and improve their chances for recovery.

Acid–base status is tightly controlled by numerous organs, receptors, and buffer systems. Dysfunction of any of the body’s vast array of cells, tissues, organs, and body systems threatens to disrupt this carefully maintained balance and further compromise cell, tissue, and organ function throughout the body. Although the human body can tolerate large quantities of exogenous acids and bases, widespread damage occurs when the body’s capacity to sequester, neutralize, and excrete these substances is exceeded. The liver, lungs, and kidneys are central players in the body’s metabolic regulation. As we discuss throughout this text, conditions that negatively impact or overwhelm any of these organs, from respiratory distress to trauma or toxicologic emergencies, will certainly affect acid–base status and lead to metabolic disarray. Detailed discussion of respiratory acidosis and respiratory alkalosis can be found in Chapter 6, *Respiratory Emergencies and Airway Management*.

Acid–Base Physiology

Hydrogen ions (H^+) are single protons released from a hydrogen atom; acids are solutions containing H^+ ions. A base (also basic or alkaline) substance can accept a free H^+. The relationship of acids to bases within the body is expressed by the pH value, which indicates the concentration of free H^+ present. Because additional basic substances are present, they become bound with free H^+, decreasing the amount of free H^+. The normal extracellular fluid pH ranges from 7.35 to 7.45. The pH value is inversely related to the amount of free H^+ present. When the free H^+ concentration increases, the pH value decreases (acidosis). When the free H^+ concentration decreases, the pH value increases (alkalosis). Cell protein activity becomes impaired when the pH falls outside the normal range, which is approximately 7.35 to 7.45. Cell death begins to occur when the pH falls below 6.8 or increases above 7.8.

Acids and bases are both absorbed into the body from dietary sources. Additionally, H^+ ions are produced during various metabolic processes. Altered cellular metabolism, changes in excretion patterns, or exposure to various exogenous substances can lead to wide variations in extracellular fluid pH. Intracellular function is altered when excess H^+ ions from extracellular fluid enter the cells through a **concentration gradient**. This concentration gradient is the dominant mode of cellular exchange with extracellular fluids. Virtually every chemical process is driven by concentration gradients and the movement of protons (which acids provide) and electrons (which bases provide). Without this ceaseless activity, enzymes and cellular machinery could not function.

Intrinsic Regulation of Acid–Base Balance

Three principal mechanisms are used to maintain a physiologic acid–base status within the body. First, chemical buffers sequester excess H^+ until a rising (alkaline) pH triggers their release. Second, the respiratory system controls extracellular P_{CO_2} concentration, which affects carbonic acid and ultimately H^+ concentration. Finally, the kidneys can either excrete acidic or alkaline (basic) urine to balance whole-body H^+ concentrations.

Chemical Buffer Systems

The human body uses several buffer systems to mitigate the effects of acid and alkali loads. Any substance that can alternately bind or release H^+ depending on the outside conditions is a **buffer**. Intracellular and extracellular buffer systems are the first line of defense against changes in pH.

The **bicarbonate-carbonic acid buffer system** is the principal extracellular buffer system. It operates primarily in the lungs and kidneys, where carbonic anhydrase is present to facilitate the chemical reaction. Carbon dioxide (CO_2) and water (H_2O) are reversibly converted into carbonic acid (H_2CO_3), which in turn is reversibly converted into H^+ and bicarbonate (HCO_3^-). This reaction reverses itself when large quantities of H^+ are present, ultimately turning excess H^+ into water and carbon dioxide. Carbon dioxide is then eliminated via respiration.

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O$$

The bicarbonate–carbonic acid buffer system is linked to the lungs and kidneys because these two organs can alter the concentrations of carbon dioxide and bicarbonate, respectively, thereby affecting the concentration of the remaining components and driving the direction of these reactions **FIGURE 17-42**. This system allows the body to dampen the effects of sudden acid or alkali loads.

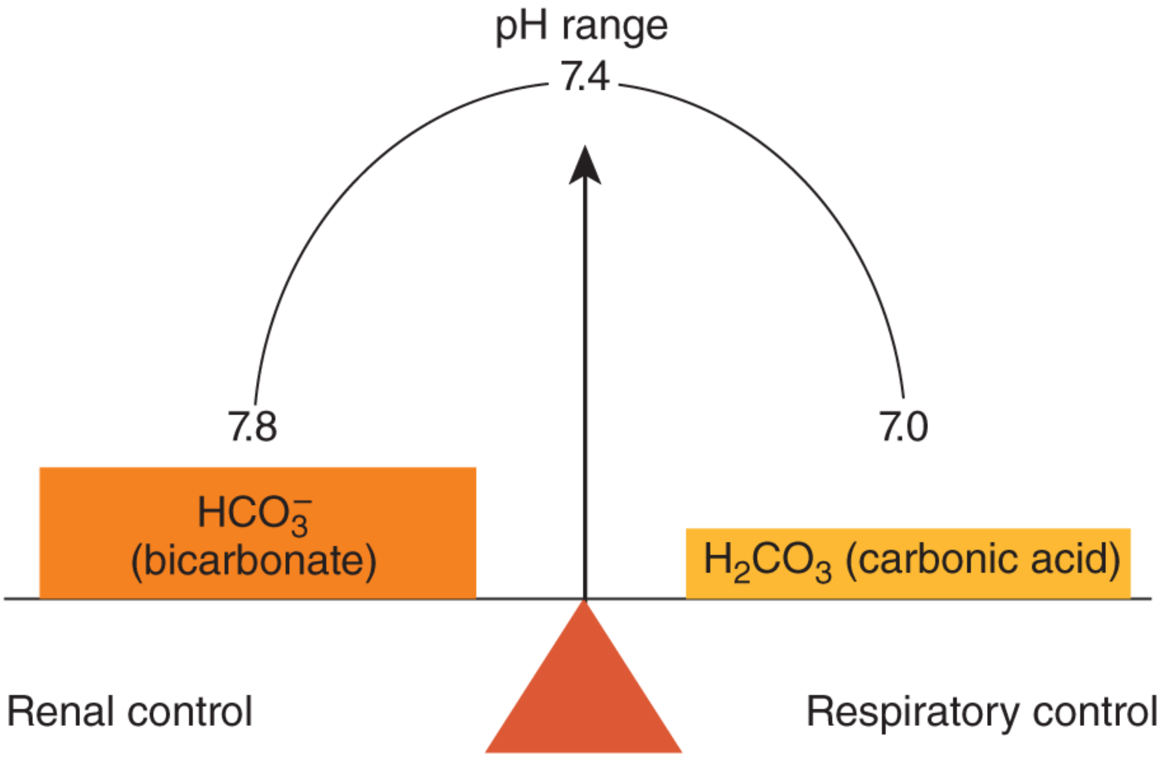

FIGURE 17-42 The balance of bicarbonate and carbonic acid shifts if either the renal or respiratory system fails, leading to an imbalance.

© Jones & Bartlett Learning.

Description

The **phosphate buffer system** operates similarly to the bicarbonate–carbonic acid buffer system, in that it allows only small pH changes following large variations of free H^+. This system functions primarily in the urine to convert strong acids or bases into weak acids or weak bases. Phosphate buffers work best in areas of the body with a normally lower pH, such as the renal tubules.

Hemoglobin, albumin, certain bone tissues, and other proteins also act as chemical buffers. Hemoglobin molecules, especially when deoxygenated (as in venous blood), can absorb a hydrogen ion, and ultimately buffer six times more H^+ than do other plasma proteins. Other protein buffers take several hours to resolve imbalances, but they provide the majority of total-body buffering capability. Bone buffers also contribute by absorbing and releasing excess H^+ when needed.

Respiratory Influence on pH

Carbon dioxide is a major determinant of the body's acid–base status. Carbon dioxide is produced during normal metabolism and must be continuously excreted. The concentration of carbon dioxide is directly related to the H^+ concentration and inversely related to the extracellular fluid pH. When the body is in an acidic state, alveolar ventilation automatically increases, resulting in decreased H^+ concentrations (and increased pH) within minutes. Conversely, any increase in alveolar ventilation above baseline will raise the pH and decrease the available concentration of free H^+. Such respiratory adjustments are rapid and effective to a certain point, but they will not completely resolve a primarily metabolic alteration in pH. Compensation of metabolic dysregulation ramps up over time in pulmonary and renal systems, with respiratory compensation reaching its maximum potential in 12 to 24 hours, while renal compensation reaches its optimal level after 3 to 5 days of exposure.

As mentioned previously, respiratory acidosis and respiratory alkalosis are discussed in depth in Chapter 6, *Respiratory Emergencies and Airway Management*.

Renal Influence on pH

The kidneys provide the body's last major line of defense against the catastrophic effects of large quantities of acids or bases. These organs excrete either acidic or basic urine depending on the pH of the body. In severe states, kidneys can excrete 500 mEq of H^+ per day. With persistent metabolic disarray, complex pathways likely involving systemic glucocorticoid and mineralocorticoid triggers up-titrate chronic renal compensation. Various types of transmembrane gates or channels exist along the nephron, through which concentration gradients and pH-dependent enzymatic reactions drive finely tuned excretion of acid or alkali loads in the urine.

To compensate for a metabolic or respiratory alkalosis, the kidneys increase bicarbonate excretion. This action decreases the available extracellular fluid bicarbonate, increasing the available free H^+ concentration and lowering the pH. The high bicarbonate filtration rate enables the kidneys to quickly eliminate metabolic alkali loads.

In acidic states, the kidneys reverse transmembrane flow of ions to address the imbalance. First, they directly excrete H^+ into the urine when excess H^+ ions are present. They then reabsorb previously filtered bicarbonate and return it into circulation, where the bicarbonate binds with excess H^+ and corrects all or part of the acidosis. Additionally, the kidneys produce additional bicarbonate to offset the excess H^+. Finally, of the net acid excreted, approximately one-half to two-thirds represents excretion of ammonium in the urine. It is interesting to note that Western diets high in animal protein tend to yield primarily acid loads that must then be excreted by the renal system. For this reason, patients with CKD are recommended to eat primarily vegetarian diets, as these are mainly alkali loads, to maintain acid–base homeostasis.

Hepatic Influence on pH

Although the renal and pulmonary systems deserve the limelight when it comes to acid–base regulation, it is important to acknowledge one of the most metabolically active organs in the body: the liver. Due to its role as an organ of digestion and its significant dual blood supply, hepatic tissue is both a source and a sink for hydrogen ions.

The digestion of food consumes energy and produces acids: Oxidation of consumed carbohydrates and fats yields carbon dioxide, which splits into H^+ and bicarbonate. During fasting states, hepatic mitochondria oxidize fatty acids and form ketones (overwhelmingly so in diabetic ketoacidosis). Hepatic tissues also convert ammonium (NH_4^+) to urea, which also yields H^+, but allows for excretion of nitrogenous waste.

The liver also produces albumin, a plasma protein that buffers carbon dioxide and fixed acids; furthermore, it metabolizes organic acid anions such as lactate (ie, lactic acidosis), consuming H^+ and turning it back to glucose (gluconeogenesis). For instance, people with liver failure often have an impressively elevated basal lactic acidosis, while decreased synthetic function (hypoalbuminemia) results in impaired ability to buffer significant acid–base fluctuations.

Laboratory Analysis

The concentration of free H^+ in extracellular fluid (pH) as well as other key variables can be obtained from an arterial blood gas (ABG) or venous blood gas (VBG) sample. Results also include P_{CO_2}, P_{O_2}, and bicarbonate measurements. Normal values are listed in **TABLE 17-16**. Additional values such as base excess, oxygen saturation, carboxyhemoglobin, lactate, and various electrolytes or blood count values are often included in these panel results. These tests are available immediately on many transport vehicles and can be obtained in most, if not all, hospitals. Many outlying clinics, treatment centers, and offices have advanced point-of-care testing (POCT) capabilities.

TABLE 17-16 Normal Arterial Blood Gas and Venous Blood Gas Values

Value	Arterial Blood Gas	Venous Blood Gas
pH	7.35–7.45	7.32–7.43
PCO_2	35–45 mm Hg	38–50 mm Hg
PO_2	80–100 mm Hg (adults)	40 mm Hg
	60–70 mm Hg (newborns)	
HCO_3^- (bicarbonate)	22–26 mmol/L (or mEq/L)	23–30 mmol/L

Data from Jacobs DS, DeMott WR, Oxley DK. *Laboratory Test Handbook*. Hudson, OH: Lexi-Comp; 2001.

Interpretation of Blood Gas Sample Results

ABG sample results provide the CCTP with valuable information about the existence or type of acidosis or alkalosis. First, consider the overall pH. A pH below 7.35 is considered an acidosis, regardless of any compensation (discussed later). A pH above 7.45 is considered an alkalosis, again regardless of any compensation.

Next, consider the primary source. An acidosis or alkalosis may be identified as primary metabolic, primary respiratory, or mixed (combined). Once the primary source of acidosis or alkalosis is determined, the presence of any compensation should also be evaluated. Overcompensation of a primary condition will not occur.

Metabolic acidosis is characterized by a decreased pH (less than 7.35) and a decreased bicarbonate level (less than 22 mmol/L). The latter suggests that an acid is consuming the bicarbonate. An individual may attempt to compensate for this acidic state by increasing respiratory rate and/or depth, thereby lowering the P_{CO_2} level. Elimination of carbon dioxide skews the equation used for the bicarbonate–carbonic acid buffer system (discussed previously) to the right, allowing for the mitigation of the excess acid. These efforts may normalize the pH but will never overcompensate **FIGURE 17-43**.

Description Description

Respiratory acidosis occurs when a patient has a decreased pH (less than 7.35) and an increased P_{CO_2} level (greater than 45 mm Hg). In this instance, the respiratory effort/exchange is inadequate to remove enough carbon dioxide to maintain a normal pH. If this condition persists, renal compensation will begin to occur via increased H^+ excretion, resulting in an elevated bicarbonate level (greater than 26 mmol/L) **FIGURE 17-44**. This finding is particularly notable in patients with conditions such as COPD.

Description Description

Metabolic alkalosis occurs when a patient has an elevated pH (greater than 7.45) and an elevated bicarbonate level (greater than 26 mmol/L). The renal system is extremely effective in excreting bicarbonate. The patient's P_{CO_2} level may increase as a result of compensation because the alkalosis inhibits respiratory drive **FIGURE 17-45**.

Description

Respiratory alkalosis occurs when a patient has an increased pH (greater than 7.45) and a decreased P_{CO_2} level (less than 35 mm Hg). This imbalance is usually the result of some type of alveolar hyperventilation (eg, resulting from anxiety or pain). Over time, renal compensation mechanisms promote the retention of H^+ and the excretion of bicarbonate **FIGURE 17-46**. Bicarbonate values will be lower if respiratory alkalosis persists for several hours to several days or longer.

Description Description

Mixed acidosis involves a low pH (less than 7.35), an elevated P_{CO_2} level (greater than 45 mm Hg), and a low bicarbonate level (less than 22 mmol/L). This imbalance occurs when both respiratory and metabolic acidosis are present at the same time in the same patient. Severe trauma, cardiogenic shock, and drug overdose are common situations in which mixed acidosis may occur.

Mixed alkalosis involves an elevated pH (greater than 7.45), a low P_{CO_2} level (less than 35 mm Hg), and an elevated bicarbonate level (greater than 26 mmol/L). This imbalance may occur when two seemingly unrelated medical issues manifest at the same time in the same patient. For example, a patient with chronic respiratory alkalosis who experiences a GI emergency may have respiratory alkalosis combined with metabolic alkalosis and, therefore, demonstrate mixed alkalosis.

A patient with one of the primary conditions just described may present to the CCTP as uncompensated, partially compensated, or well compensated. Practice is essential for the CCTP to become comfortable in identifying complex acid–base disorders. Various formulas exist to calculate expected compensation in different acid–base states. For instance, the Winters formula calculates the expected P_{CO_2} level in a metabolic acidosis:

$$P_{CO_2} = (1.5 \times H_{CO_3}) + 8 \pm 2$$

VBG analysis has limitations compared to an ABG determination in certain situations. Both pH and bicarbonate levels generally remain consistent between venous and ABG measurements. The Pa_{O_2} level does not, however, and it should not be inferred from the result of a VBG analysis. A VBG analysis can be used as a screening tool for an elevated P_{CO_2} level. The P_{CO_2} values generally correlate well between ABG and VBG analyses, although the relationship becomes less accurate as the patient's perfusion or hemodynamic status deteriorates.

Indirect Measurement of Acid–Base Status

Total blood carbon dioxide, which can be written as either T_{CO_2} or "bicarbonate" in clinical practice, provides an indication of an acid–base abnormality on routine blood work. This test is often included on the basic metabolic panel and may provide the information necessary to determine a patient's acid–base abnormality. The normal plasma bicarbonate value is 23 to 30 mmol/L.

An elevated bicarbonate value may indicate either chronic respiratory acidosis with carbon dioxide retention or metabolic alkalosis. Low bicarbonate values may indicate either metabolic acidosis or respiratory alkalosis. In either instance, further evaluation is warranted to determine the cause of the imbalance. The clinical context will help the CCTP infer the etiology of the change; for example, someone in a hypermetabolic state (fever) with a low bicarbonate value on the metabolic panel probably has a metabolic acidosis. Although a bicarbonate value provides limited information by itself, it may alert an attentive clinician to the presence of a significant acid–base disorder. A blood gas with pH measurement remains the definitive test, however.

Evaluation of the Anion Gap

When an acidosis is suspected, its origin can be examined using the anion gap (AG). Acidosis may be present with or without an AG, but its identification will help exclude or narrow the list of potential causes of the acidosis. The AG is a calculated value using the sodium (Na), chloride (Cl), and bicarbonate results. Many laboratory instruments automatically perform this calculation as part of the electrolyte panel. Some labs include potassium (added to sodium) in the calculation. The formula is as follows:

$$\text{AG} = \text{Na} - (\text{Cl} + \text{HCO}_3^{-)}$$

The normal AG is in the range of 8 to 12 mEq/L. The AG is calculated to determine the presence of unmeasured anions (eg, lactate, ketones). The normal AG is a representation of serum phosphate and albumin, the major unmeasured anion in the blood. An elevated AG can occur when the lactic acid level has become elevated as a result of trauma, shock, seizure, hypoxia, or contact with a toxic substance. Some toxic substances, including methanol, ethylene glycol, salicylates, and valproic acid, cause an elevated AG without lactic acid production. **Alcoholic ketoacidosis** and **diabetic ketoacidosis** also cause an elevated AG acidosis as a result of ketones, without increased lactic acid. Serum lactate levels greater than 4.0 mmol/L indicate lactic acidosis.

An acidosis with a normal AG results from a loss of bicarbonate or excess chloride, which happens most commonly with diarrhea, use of certain diuretics (eg, acetazolamide), and large-volume resuscitation with normal saline (chloride load). A lower than expected AG may be due to hypoalbuminemia or excess cations (hypercalcemia), for example.

Metabolic Alkalosis

When metabolic conditions create an excess of bicarbonate accompanied by a pH of greater than 7.45 on an ABG sample, the disorder is termed metabolic alkalosis. This disorder is further described as “chloride resistant” or “chloride responsive,” depending on the urine chloride concentration. Metabolic alkalosis results from either H^+ losses or gains of bicarbonate, either relative or actual. Relative gains of bicarbonate occur when there is a disproportional loss of chloride, usually accompanying a sodium loss that alters electroneutrality, leading to renal bicarbonate retention.

Vomiting or gastric suction is a common cause of metabolic alkalosis. The use of certain diuretics can cause metabolic alkalosis when it leads to excretion of excess chloride ions in the urine. Various endocrine conditions, including primary aldosteronism, Bartter syndrome, Liddle syndrome, and hyperglucocorticoidism, may also produce this kind of imbalance.

Prehospital providers risk causing metabolic alkalosis when they place a patient with a previously compensated respiratory acidosis from hypercapnia or chronic obstructive pulmonary disease with an elevated $P\text{CO}_2$ level on a ventilator and aggressively ventilate that individual. Prior to ventilation, the body compensates for a chronically elevated $P\text{CO}_2$ level through enhanced bicarbonate retention by the kidneys to maintain a neutral pH. Following aggressive ventilation, the carbon dioxide level normalizes, creating a relative bicarbonate excess, allowing a metabolic alkalosis to predominate.

Overzealous administration of sodium bicarbonate may cause significant and prolonged metabolic alkalosis. Even with renal excretion of the excess bicarbonate, reduced tissue perfusion related to persistent alkalosis can lead to serious sequelae.

Clinical Features

Patients with metabolic alkalosis demonstrate many significant clinical effects, often related to concomitant electrolyte abnormalities. Elevated blood pH increases hemoglobin's affinity for oxygen molecules, thereby inhibiting the tissues' ability to detach oxygen from the hemoglobin and leading to tissue hypoxia. Compensatory hypoventilation and hypercarbia further undermine tissue oxygenation. Expect P_{CO_2} levels to increase 0.7 mm Hg for every 1 mmol/L increase in bicarbonate. Seizures, altered mental status, refractory arrhythmias, and weakness may occur as well. Alkalosis will decrease ionized calcium levels and sequester potassium within cells (causing a transient hypokalemia), with both of these imbalances then causing additional symptoms. Potassium and hydrogen ions can be envisioned as moving in opposite directions. For this reason, bicarbonate is administered to patients with severe hyperkalemia to (transiently) remove potassium from the extracellular space.

Treatment

The treatment of metabolic alkalosis is directed toward the identification and correction of the cause in a specific patient. Urgent treatment should occur when the bicarbonate level exceeds 40 mmol/L or the pH exceeds 7.55. Many patients experiencing metabolic alkalosis have potentially massive hypovolemia from large GI- or renal-related fluid volume losses. These patients require volume resuscitation and electrolyte repletion with careful monitoring. Potassium, sodium, calcium, and chloride repletion are often required as well.

Specific management includes surgical management for pyloric stenosis, which causes protracted vomiting and massive GI fluid and H^+ losses in affected children. Other GI fluid and H^+ losses can be controlled with treatment of emesis or obstruction, or the discontinuation of gastric suction devices. Discontinuation of a diuretic medication or a change in the type of diuretic is indicated when excess renal chloride losses cause the alkalosis.

Several pharmacologic options exist for the treatment of severe metabolic alkalosis. Hydrochloric acid can be given intravenously to replete H^+ and correct chloride losses. Potassium chloride will replete potassium and correct chloride losses. Acetazolamide (Diamox) is a diuretic and carbonic anhydrase inhibitor that can correct fluid volume excess and promote the excretion of bicarbonate in the urine. Chloride-responsive alkalosis is generally treated with the previously described medications. Chloride-resistant alkalosis often benefits from potassium chloride repletion, but also requires correction of the underlying condition to resolve the alkalosis. Certain endocrine disorders have specific treatment requirements that necessitate consultation with medical direction.

Metabolic Acidosis

Metabolic acidosis is demonstrated by a decreased serum pH (less than 7.35) accompanied by a decreased bicarbonate concentration (less than 22 mmol/L). This disorder occurs through three possible mechanisms:

- The kidneys may be unable to excrete enough of the H^+ produced or absorbed each day.
- An increased amount of H^+ is present because of exogenous loading or altered metabolism.
- The kidneys or GI tract excretes too much bicarbonate, causing an imbalance.

A myriad of situations cause metabolic acidosis. Cellular starvation states, such as diabetic ketoacidosis, alcoholic ketoacidosis, and profound malnutrition, lead to accumulation of acids through altered metabolism and, therefore, an increased AG acidosis. GI bicarbonate losses may occur from diarrhea, fistulas, or lower GI suctioning, causing metabolic acidosis. Many toxic chemicals (eg, iron, salicylates, toxic alcohols) produce either an AG or non-AG metabolic acidosis following exposure or absorption.

Excess accumulation or impaired excretion of lactate leads to acidosis and an elevated AG. Lactic acidosis has a large number of etiologies, including the following:

- Exposure or overdose (eg, ethylene glycol, iron, salicylates, metformin)
- Shock and inadequate tissue perfusion
- SIRS and organ dysfunction
- Infection
- Malignancy
- Exertion or exercise
- Metabolic disorders (eg, glucose-6-phosphatase deficiency)
- Liver failure

Renal Metabolic Acidosis

Kidney dysfunction may cause metabolic acidosis through a variety of mechanisms. Uremic states from the accumulation of cellular waste products directly cause a metabolic acidosis. As previously discussed, processes such as decreased bicarbonate secretion and inadequate renal ammonium production can also lead to acidosis. Certain congenital or acquired causes of acidosis are specific to the renal system.

Type 1 (distal) **renal tubular acidosis (RTA)** impairs the kidney’s ability to excrete H^+. This state is often characterized by plasma bicarbonate levels of less than 15 mmol/L, hypokalemia, increased urine calcium levels, and kidney stones. Urine pH remains greater than 5.5 despite the acidosis. This condition, which is relatively rare, may be hereditary, autoimmune, or linked to other diseases or chemicals.

Type 2 (proximal) RTA involves impaired bicarbonate reabsorption, which translates into increased renal bicarbonate excretion. It is characterized by an initially elevated urine pH; when plasma bicarbonate levels drop, the urine pH then decreases significantly. Glucose, protein, and phosphate are increasingly excreted in the urine in addition to bicarbonate. This condition, like type 1 RTA, is rare. It may be congenital or caused by numerous medications or various medical conditions.

Type 4 (generalized or hyperkalemic) RTA results from impaired liberation of renin by the kidneys or altered synthesis of, excretion of, or response to aldosterone by the kidneys or adrenal glands. In addition to hyperkalemia, the patient often demonstrates an elevated urine sodium level (greater than 40 mmol/L) and hyperchloremia. Type 4 RTA is the most common manifestation of RTA. It is linked with toxicity of numerous medications and genetic disorders, and may also arise as a consequence of diabetes, HIV, systemic lupus erythematosus, and sickle cell anemia.

Types 1, 2, and 4 RTA present as a metabolic acidosis without an elevated AG. Type 3 RTA is a rare classification, with characteristics of types 1 and 2, and is not clinically relevant.

Clinical Features

Metabolic acidosis is rarely a clinically isolated occurrence. Instead, the underlying pathologic conditions causing the acidosis will typically shape the patient’s clinical status. Patients with metabolic acidosis may exhibit Kussmaul respirations (tachypnea with large tidal volumes) because a decreasing pH will stimulate the respiratory centers, causing an increase in alveolar ventilation. Hypotension and hypovolemia are also noted in conjunction with severe metabolic acidosis, demonstrating the progression of widespread cell, tissue, organ, and body system dysfunction. In response to acidosis, potassium ions shift out of the cell while excess H^+ moves into the cell, resulting in a pseudohyperkalemia even when the whole-body potassium presence is actually normal or perhaps decreased.

Treatment

CCTPs should resist the temptation to treat every metabolic acidosis with IV sodium bicarbonate. Certain conditions, such as RTA, hyperchloremic acidosis, and isolated GI bicarbonate losses, are amenable to treatment with IV sodium bicarbonate, but other causes of metabolic acidosis require a more specific approach. Indeed, it is usually better to correct the underlying cause of acidosis and provide supportive care. Furthermore, adequate ventilation is mandatory to allow elimination of the extra carbon dioxide produced with sodium bicarbonate administration. Sodium bicarbonate is indicated in patients with significant bicarbonate losses (eg, RTA, fistula), hyperkalemia, and sodium channel blocker overdose.

Lactic acidosis requires correction of cellular metabolism, which cannot be accomplished with administration of sodium bicarbonate. Improving cellular metabolism will cause production of excess H^+ to cease and will allow normal acid–base control mechanisms to restore a physiologic pH. Optimal tissue oxygen delivery and adequate perfusion are the primary goals of lactic acidosis treatment, along with more specific management of potential underlying causes.

The various types of RTA are treated with agents such as sodium bicarbonate or sodium citrate, often over long periods of time. Calcium, potassium, and other electrolytes require careful monitoring and often repletion, depending on the particular type of RTA. Type 2 RTA is characterized by urine bicarbonate and potassium wasting, so it often requires potassium repletion. Type 4 RTA is characterized by hyperkalemia; it often requires volume expansion, potassium-wasting diuretics, or even mineralocorticoid replacement therapy in certain situations.

Sodium bicarbonate is not recommended for the treatment of diabetic ketoacidosis and has been shown to cause cerebral edema when administered to children with this condition. Diabetic ketoacidosis is best managed with fluid volume restoration, IV insulin, and electrolyte (especially potassium and sodium) correction.

Alcoholic ketoacidosis, another cellular starvation acidosis, is not treated with IV sodium bicarbonate unless the patient has a profound, life-threatening acidosis (pH <7.1) that is refractory to fluid repletion and dextrose supplementation. Instead, this condition is treated with IV fluids and carbohydrates to improve the patient's nutritional status and allow normal metabolic processes to resume. Crystalloid resuscitation with supplementation of dextrose and thiamine (administered before the dextrose solution to correct deficiencies and prevent Wernicke encephalopathy) are generally the only medications needed for treatment of these patients.

Other causes of metabolic acidosis, such as uremia and exposure to toxic chemicals, require specialty consultation and often complex treatment. CCTPs should seek medical direction when transporting patients with these conditions.

Diagnosis and management of patients with metabolic alterations of acid–base status can challenge CCTPs. Clinical suspicion, focused investigation, and optimal treatment of these disorders will improve patient outcomes and minimize the adverse impacts of many serious medical conditions. Providers should consider the potential for and consequences of metabolic acid–base alterations during every critical care transport.

Flight Considerations

CCTPs must take precautions and sometimes modify care-related techniques when performing air medical patient transport. Unpressurized or underpressurized aircraft place patients with GI/GU conditions at increased risk for complications related to transport. Careful assessment and simple interventions can eliminate or minimize many of these potential adverse effects.

GU complications specifically related to air medical transport are rare. Prolonged exposure to altitude will alter urinary pH. Pneumaturia (the presence of gas within the bladder) can occur following a UTI caused by certain microorganisms, after manipulation of the GU tract, and when a fistula develops between the digestive tract and bladder (causing the bowel contents to contaminate the normally sterile bladder environment). Pneumaturia requires more specific interventions, often including an indwelling urinary (Foley) catheter for bladder and urinary tract decompression. Although placement of a catheter offers some benefits—it eliminates the need for the patient to void during transport, allows the CCTP to observe urine output, and prevents complications associated with urinary retention—the risks of infection are now considered to outweigh these benefits. Thus, routine placement of a Foley catheter is no longer a recommended practice.

Compared to GU complications, GI complications during air medical transport are much more common. Sequestered gases due to abdominal surgery, bowel obstruction, and abdominal trauma will expand significantly as cabin altitude increases. Indeed, ascending from sea level to 9,000 feet will cause any sequestered gas to expand by 50%. In severe situations, this gas expansion can lead to respiratory compromise, severe discomfort, syncope, and vasovagal episodes.

Patients with any of the previously mentioned conditions should have an NG or OG tube placed prior to any increase in cabin altitude.

Once these tubes are in place, they should be either vented to ambient air or connected to suction for the duration of the transport. Patients with a colostomy should have their devices frequently monitored for excessive amounts of gas and either emptied or changed if this complication occurs. If at all possible, patients who have undergone abdominal surgery should wait 24 to 48 hours after their procedure before being transported by air.

Summary

The GI and GU systems are complex pathways through the body that support critical functions—the digestion of food and the elimination of wastes, respectively. Over the life span, these systems must withstand constant usage, leading to inevitable wear and tear. The many GI/GU pathologies that can occur require prompt recognition and treatment to preserve function. Because of the many interactions of these systems with accessory organs and other systems, local problems can quickly evolve into systemic ones. Through awareness of the possible diseases, history taking, and proper assessment, many complications can be prevented or corrected at an early stage.

The CCTP serves as the connection between the patient and the tertiary care required to manage GI/GU conditions. The continuity of care provided by the CCTP is a fundamental contributor to the treatment and recovery of the critically ill patient with such a condition. When a problem arises during transport, the CCTP is responsible for correcting it and preventing its recurrence. Being equipped with this knowledge provides the CCTP and the patient with the greatest likelihood for a safe, uneventful transfer.

CASE STUDY

Your CCT crew is called to a community hospital ICU for transport of a 48-year-old man with a Mallory-Weiss tear and uncontrolled hemorrhage to a tertiary hospital 35 miles away. On arrival, your partner begins an assessment of the patient while you obtain a report from the patient's nurse and transferring physician.

The patient is described as having a drinking problem; he told staff that he normally consumes half a case of beer each day. The patient was admitted at 0500 hours, 14 hours before you were called, because of protracted vomiting that began the previous evening. The emesis initially appeared to the patient to be gastric contents, but after several hours it changed to have the color of bright red blood. His stools were also melanotic. The patient reported epigastric pain radiating to his back as an 8 on a scale of 0 to 10. He was hemodynamically unstable with the following values: pulse rate, 130 beats/min; BP, 80/50 mm Hg; and unlabored respirations, 26 breaths/min. He was afebrile. Past medical history included hypertension, hyperlipidemia, coronary artery disease, depression, alcohol use disorder, and obstructive sleep apnea. His medications included metoprolol, 50 mg twice daily; aspirin, 81 mg daily; and a statin. He denies having any allergies. Admission lab work revealed the following values: blood alcohol level, 160 mg/dL, hemoglobin level, 7.3 g/dL (normal, 14.0–17.5 g/dL); platelet count, 100,000/µL (normal, 150,000–350,000/µL); and clotting times (an international normalized ratio) that were 1.5 times normal. Electrolytes were normal except for a potassium level of 3.1 mEq/L (normal, 3.5–5.0 mEq/L). Cardiac enzymes and a 12-lead ECG were normal.

The patient received 1 L of normal saline while awaiting blood bank type and crossmatching for transfusion of packed red blood cells. His BP increased to 130/80 mm Hg, pulse rate slowed to 90 beats/min, and respirations slowed to 18 breaths/min. He was transfused with 2 units of packed red blood cells, and a bolus of pantoprazole was administered intravenously. Nausea was controlled by IV ondansetron, and morphine was administered for analgesia.

A gastroenterologist performed an endoscopy to determine the cause of the bloody emesis, which revealed a single, longitudinal tear in the esophagus, extending from the stomach cardia through the esophagogastric junction and upward into the esophagus. A second tear extended from the junction upward into the esophagus. Both appeared to be actively bleeding. Control of bleeding was attempted with epinephrine injections; when oozing continued, several hemoclips were applied that achieved seemingly good control of the bleeding. The patient remained in the ICU. A repeat hemoglobin level was 8.1 g/dL, and vital signs remained stable.

Serial hematocrit levels showed a gradual decline, and the patient became increasingly tachycardic and hypotensive. Three additional units of packed red blood cells and two units of fresh frozen plasma were transfused. When his BP remained low, an infusion of norepinephrine was titrated to maintain a MAP greater than 60 mm Hg. The patient had two additional episodes of hematemesis and was intubated for airway protection after he was noted to have an aspiration event. A CVC was placed in the right internal jugular vein. A Foley urinary catheter was placed for fluid monitoring. The ICU physician decided that the patient needed to be transferred for a higher level of care.

Your partner’s assessment of the patient showed a sedated and mechanically ventilated 48-year-old man who appears malnourished. He has a mildly distended but soft abdomen and coarse respirations in the right lung base. His MAP is 68 mm Hg on 10 µg/min of norepinephrine infusing in one of the three lumens of a right internal jugular CVC. Assessment also reveals a heart rate of 130 beats/min and oxygen saturation of 98%. The patient is mechanically ventilated via assist-control with a tidal volume of 450 mL, respiratory rate of 20 breaths/min, FiO_2 of 60%, and PEEP of 8 cm H_2O. The most recent hemoglobin level, measured approximately 3 hours after the last transfusion but before his latest hematemesis, was 9.0 g/dL. His pH on the most recent ABG sample is 7.25, and his bicarbonate is 10 mEq/L. Per the Foley bag, his urinary output has been approximately 0.5 mL/kg/h. He had been medicated with ondansetron for his last bout of vomiting and is receiving an infusion of propofol running at 60 mg/h, with intermittent push doses of fentanyl. He appears to be adequately sedated. The patient is currently receiving a sixth unit of packed red blood cells through his peripheral IV line and just received 4 mg of calcium gluconate. The medications infusing match the doses stated in the report, and both the IV and the CVC appear to be functioning well.

During transport, the patient became aroused and was slightly agitated, so the propofol infusion was increased to 80 mg/h. His BP began to drop, and norepinephrine was titrated to 20 µg/min to maintain a MAP of 60 to 65 mm Hg, and the blood transfusion continued. No further hypotension occurred, and the patient was transferred to the ICU at the tertiary medical center.

1. Why was the initial hypokalemia not treated? Why did the patient receive a dose of calcium gluconate?
2. Did the patient have an adequate response to transfused blood products?
3. Discuss his volume status. What is his acid–base status?
4. Would a fluid bolus have been preferable to increasing the vasopressor infusion to maintain BP?

Analysis

Packed red blood cell transfusion is directly associated with hyperkalemia, especially in patients who receive multiple units of blood. Cell breakdown results in increased potassium extracellularly as intracellular stores are released. The hospital staff recognized from the admission laboratory work and patient presentation that multiple units of blood would be required. Furthermore, significant blood product transfusion is associated with hypocalcemia and cardiac dysrhythmias. In a patient with a history of cardiac disease, the staff was right in anticipating and preventing complications by administering calcium gluconate.

The patient did not have an adequate response to the transfused blood products. He received 5 units of packed red blood cells. The subsequent hemoglobin level was 9.0 g/dL, an increase from his initial level of 7.3 g/dL. Since we can expect each unit of packed red blood cells to increase the hemoglobin by 1 g/dL, it is apparent that the patient is having ongoing bleeding. He received 1 L of normal saline during initial resuscitation, as well as several units of blood products. His urine output is not optimal, likely as a result of hypotension and subsequent kidney injury. He may benefit from a small bolus of crystalloid (such as 500 mL) to determine if his urine output increases, but fluid resuscitation needs to be judicious. He has a history of cardiac disease, and is receiving a large volume of fluid in total through his infusions and carriers, and we know that his hypotension is likely the result of ongoing bleeding and hemorrhagic shock. His clinical course will improve with control of bleeding and continued replacement of blood products. Based on the overall picture and his lab values, he appears to have a metabolic acidosis, likely from a mixed picture of alcoholic ketoacidosis and lactic acidosis in the setting of tissue hypoperfusion.

Unstable patients vomiting blood originating in their esophagus or stomach can present significant airway concerns, especially if their mental status deteriorates. This patient tolerated an endoscopy and maintained his airway appropriately until he had repeat episodes of hematemesis. He was noted to have aspiration followed by oxygen desaturation, likely from a combination of altered mental status from acidosis and anemia, and lung tissue irritation from aspirated vomitus. He was appropriately intubated for airway protection.

The latest hemoglobin level was still low at 9.0 g/dL, and he had subsequent hematemesis and hypotension. He is receiving a sixth unit of blood during transport and already has norepinephrine running. His BP likely decreased from the vasodilatory effects of the increased dosage of propofol that was administered to manage his agitation. The

CCTP could have opted to provide an increased amount or more frequent doses of fentanyl instead. To support the patient's BP, the CCTPs had a choice of increasing the norepinephrine infusion or the rate of the blood transfusion. They chose to increase the vasopressor dose, which served to support BP until the patient's volume status could be restored. Administration of crystalloid is an option if vasopressors and increased blood replacement rate are not effective, although a preferable alternative would have been to add a second vasopressor agent, vasopressin. Vasopressin would have the added benefit of reducing splanchnic circulation, possibly accelerating hemostasis.

Bleeding associated with Mallory-Weiss tears stops spontaneously in most cases. Factors likely responsible for the excessive bleeding in this patient include his history of alcohol use disorder and the associated liver dysfunction as evidenced by prolonged clotting times. He was also thrombocytopenic. While these factors could have resulted in the declining hematocrit, it is also possible that the patient had another source of bleeding in his GI tract.

PREP KIT

Ready for Review

- Homeostasis depends on a number of metabolic processes involving the gastrointestinal (GI) and genitourinary (GU) systems, but these processes can be affected by a number of pathologic conditions. Assessment and management of GI and GU pathologies are inherently difficult because the signs and symptoms that accompany them may be vague and difficult to recognize.
- The GI system consists of a network of organs and ducts devoted to the digestion of food and the extraction of its nutritional content.
- The alimentary canal contains numerous specialized cells and tissues. Four layers are seen almost continuously from the esophagus to the rectum: the mucosa, the submucosa, the muscularis externa, and the serosa.
- The alimentary canal maintains a chemical environment that is effective in digesting food, yet does not alter the environment of the rest of the body.
- The alimentary canal consists of the mouth, pharynx, esophagus, stomach, small intestine, and large intestine; food travels through these structures and finally exits the body via the rectum.
- The renal system provides a path for wastes to leave the body and maintains proper electrolyte parameters.
- The kidneys continuously filter blood, manage volume, maintain appropriate balances between acids and bases, and discard toxins and excesses by producing urine. The remainder of the urinary system—the ureters, urinary bladder, and urethra—provides for the transport and storage of urine during its journey out of the body.
- The purpose of the male reproductive system is to generate sperm and provide a means for its delivery to a fertilizable egg in

the female partner.

- The female reproductive system produces and develops eggs. In addition, the uterus of the female provides a home for a developing embryo during gestation.
- Pregnant patients who present with an acute abdomen are considered a surgical emergency and require an appropriate diagnosis to avoid the risk of maternal and fetal mortality.
- Women of childbearing age may present with severe abdominal pain that may appear to be caused by GI or GU etiologies, although complications of pregnancy must always be considered.
- Symptoms of GI abnormalities typically include abdominal pain, tenderness, and bleeding.
- GI bleeding can be classified into two categories based on the location of the bleeding: upper GI bleeding and lower GI bleeding.
- Endoscopy is the preferred method for locating the source of GI bleeding. Vessel imaging and interventional angiographic approaches provide alternative means of localizing and treating such bleeding.
- Colonoscopy can visualize the entire rectum and large intestine, up to the ileocecal junction.
- In angiography, dye is injected into blood vessels, which will leak into the lumen of the GI tract at the site of GI bleeding.
- Peptic ulcers are the leading cause of upper GI bleeding.
- Widespread implementation of proton pump inhibitors and histamine-2 blockers have reduced the prevalence of gastric mucosal erosion.
- Acute gastritis is characterized by a rapid onset of mucosal inflammation, frequently accompanied by mild to severe upper GI bleeding.
- Alcohol and tobacco use, diet, and NSAID use are major patient-driven factors that can lead to GI bleeding.
- Reactive gastritis is a chronic mucosal edema that results from recurring contact of the mucosa with antagonistic substances such

as bile, pancreatic juice, or NSAIDs.

- When portal hypertension occurs, venous blood will use alternative pathways for its return to the vena cava via the azygos system. An esophageal varix occurs when the swelling of esophageal veins intrudes into the lumen of the esophagus.
- In cirrhosis, buildup of fatty acids, in combination with chronic destruction of liver tissue and fibrosis, obstructs blood flow.
- The leading cause of cirrhosis is infection with the hepatitis C virus, with alcoholic liver disease closely following as the second most common cause.
- Mallory-Weiss syndrome involves a longitudinal laceration of the esophageal mucosa as a result of repeated significant changes in local pressure, such as those seen in forceful vomiting.
- Diverticulosis is a disease of the lower GI tract that is commonly seen in older adults. Diverticula are a common source of lower GI bleeding.
- Diverticulitis, an inflammation of the diverticula, is frequently a result of infection from invading intestinal bacteria.
- Angiodysplasia is a malformation of submucosal blood vessels in the GI tract.
- Inflammation and infection of the appendix cause appendicitis. The classic presentation is a relatively rapid onset of right lower quadrant pain, nausea and vomiting, and fever.
- Inflammatory bowel disease is a collective term covering ulcerative colitis and Crohn disease.
- Ulcerative colitis is an inflammation of the rectal mucosal and submucosal tissues. Bloody diarrhea is common in patients with this condition.
- Crohn disease is a less organized inflammation of the GI tract, in which all layers of the mucosa may be affected.
- Radiation colitis and immune checkpoint inhibitor colitis may also result in lower GI bleeding.

- Symptoms of GI bleeding include melena, diffuse abdominal pain, emesis and hematemesis, fever, complaints of frequent dizziness and syncope, diarrhea, dehydration, and cardiac arrhythmias.
- Symptoms of significant GI bleeding include hemodynamic instability, shock, large amounts of bright red blood in emesis, hematochezia, hypotension, tachycardia, diaphoresis, altered mental status, and a decreased level of consciousness.
- Ongoing decreases in the hemoglobin and hematocrit values indicate active bleeding.
- Pressure ulcers can arise from prolonged pressure on body tissues; they are commonly seen in patients confined to a bed.
- During acute GI bleeding, airway compromise occurs primarily by physical obstruction or mechanical obstruction.
- Any patient with acute GI bleeding should be designated as nothing by mouth (nil per os [NPO]), and blood samples should be drawn concurrently with IV placement.
- Treatments for endoscopic- and pharmacologic-refractory variceal hemorrhage include balloon inflation (during emergent, life-threatening bleeding) and transjugular intrahepatic shunt placement.
- The introduction of a transjugular intrahepatic portosystemic shunt into the systemic venous circulation results in a significant decrease in the hepatic portal pressure and, in turn, a significant decrease in the pressure in the esophageal collateral veins.
- A mechanical intestinal obstruction results from a physical blockage of the intestinal lumen and can be classified into one of three categories: extrinsic, intrinsic, or intraluminal.
- Ileus is the lack of movement of the GI contents through the intestines in the absence of a mechanical obstruction.
- In a patient with an intestinal obstruction, the abdomen is diffusely tender and distended on palpation.
- A computed tomographic (CT) scan can be used to diagnose a bowel obstruction with exceptional specificity.

- After addressing any life threats to the patient’s airway, breathing, or cardiac functioning, initial treatment of a patient with intestinal obstruction focuses on fluid resuscitation and bowel rest.
- A nasogastric or orogastric tube may already be in place when the CCTP first encounters the patient, particularly during interfacility transports.
- Air transport should be postponed or avoided for any patient with a bowel obstruction, if possible.
- In general, an insult to the liver is either infectious or noninfectious. If the insult resolves within 6 months without any permanent function deficit, it is termed acute. When symptoms persist longer, the patient is diagnosed with chronic liver disease.
- Hepatitis, an inflammation of the liver, is the physiologic result of any liver disease.
- Fulminant hepatic failure is the result of a sudden significant insult to the liver, such as severe alcohol intoxication, drug overdose (eg, acetaminophen), or acute hepatitis viral infection.
- When bilirubin, which is normally conjugated by hepatocytes and excreted via bile, begins to build up in the blood as part of the hepatitis pathway, it results in jaundice and scleral icterus.
- Symptoms of early acute hepatitis include general malaise, generalized fatigue, and fever and chills. Symptoms of chronic hepatitis include portal hypertension, melena, hematochezia, shortness of breath, hypotension, tachycardia, and hair loss.
- Patients with cirrhosis and ascites are at risk of infection of the ascitic fluid, termed spontaneous bacterial peritonitis.
- Spontaneous bacterial peritonitis and hepatorenal syndrome portend poor outcomes for patients with end-stage liver disease.
- Liver function is assessed by evaluating the presence of the liver’s synthesized products as well as the absence of its cellular enzymes in the blood. It is important to recognize the distinction between tests for liver function and markers of injury.

- Treatment of hepatitis focuses on preventing further injury, with a goal of avoiding progression to cirrhosis.
- Blockage of the biliary tracts at any point will result in a backup of bile and, possibly, depending on the location of the obstruction, pancreatic enzymes.
- Gallstones in the gallbladder (cholelithiasis) are a fairly common condition that causes colicky pain in the right upper quadrant of the abdomen. Patients may present with nausea and vomiting and a positive Murphy sign.
- Techniques for imaging and detecting choledocholithiasis include transabdominal ultrasonography, endoscopic ultrasonography, hepatoiminodiacetic acid scanning, magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography, and percutaneous transhepatic cholangiography.
- Immediate treatment of symptomatic cholecystitis, cholelithiasis, and choledocholithiasis focuses on pain management, antiemetics, and maintaining NPO status. Hypotension may need to be addressed with fluid resuscitation.
- Ascending cholangitis is a serious infection of the biliary system, which usually occurs after a blockage. Patients may present with right upper quadrant pain, jaundice, fever, shock, and altered mental status. IV antibiotics must be administered promptly in anticipation of interventional management of the obstruction.
- Inflammation of the pancreas (pancreatitis) can lead to significant impairment of the GI physiology depending on its level of severity and etiology.
- Upper abdominal pain is the primary symptom of pancreatitis; other symptoms include tenderness and guarding of the abdomen, tachycardia, nausea and vomiting, and a fever. Turner sign, Cullen sign, jaundice, hemodynamic instability, and shock may result from severe pancreatitis.
- Elevated serum amylase and serum lipase support a diagnosis of pancreatitis, with serum lipase being the diagnostic test of choice.

- A CT scan with contrast can provide a direct visual observation of pancreatic necrosis, peripancreatic abnormalities, abscesses, and overall size of the pancreas.
- General treatment of pancreatitis includes fluid resuscitation, analgesia, and antiemetics.
- Significant decreases in renal perfusion pressure disrupt the elimination of waste from the bloodstream by lowering the glomerular filtration rate (GFR). When this condition develops in the absence of preexisting renal dysfunction, it is termed acute kidney injury (AKI).
- Symptoms of AKI include dizziness, poor skin turgor, thirst, flat neck veins, dry mucous membranes, weight loss, orthostatic BP changes, fever, edema, ascites, and low back pain.
- A family history of renal disease indicates a predisposition to AKI when a precursory disease of AKI is present. The incidence of AKI is increased in patients with diabetes, hypertension, and lupus.
- The retention of wastes in the bloodstream that results from a decreased GFR provides an easy way to monitor for the existence and severity of AKI. Renal ultrasonography is the gold-standard imaging modality for assessing suspected postrenal AKI.
- A gradual decrease in renal function over a long time interval is known as chronic kidney disease (CKD).
- The results of lab studies for CKD and end-stage renal disease (ESRD) generally parallel the results seen for AKI. The most important factor in determining whether the renal failure is acute or chronic is disease duration.
- Elevations in BUN and creatinine are common in patients with kidney injury. Additional studies that evaluate excretion of electrolytes and osmolality can help determine whether injury is prerenal, intrinsic, or post-obstructive.
- Both patients with ESRD and those with acute renal failure require renal replacement therapy, which can be performed via various

approaches, including IHD, continuous venovenous hemodialysis, and peritoneal dialysis.

- The bacterial flora that live symbiotically in the GI system can cause considerable damage when these organisms are introduced into the urinary system. A urinary tract infection typically begins in the urethra, because this location is the most proximal to the external environment.
- Nephrolithiasis is the condition in which the body produces renal calculi, commonly referred to as kidney stones. Kidney stones cause considerable pain during their transit through the ureters, and larger stones risk becoming impacted and causing obstruction, which may result in severe infection, hydronephrosis, and kidney injury.
- Testicular torsion, a condition in which one or both of the testes rotate to the point of occluding their blood supply, is a urologic emergency that needs to be addressed within 6 hours of symptom onset.
- Direct blunt trauma to the penis during penile erection can result in penile fracture—that is, a rupture of one or more of the vascular spaces within the penis.
- Priapism is a prolonged erection of the penis that can be painful and damaging to tissues in the immediate area. It is generally classified as either high-flow priapism or low-flow, ischemic priapism.
- A simple nasogastric tube can be used to administer food into the stomach or to remove food. For long-term situations, a gastrostomy tube (G tube) or percutaneous endoscopic gastrostomy (PEG) tube can be inserted.
- Total parenteral nutrition (TPN) is an alternative feeding method used when the GI tract is not functioning adequately.
- When transporting a patient with a feeding tube, contact medical direction if the patient has vomiting, abdominal distention, or diarrhea.

- Straight catheters (intermittent catheters) are ideal for removal of urine in patients who do not have chronic urinary retention or sedation, as these devices are not associated with increased risk of urinary tract infection.
- When surgery or trauma contraindicates introduction of a urethral catheter, a suprapubic tube can be placed directly into the urinary bladder through the abdominal wall by way of a surgically created stoma.
- Common complications of urine collection catheters include clogging, infection, pain, leakage, and dislodgement.
- An ostomy is a surgically created opening of the GI tract through the abdomen that allows for waste removal.
- The patient with an ostomy should be monitored for signs of tissue necrosis and infection, which, if detected, may warrant treatments ranging from antibiotic therapy to surgical intervention.
- Jackson-Pratt drains are inserted to remove postoperative buildup of fluid and blood in the abdominal cavity. During liver transplant surgery, a T tube is placed to monitor bile drainage from the gallbladder.
- In-flight complications need to be considered for patients with any of the numerous drainage systems that include closed bags containing air. Excess air should be vented from any drainage bag such as a colostomy or urostomy prior to flight in anticipation of changes in air pressure.
- Be sure to unclamp any feeding or drainage catheters prior to departure, and ensure that they remain unclamped for the duration of travel.
- Significant alterations of oxygen and carbon dioxide levels, electrolyte concentrations, temperature, glucose levels, and acid–base status will impair cell, tissue, and organ function, eventually leading to death if not corrected.
- The relationship of acids to bases within the body is expressed by pH, which represents the concentration of free hydrogen ions (H^+) present.

- The bicarbonate–carbonic acid buffer system is the principal extracellular buffer system that operates primarily in the lungs and kidneys, where carbonic anhydrase stimulates the chemical reaction.
- The phosphate buffer system operates similarly to the bicarbonate–carbonic acid buffer system in that it allows only small pH changes following large variations in the presence of free H^+.
- The concentration of free H^+ in extracellular fluid (pH) as well as other key variables can be obtained from an arterial blood gas (ABG) or venous blood gas (VBG) sample.
- Results from an ABG sample provide the CCTP with valuable information about the existence or type of acidosis or alkalosis.
- In most cases, the VBG sample is adequate for evaluation of $P\text{CO}_2$ and pH when an ABG is not available. Patients in severe shock or with mechanical ventilation warrant use of an ABG sample for measuring lab values.
- Total blood carbon dioxide (written as either $T\text{CO}_2$ or “bicarbonate” in clinical practice) provides an indication of an acid–base abnormality on routine blood work.
- When an acidosis is suspected, its origin can be examined using the anion gap.
- When metabolic conditions create an excess of bicarbonate accompanied by a pH greater than 7.45 on an ABG sample, the disorder is termed metabolic alkalosis.
- Metabolic acidosis is demonstrated by a decreased serum pH (less than 7.35) accompanied by a decreased bicarbonate concentration (less than 22 mmol/L).
- Renal and hepatic dysfunction cause metabolic acidosis through a variety of mechanisms.
- Metabolic acidosis is rarely a clinically isolated occurrence. The underlying pathologic conditions that cause the acidosis predominantly determine the patient’s clinical status.

- IV sodium bicarbonate will not provide adequate treatment of an acidosis.

Vital Vocabulary

acute kidney injury (AKI) Decreased renal function in the absence of preexisting renal disease. Classified into three categories: prerenal, intrarenal, and postrenal.

acute tubular necrosis Damage to the tubules of the nephron, preventing proper ion and fluid exchange in the kidneys.

adhesions Bands of connective tissue that can distort the normal GI anatomy; the result of improper healing or scar tissue growth following surgery.

alcoholic ketoacidosis A type of acidosis characterized by a buildup of ketones in the blood, caused by a large intake of alcohol and poor nutritional intake.

angiodysplasia Deformed submucosal blood vessels in the GI tract that are susceptible to bleeding.

appendicitis Inflammation and/or infection of the appendix.

ascites A buildup of fluid in the abdominal cavity.

azotemia Increased nitrogenous wastes in the blood.

azygos system A network of blood vessels that connects the superior and inferior vena cava; it also drains a portion of the esophageal venous blood.

bicarbonate–carbonic acid buffer system The principal extracellular buffer system, which operates primarily in the lungs and kidneys; in this system, carbon dioxide and water are reversibly converted into carbonic acid, which in turn is reversibly converted into hydrogen ions and bicarbonate.

bilirubin A waste product of heme formed during erythrocyte metabolism. It is moved to the small intestine within bile and then converted into urobilinogen, resulting in brown pigmented feces.

Boerhaave syndrome Esophageal rupture, associated with subcutaneous emphysema, chest pain, and vomiting.

buffer Any substance that can alternately bind or release hydrogen ions depending on the outside conditions.

Charcot triad Fever, jaundice, and right upper quadrant abdominal pain suggestive of choledocholithiasis.

cholangitis A serious ascending infection due to biliary tract obstruction that can result in fever, transaminitis, and altered mental status.

cholecystitis Inflammation of the gallbladder.

choledocholithiasis Gallstones in the biliary tract system, which put the patient at high risk for developing a biliary tract obstruction; typically initially managed with endoscopic retrograde cholangiopancreatography rather than cholecystectomy.

cholelithiasis Gallstones in the gallbladder.

chronic kidney disease (CKD) A gradual decrease in renal function resulting from irreversible damage to the nephrons. It is characterized by a glomerular filtration rate of less than 60 mL/min, and eventually progresses to end-stage renal disease.

cirrhosis Irreversible structural changes to the liver that impair its proper functioning.

colitis Inflammation of the colon.

colonoscopy An endoscopy of the lower GI tract.

concentration gradient The natural tendency for substances to flow from an area of higher concentration to an area of lower concentration, within or outside the cell.

creatinine The metabolized form of creatine that is eliminated through the urine. Increased levels indicate decreased GFR and renal function.

Crohn disease An inflammation of the GI tract in which all layers of the mucosa may be affected. It results in scattered ulcerations and fibroses throughout the large and small intestines.

CT angiography Radiographic observation of dye injected into the bloodstream.

diabetic ketoacidosis A form of acidosis observed in uncontrolled diabetes in which ketones accumulate when insulin is not available; usually associated with hyperglycemia.

diverticula Small pouches of tissue that develop as outcroppings of the large intestine, typically in the descending colon and sigmoid colon.

diverticular bleeding Bleeding from diverticula that have developed in the colon.

diverticulitis Inflammation of diverticula.

diverticulosis Presence of intestinal diverticula, which may then become inflamed or bleed.

endoscopic retrograde cholangiopancreatography (ERCP) A technique combining endoscopy and fluoroscopy to diagnose and treat biliary or pancreatic ductal obstruction.

end-stage renal disease (ESRD) A loss of proper kidney functioning, with renal replacement therapy becoming a requirement for survival.

enteroclysis Infusion of barium contrast into the GI tract to observe for obstruction.

esophageal varix Swelling of esophageal veins that intrudes into the lumen of the esophagus.

esophagitis Inflammation of the tissues of the esophagus; commonly associated with severe gastroesophageal reflux disease, alcohol abuse, or irritation caused by pills or infection.

esophagogastroduodenoscopy (EGD) A technique to directly observe the GI tract in which a camera is passed into the GI tract, allowing for diagnosis and treatment of disease or injury.

fulminant hepatic failure A sudden and significant insult to the liver characterized by encephalopathy and a high mortality rate; commonly caused by toxins/overdose or viral infection.

gallstone pancreatitis A type of pancreatitis in which pancreatic enzymes accumulate proximal to a bile duct obstruction from a gallstone and digest the tissues of both the duct and the pancreas.

gastritis Inflammation of the gastric mucosa that occurs when the equilibrium of active and protective mechanisms for the lining is altered; may be accompanied by upper GI bleeding.

gastroenteritis Watery diarrhea and vomiting during inflammation of the digestive tract as a result of a viral, bacterial, or parasitic infection.

glomerular filtration rate (GFR) The amount of fluid filtered by the glomerulus per minute; a benchmark for renal function.

Helicobacter pylori A bacterium that is commonly associated with gastritis and peptic ulcers.

hematemesis Emesis containing blood, which may be bright red or partially digested (coffee-ground emesis).

hematochezia Stool streaked with bright red blood.

hepatic encephalopathy Encephalopathy secondary to hepatic disease, usually associated with hyperammonemia.

hepatitis Inflammation of liver cells that can impede proper functioning of the liver and lead to chronic conditions such as cirrhosis.

hepatitis C virus The virus that is the most common cause of cirrhosis and is especially pathogenic in causing hepatitis.

hepatorenal syndrome A condition characterized by renal injury and renal failure in patients with cirrhosis; decreased cardiac output and decreased systemic vascular resistance result in a cycle of worsening renal perfusion and renal vasoconstriction.

hernia A protrusion of an organ from its tissue lining.

homeostasis Stability in the body’s internal environment.

ileus A lack of movement of GI contents in the absence of an obstruction, usually occurring post-surgery.

inflammatory bowel disease (IBD) Term covering two colon inflammation pathologies: ulcerative colitis and Crohn disease.

intussusception A telescoping of the intestine into an adjacent segment.

ischemic colitis A potentially life-threatening form of colitis that results from diminished blood flow to the GI tract.

Jackson-Pratt drain A surgical drain used to remove fluid buildup from the wound site during the postoperative healing process.

jejunostomy tube (J tube) A feeding tube placed through the abdominal wall into the jejunum.

lactic acidosis A form of acidosis caused by an excess accumulation or impaired excretion of lactate, leading to an elevated anion gap; it can result from exposure to various toxic substances, inadequate tissue perfusion in various shock states, dysfunction of certain organs, nutritional deficiency, infection, malignancy, diabetes, or hereditary metabolic disorders.

ligament of Treitz A small ligament supporting the small intestine at the junction between the duodenum and the jejunum. It serves as the dividing point between the upper and lower GI tract.

lithotripsy Use of external vibrations to break up gallstones.

Mallory-Weiss syndrome Laceration and bleeding of the esophagus, often following forceful vomiting.

melena Black, tarry stool containing partially digested blood, with the bleeding usually originating from the upper GI tract.

metabolic acidosis A pathologic condition (blood pH <7.35) resulting from an accumulation of acids in the body caused by any number of systems in the body, including the gastrointestinal system, or by major organ failure.

metabolic alkalosis A pathologic condition (blood pH >7.45) resulting from an accumulation of bases in the body caused by any number of systems in the body, including the gastrointestinal system, or by major organ failure.

Minnesota esophagogastric tamponade tube A tube that is placed to stop bleeding of esophageal varices. It is similar to the Sengstaken-Blakemore tube, but has a built-in suction catheter.

mixed acidosis A pathologic condition in which there is a low pH (<7.35), an elevated Pco_2 level (>45 mm Hg), and a low bicarbonate level (<22 mmol/L); it occurs when both respiratory and metabolic acidosis are present at the same time.

mixed alkalosis A pathologic condition in which there is an elevated pH (>7.45), a low Pco_2 level (<35 mm Hg), and an elevated bicarbonate level (>26 mmol/L); it occurs when both respiratory and metabolic alkalosis are present at the same time.

mucosa The outermost layer of the alimentary canal. It consists of three sublayers: surface epithelium, lamina propria, and muscularis mucosae.

Murphy sign Pain following palpation of the right upper abdomen, especially with deep inspiration.

muscularis externa The third tissue layer of the alimentary canal. It contains two levels in most places: the circular layer and the longitudinal layer.

nephrolithiasis A condition in which the body produces renal calculi (kidney stones), which are often symptomatic as they travel through the ureters; may produce impaction and infection of the urinary tract.

nonalcoholic fatty liver disease (NAFLD) Accumulation of fat in the liver, for which alcohol consumption is not believed to be a contributing factor.

ostomy A surgically created opening through which feces can be voided in the absence of some or all of the large intestine or rectum.

pancreatitis Inflammation of the pancreas leading to autodigestion, tissue destruction, and impaired function.

paracentesis Insertion of a needle into the abdomen to aspirate ascites; often done to diagnose spontaneous bacterial peritonitis.

penile fracture A rupture of one of the blood-containing sacs in the penis, resulting in deformity and possible loss of function.

peptic ulcer An erosion of the mucosal lining of the GI tract.

percutaneous endoscopic gastrostomy (PEG) tube A feeding tube that is placed through the abdominal wall into the stomach.

peristalsis A general term describing wavelike muscular contractions of tubular organs, which carry forward materials or liquids contained in those organs.

peritoneal dialysis (PD) Dialysate solution injected into the abdomen, using the peritoneum as a natural semipermeable membrane to separate solutes.

peritonitis Inflammation of the peritoneum; typically results in generalized abdominal tenderness and guarding.

phosphate buffer system The buffer system that functions in the renal tubules and intracellular fluids to convert strong acids or bases into weak acids or bases so that they have a minimal effect on the body’s overall pH.

point-of-care testing (POCT) Laboratory testing that is performed at the patient’s bedside, so that results can be obtained quickly and considered while decisions are still being made about patient care.

portal hypertension An increase in vascular resistance through the hepatic portal system. It can cause high venous pressure in the gastric and esophageal veins, leading to varices, among other problems.

pressure ulcer A sore on the skin arising from prolonged pressure. Such ulcers are classified into four stages, with stage 4 being the most severe (tissue necrosis and muscle and bone involvement); all stages are painful and susceptible to infection.

priapism Prolonged, painful erection of the penis; a urologic emergency.

pyelonephritis An infection of the kidney, typically the result of an ascending urinary tract infection.

reactive gastritis Gastric irritation that results from recurring contact of the mucosa with antagonistic substances such as bile, pancreatic juice, or nonsteroidal anti-inflammatory drugs.

renal perfusion pressure The gradient between renal arterial and venous flow. A significant decrease in this pressure results in ischemia.

renal tubular acidosis (RTA) A form of metabolic acidosis caused by dysfunction of the kidneys or renal system; it presents without an elevated anion gap.

respiratory acidosis A pathologic condition (blood pH <7.35) resulting from an accumulation of acids in the body owing to a breathing problem or insufficient function of the respiratory system.

respiratory alkalosis A pathologic condition (blood pH >7.45) resulting from an accumulation of bases in the body caused by inappropriate tachypnea.

scintigraphy An imaging technology that is similar to angiography except that the red blood cells themselves are radiologically labeled to allow greater specificity.

Sengstaken-Blakemore tube A tube with an inflatable balloon at its end that is inserted into the GI tract and inflated to tamponade bleeding.

serosa A protective layer of connective tissue over most of the alimentary canal; also called the visceral peritoneum.

spontaneous bacterial peritonitis A bacterial infection of ascitic fluid.

stress-related erosive syndrome A condition in which stress-related mucosal disease develops in critically ill patients, such as those with severe head trauma or burns.

submucosa The layer of connective tissue below the mucosa; it contains blood vessels, lymph, and nerves.

systemic inflammatory response syndrome (SIRS) An immune response to an insult that typically leads to hypotension, shock, and worsened tissue function.

testicular torsion Twisting of a testicle about the spermatic cord to the point of ischemia.

third spacing An abnormal increase in the amount of fluid that exits the vascular space and moves into other areas (eg, gut wall, subcutaneous tissue); it can lead to dehydration, electrolyte imbalances, and hypovolemia.

total parenteral nutrition (TPN) The IV administration of all necessary nutrients in a patient whose GI tract does not function.

transjugular intrahepatic portosystemic shunt The placement of a shunt in the abdomen that bypasses much of the hepatic portal system; it is intended to decrease portal hypertension and its effects.

T tube A T-shaped tube used to drain bile from the gallbladder.

ulcerative colitis An inflammation of the rectal mucosal and submucosal tissues.

uremia The presence of excessive amounts of urea and other waste products in the blood; can lead to altered mental status.

volvulus A twisting of the intestine onto itself, usually causing strangulation and ischemia.

CHAPTER 18

Endocrine Emergencies

Eric Silverman, MD, MPH

OBJECTIVES

After completing this chapter, you will be able to:

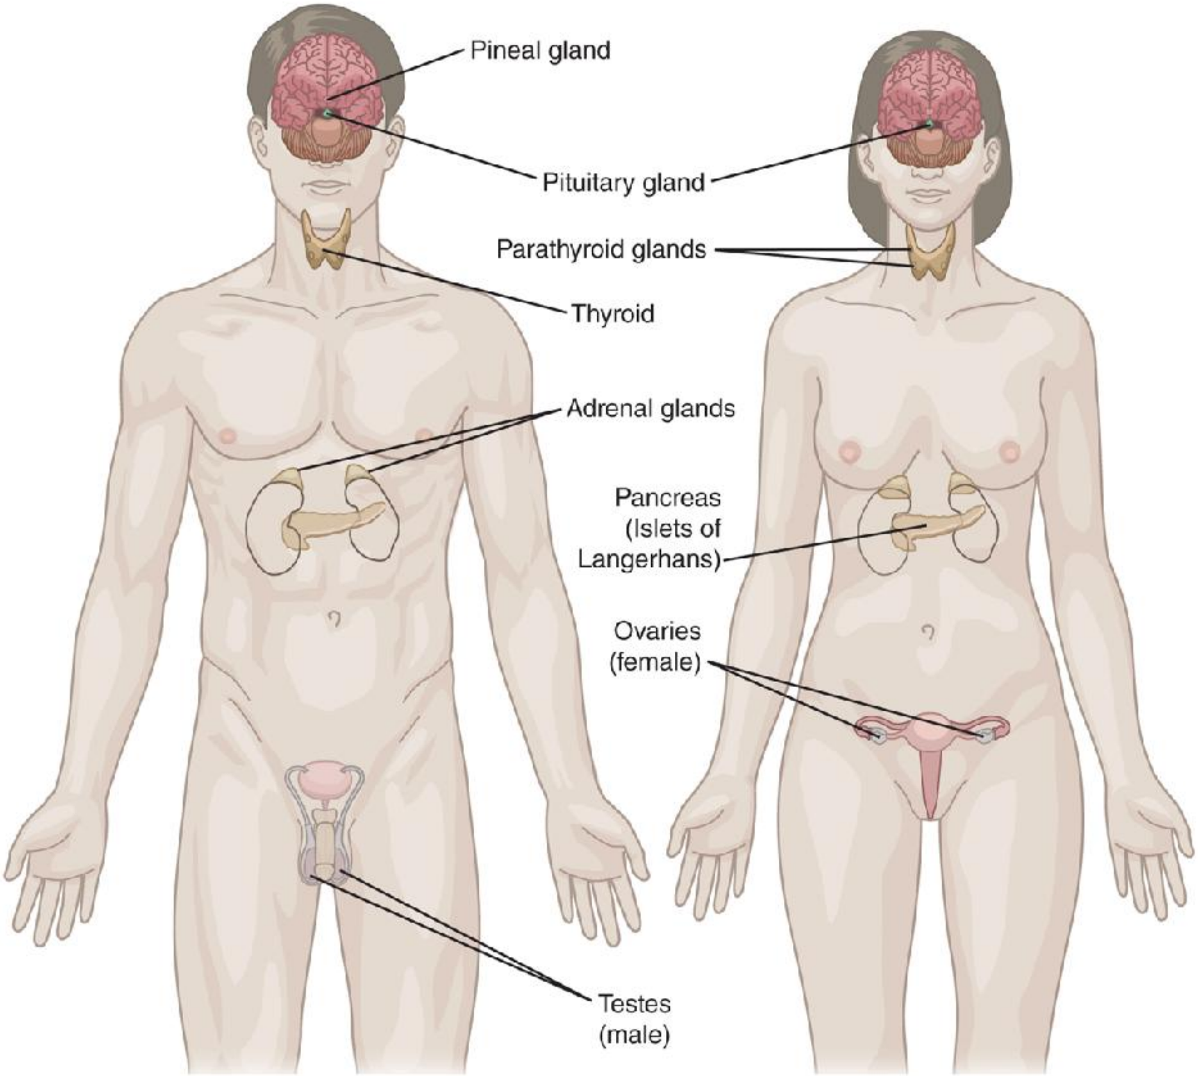
1. Describe the anatomic structures and physiology of the endocrine system (p 981).
2. Discuss the pathophysiology, assessment, and critical care transport management of conditions related to diabetes, including hypoglycemia, hyperglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic state (pp 985–991).
3. Discuss the pathophysiology, assessment, and critical care transport management of pituitary disorders, including central diabetes insipidus, pituitary lesions, acromegaly, and gigantism (pp 991–993).
4. Discuss the pathophysiology, assessment, and critical care transport management of adrenal abnormalities, including adrenal insufficiency, Addison disease, Cushing disease, pheochromocytoma, aldosteronism, and amyloidosis (pp 993–998).
5. Discuss the pathophysiology, assessment, and critical care transport management of thyroid abnormalities, including hyperthyroidism, hypothyroidism, myxedema coma, thyrotoxicosis and thyroid storm, and Hashimoto disease (pp 998–1001).
6. Discuss the pathophysiology, assessment, and critical care transport management of lipid disorders, including antiphospholipid syndrome and metabolic syndrome (p 1002).

Introduction

Patients with an endocrine disorder may present with overt or subtle signs and symptoms that require a thorough knowledge of the history of the present illness or injury, the patient's past medical history, and a detailed physical exam. In addition, the critical care transport professional (CCTP) will need to consider disorders that involve the endocrine system when assessing a patient's overall condition. For example, adrenal insufficiency after surgery can easily be overlooked during the unstable postoperative period. If not quickly identified and treated, this condition can result in refractory hypotension leading to death.

Anatomy and Physiology

As a CCTP student, you are likely already familiar with the components of the endocrine system, which are reviewed in **FIGURE 18-1**. **FIGURE 18-2** provides a review of substances secreted by the pituitary gland and their destinations in the body.



Pineal gland
Pituitary gland
Parathyroid glands
Thyroid
Adrenal glands
Pancreas (Islets of Langerhans)
Ovaries (female)
Testes (male)

FIGURE 18-1 The endocrine system uses various glands to deliver chemical messages to organ systems throughout the body.

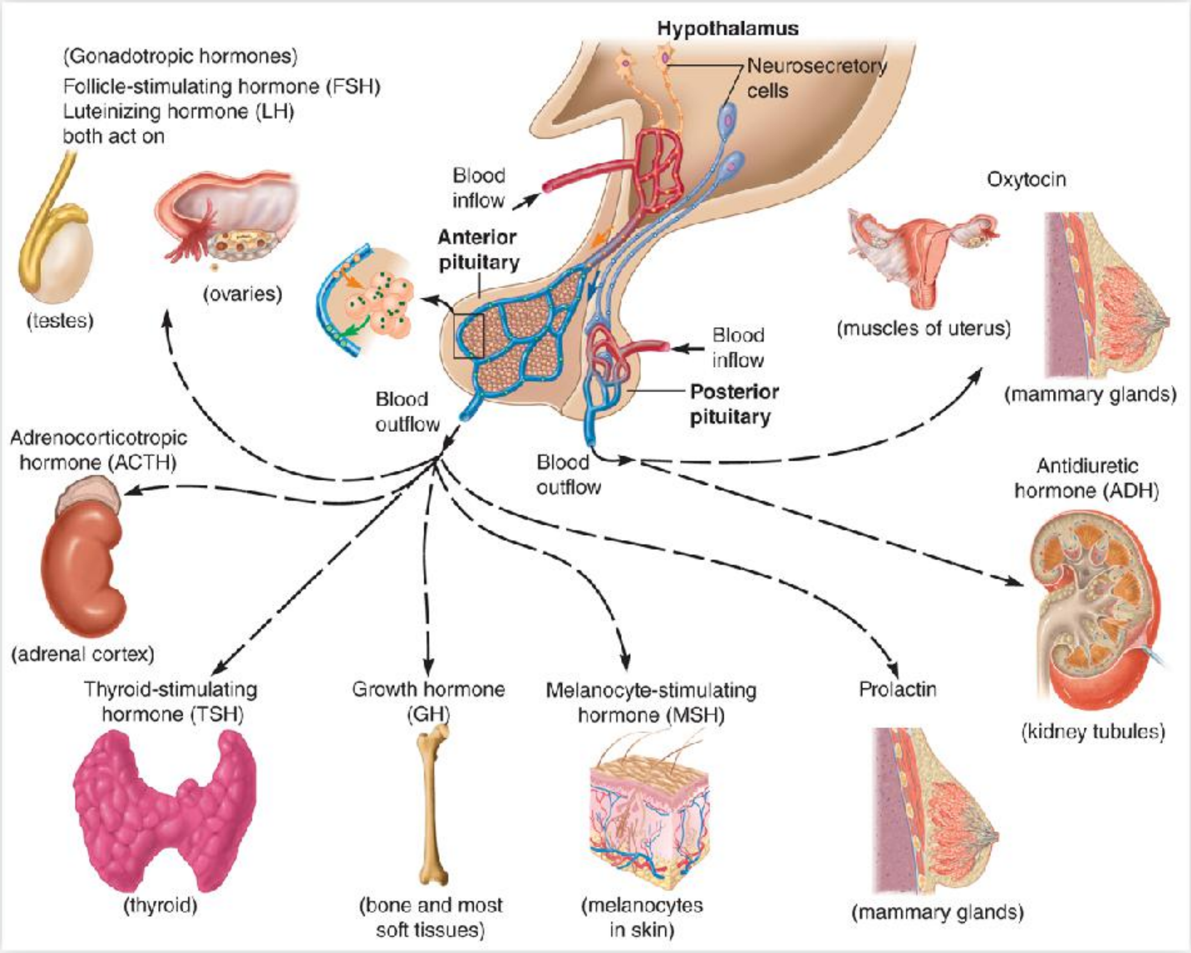
Description



Hypothalamus
Neurosecretory cells
(Gonadotropic hormones)
Follicle-stimulating hormone (FSH)
Luteinizing hormone (LH)
both act on
(testes)
(ovaries)
Blood inflow
Anterior pituitary
Blood inflow
Posterior pituitary
Blood outflow
Blood outflow
Oxytocin
(muscles of uterus)
(mammary glands)
Adrenocorticotropic hormone (ACTH)
(adrenal cortex)
Antidiuretic hormone (ADH)
(kidney tubules)
Thyroid-stimulating hormone (TSH)
(thyroid)
Growth hormone (GH)
(bone and most soft tissues)
Melanocyte-stimulating hormone (MSH)
(melanocytes in skin)
Prolactin
(mammary glands)

FIGURE 18-2 The pituitary gland secretes hormones from its two regions: the anterior pituitary lobe and the posterior pituitary lobe.

Description

Thyroid

The thyroid gland is the largest gland in the neck and is situated anteriorly below the skin and muscle layers. It resembles the shape of a butterfly, with the left and right thyroid lobes wrapping around the trachea. The function of the thyroid gland is to regulate the body's metabolism by secreting thyroxine (T_4) when the body's metabolic rate decreases. Thyroxine—the body’s major metabolic hormone—stimulates energy production in cells, which increases the rate at which cells consume oxygen and use carbohydrates, fats, and proteins. When the body’s temperature drops, for example, this increased cellular metabolism creates heat. Iodine is an important component of thyroxine. Without the proper level of dietary iodine intake, thyroxine cannot be produced, which results in physical and cognitive impairments.

The thyroid gland also secretes calcitonin, which helps maintain normal calcium levels in the blood. This hormone is secreted directly into the bloodstream when the thyroid detects high levels of calcium. Calcitonin travels to the bones, where it stimulates the bone-building cells to absorb the excess calcium. It also stimulates the kidneys to absorb and excrete excess calcium.

It is important to correctly identify the anatomic location of the thyroid gland because it is highly vascularized. If this gland is inadvertently injured during an emergency cricothyrotomy, it can hemorrhage uncontrollably.

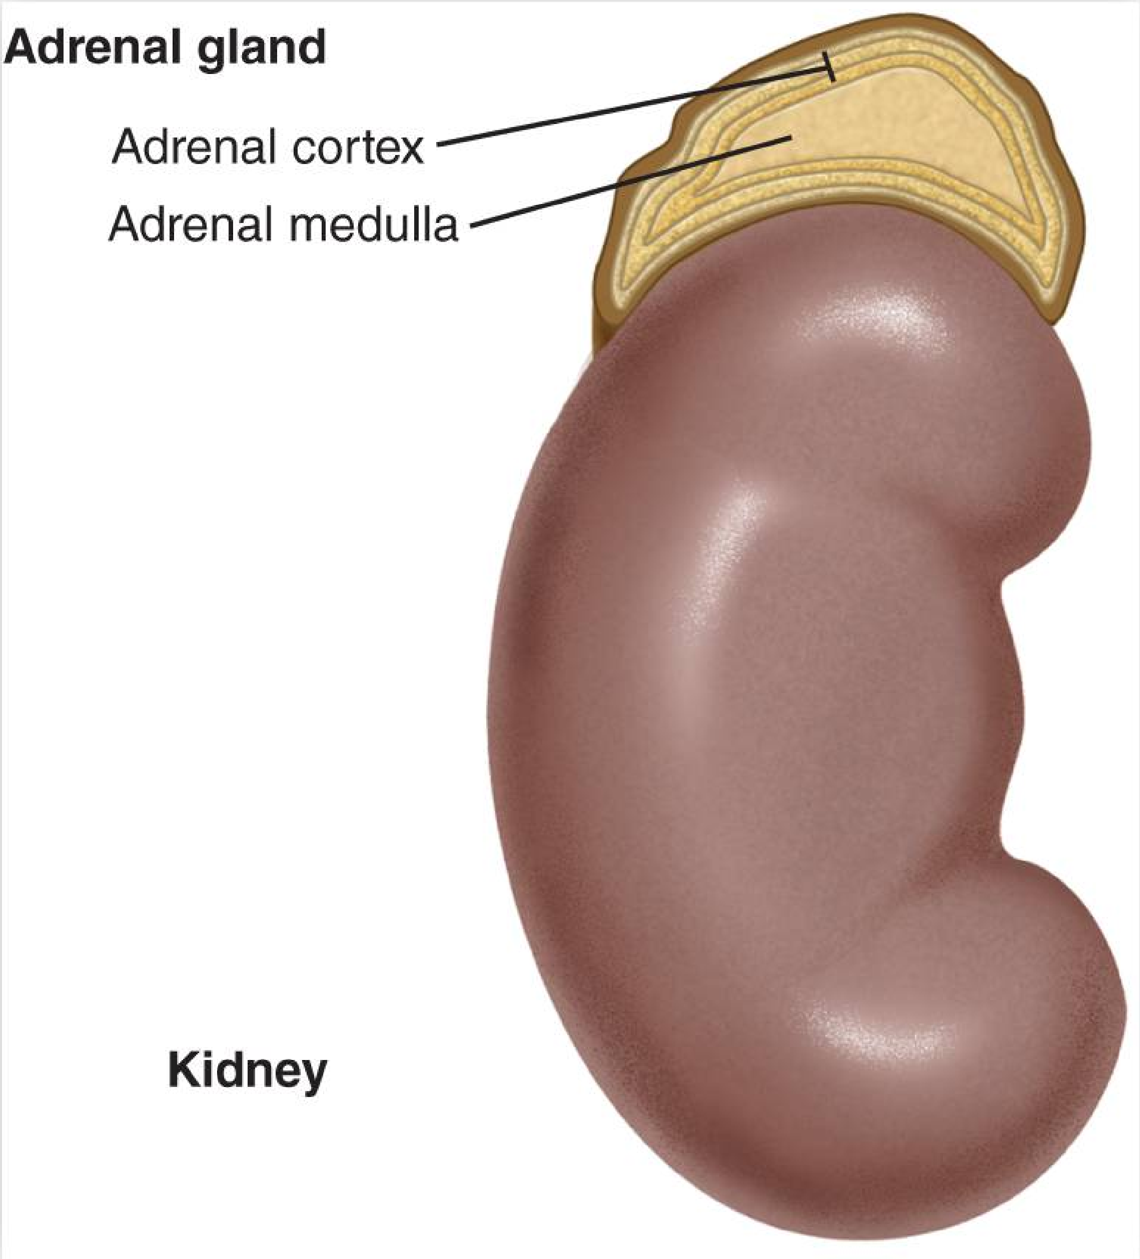
Parathyroid Glands

The parathyroid glands are small, ovoid glands located on the posterior lobes of the thyroid gland. There are usually four parathyroid glands, each about the size of a grain of rice, which secrete parathyroid hormone (PTH). PTH plays an important role in calcium and phosphate homeostasis by working antagonistically to the calcitonin secreted by the thyroid gland.

Hyperparathyroidism is a disease characterized by oversecretion of PTH by the parathyroid glands, leading to increased bone resorption and hypercalcemia. Hypoparathyroidism can be caused by damage to the parathyroid glands during thyroid surgery or removal (ie, thyroidectomy). This condition can lead to hypocalcemia, which is usually treated with calcium and vitamin D supplementation.

Adrenal Glands

The adrenal glands, which are located at the superior portion of each kidney, produce several types of hormones. Each of these glands has an outer portion called the adrenal cortex and an inner portion called the adrenal medulla **FIGURE 18-3**. The adrenal cortex manufactures corticosteroids—hormones that regulate metabolism, the immune system, and sexual function. They also contribute to maintaining the balance of salt and water within the body. The adrenal medulla produces the catecholamines epinephrine and norepinephrine. These catecholamines are involved in regulating autonomic functions, such as increasing heart rate, respiratory rate, and blood pressure as needed when responding to stress.



Adrenal gland
Adrenal cortex
Adrenal medulla
Kidney

FIGURE 18-3 The adrenal glands, which sit on top of each kidney, consist of two parts: the adrenal cortex and the adrenal medulla.

© Jones & Bartlett Learning.

Description

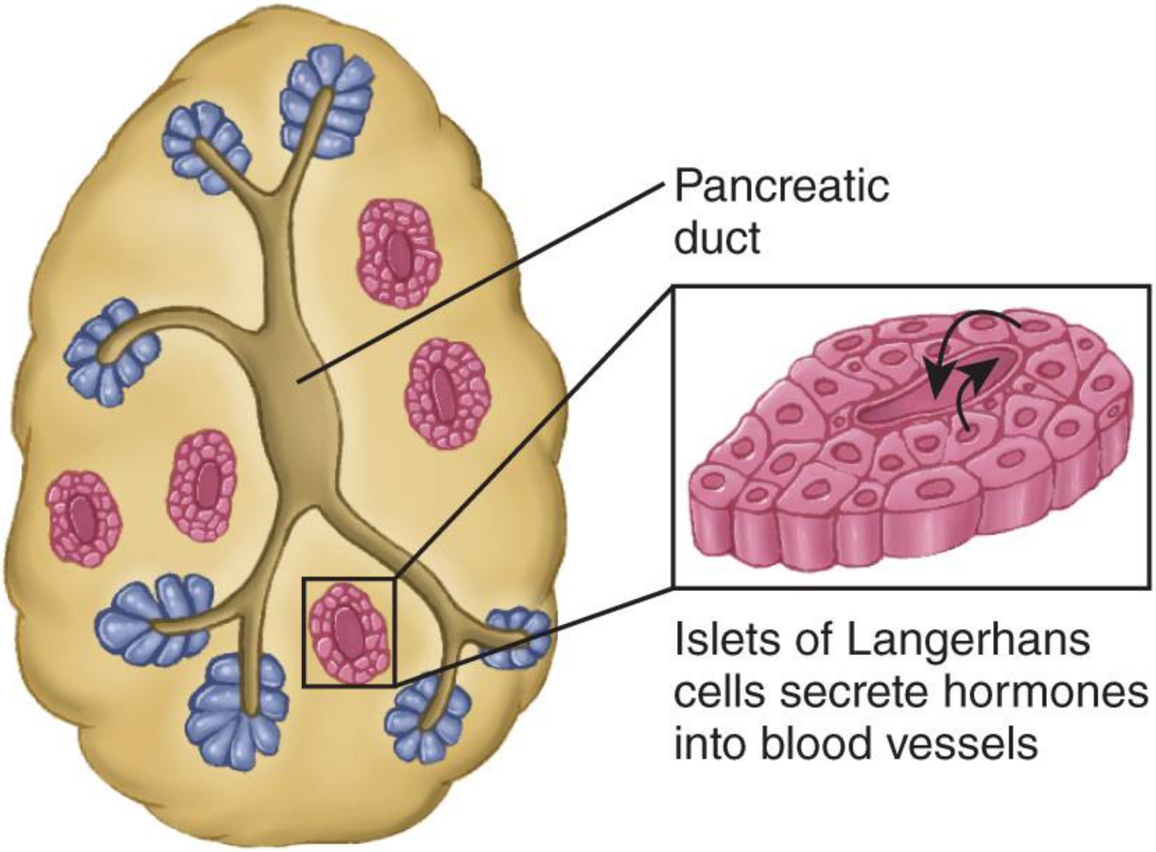
During times of physiologic stress, the hypothalamus secretes a hormone that stimulates the anterior pituitary to release adrenocorticotropic hormone (ACTH). ACTH targets the adrenal cortex, causing it to secrete cortisol, a glucocorticoid. Cortisol stimulates most of the body's cells to increase energy production to meet the body's increased demands.

If the body experiences a drop in blood pressure or cardiac preload, a decrease in serum sodium concentration, or an increase in serum potassium concentration, the zona glomerulosa (outer zone) of the adrenal cortex is stimulated to secrete **aldosterone**, a mineralocorticoid that acts primarily at the distal renal convoluted tubes. Aldosterone prompts the kidneys to reabsorb sodium from the urine and excrete potassium by altering the osmotic gradient in the blood. This adjustment indirectly leads to increases in blood volume and blood pressure. This mineralocorticoid is vital for the management of sodium in the kidneys, salivary glands, sweat glands, and colon; it reduces the loss of salt and water through the sweat and salivary glands. Abnormal overproduction of aldosterone, resulting from either primary or secondary disorders, is common in the general population and is a substantial cause of morbidity and mortality.

The body's reaction to physical or emotional stress is commonly referred to as the "fight-or-flight" response. Following stimulation from the hypothalamus, the adrenal medulla secretes small amounts of norepinephrine and large amounts of epinephrine. Norepinephrine raises the blood pressure by constricting blood vessels and skeletal muscle. Epinephrine stimulates sympathetic nervous system receptors throughout the body. In addition, epinephrine stimulates the liver to convert glycogen to glucose, which is then used as energy in the cells. Collectively, the actions of both hormones result in increased levels of oxygen and glucose in the blood, as well as increased perfusion of the brain, heart, and muscles. These physiologic changes enhance the body's ability to rapidly respond to stressful situations.

Pancreas

The pancreas is a digestive gland that is considered both an endocrine and an exocrine gland. In its role as an endocrine organ, it secretes digestive enzymes into the duodenum through the pancreatic duct. The endocrine component comprises the islets of Langerhans, which are cell groups within the pancreas that act like "an organ within an organ." The main hormones that are secreted—glucagon and insulin—are responsible for the regulation of blood glucose levels **FIGURE 18-4**.



Pancreatic duct
Islets of Langerhans cells secrete hormones into blood vessels

FIGURE 18-4 The islets of Langerhans secrete hormones into blood vessels.

© Jones & Bartlett Learning.

Description

When the body's blood glucose level falls, such as between meals, the pancreas secretes glucagon to raise the glucose level and bring the body's energy back to normal. On entering the bloodstream, this hormone stimulates the liver to convert glycogen (a storage starch form of the sugar glucose, made up of thousands of glucose units) into glucose. This glucose then enters the bloodstream, and the blood carries it to the cells for use as energy.

Insulin is responsible for the removal of glucose from the blood for storage as glycogen, fats, and protein; in fact, it is the only hormone that decreases the blood glucose levels. When blood glucose levels are elevated, the islets of Langerhans secrete insulin, which is carried by the bloodstream to the cells. The cells then take in more glucose to produce energy. Insulin also stimulates the liver to convert glucose to glycogen for later use by the body. Once blood glucose levels have returned to normal, the islets of Langerhans discontinue the secretion of insulin.

Diabetes

The term **diabetes mellitus** refers to a metabolic disorder in which the pancreas's ability to metabolize simple carbohydrates (glucose) is impaired because of a lack of insulin or a decreased sensitivity of the cells to insulin. As mentioned earlier, the pancreas is the primary regulator of blood glucose levels. Production of digestive enzymes and the hormones insulin and glucagon takes place in the islets of Langerhans. Beta cells in the islets of Langerhans (65% to 80% of the islet cells) produce insulin and amylin, alpha cells (15% to 20%) release glucagon, and delta cells (3% to 10%) produce somatostatin. Insulin and glucagon are the hormones responsible for keeping the blood glucose level within the normal range, 70 to 100 mg/dL. Diabetes is characterized by abnormally elevated blood glucose concentration, which can result in the passage of large quantities of urine containing glucose (polyuria), increased thirst (polydipsia), and significantly impaired immune function.

Glucose that is not used immediately for energy is stored in the liver and muscles as glycogen, or converted by adipose tissue into fat. The liver releases glucose back into the bloodstream when the levels there decrease, and it removes glucose from the blood when the levels are too high. Only glycogen in the liver can be converted back to glucose; the glycogen stored in muscle can be used only by the muscle for energy.

Insulin is essential for glucose to be taken up and used by cells. This hormone is secreted by the beta cells of the pancreas in response to increased blood glucose levels. After eating a meal, blood glucose levels in the body rise. Glucose in the blood then triggers the release of more insulin from the pancreas. Insulin transports glucose into the cells via facilitated diffusion, a process in which the glucose is converted into energy. Insulin also has an effect on many cells that play a part in absorbing the glucose, causing the blood glucose concentration to return to normal.

Glucagon, which is secreted by the alpha cells, has the opposite effect. When blood glucose levels are low, the pancreas releases more glucagon. The presence of glucagon stimulates the release of glucose stored in liver cells, making energy available to the tissues between meals.

Diabetes mellitus results from an impairment of the body's ability to produce or use insulin. Traditionally, the two predominant types of diabetes mellitus are known as type 1 and type 2. Functionally, many clinicians categorize diabetes mellitus as either insulin-dependent or non–insulin-dependent.

Pathophysiology

Type 1 diabetes generally affects children and has historically been referred to as juvenile diabetes, although this form of diabetes is now appearing in adulthood as well. Type 1 diabetes has a hereditary predisposition, but environmental factors may be partly responsible for its development; for example, an infection may trigger an autoimmune response, causing antibodies to destroy the islets of Langerhans.

Most people with type 1 diabetes do not produce insulin. Consequently, they require daily injections of supplementary insulin throughout their lives to control their blood glucose levels. In addition to daily replacement of insulin through injections or a continuous infusion pump, and careful balancing of dietary intake of carbohydrates and simple sugars, physical activity is important to achieve optimal glucose control. This can be a particular challenge in young children, performance athletes, people with alcoholism, and patients with multiple medical comorbidities.

Type 2 diabetes (previously called adult-onset diabetes) traditionally develops later in life, usually when the patient is middle-aged, although the disease is becoming more common in younger people. Approximately 90% of all people with diabetes in the United States have type 2 diabetes. In many people with type 2 diabetes, the pancreas actually produces enough insulin; however, for reasons not fully understood, the body cannot effectively use it—a condition known as **insulin resistance**. One hypothesis proposed for this phenomenon is that insulin receptor cells become altered and are no longer able to use the insulin when it arrives at the target cell. Type 2 diabetes can also be caused by a deficiency in insulin production.

The distinction between type 1 and type 2 diabetes has become less important to emergency and critical care providers due to the frequent overlap in treatments and potential complications between both types.

Special Populations

Gestational diabetes is diabetes first diagnosed during pregnancy. Its prevalence in the United States is 2% to 10%. Risk factors include prior episodes of gestational diabetes, family history of diabetes, and prepregnancy obesity. Symptoms generally present after 20 weeks' gestation and most commonly between weeks 24 and 30. Treatment consists of insulin or certain oral agents. These patients are considered to have high-risk pregnancies and require close monitoring. Patients with gestational diabetes also have a higher lifetime risk of the development of diabetes than the general population.

Hypoglycemia

Hypoglycemia in patients with diabetes most commonly occurs from taking too much medication, not eating enough food, engaging in intense or unexpected physical activity, or drinking excessive amounts of alcohol. The tissues of the central nervous system (including the brain) depend primarily on glucose as their source of energy; in contrast, other tissues can metabolize fat or protein in addition to glucose. In severe hypoglycemia, cerebral dysfunction can progresses quickly to irreversible neuronal death.

The normal blood glucose level is approximately 70 to 100 mg/dL; hypoglycemia is diagnosed when blood glucose drops below the normal level and, in people without diabetes, when accompanied by corresponding signs and symptoms. Generally, mild hypoglycemia can be treated with oral glucose, with rapid intravenous (IV) dextrose infusions reserved for patients with blood glucose levels less than 60 mg/dL or signs of clinical instability. In emergency situations or when IV or intraosseous (IO) access is not readily available, glucagon can be administered via the intramuscular, subcutaneous, or intranasal routes to treat severe hypoglycemia. Hypoglycemia can develop rapidly, within a span of minutes to a few hours. It should be suspected in any patient with altered mental status or new neurologic deficits.

Signs and Symptoms

Hypoglycemia

- Headache
- Altered mental status
- Memory loss
- Blurred or double vision
- Lack of coordination
- Slurred speech
- Stroke like symptoms
- Seizure
- Hypertension
- Tachycardia
- Diaphoresis
- Chest pain
- Abdominal pain
- Tremor
- Anxiety
- Confusion
- Paranoia
- Hunger
- Coma

Hyperglycemia and Diabetic Ketoacidosis

Hyperglycemia is the hallmark sign of diabetes mellitus, which is typically diagnosed by a fasting blood glucose level of 126 mg/dL or higher, hemoglobin A1c of 6.5% or greater, or random blood glucose level of 200 mg/dL or higher with symptoms of hyperglycemia. Hyperglycemia can be caused by excessive food intake, insufficient medications, infection or illness, injury, recent surgery, or physiologic stressors. Onset may be rapid (within minutes) or gradual (hours to days), depending on the cause. For example, excessive food intake may cause blood glucose levels to rise quickly, whereas an infection or illness may result in gradually worsening hyperglycemia over the course of several days.

If left untreated, hyperglycemia in a patient with diabetes can progress to **diabetic ketoacidosis (DKA)**, a life-threatening condition characterized by hyperglycemia, metabolic acidosis, and elevated serum ketone levels. DKA usually evolves rapidly (over a 24-hour period). Patients with DKA tend to be younger, with type 1 diabetes. In DKA, an insulin deficiency prevents cells from taking up the extra glucose. Because the body cannot use glucose, it turns to other sources of energy—principally, fat. The metabolism of fat generates acids and ketones as waste products. The ketones, which are exhaled as acetone, can cause the breath of a patient with DKA to have a characteristic fruity odor. High blood glucose concentrations lead to glucose being excreted in the urine, osmotically pulling excessive amounts of water and electrolytes (sodium and potassium) with it. This diuresis, together with the vomiting and the rapid, deep respirations (Kussmaul respirations) that patients may exhibit, leads to progressive dehydration and metabolic acidosis, ultimately progressing to shock, coma, and death. Blood glucose levels in DKA rarely exceed 800 mg/dL; in fact, they are most often observed to range from 350 to 500 mg/dL. In patients with DKA who are unresponsive (comatose), blood glucose levels can exceed 900 mg/dL.

Special Populations

Caring for pediatric patients with DKA can pose a greater challenge than caring for adult patients with this condition. Children are more susceptible to rapid shifts in fluid volume and osmolarity, which puts them at much greater risk for cerebral edema as a result of treatment. Although fluid resuscitation is the mainstay of therapy for both children and adults with DKA, a more cautious approach must be used with the pediatric patient. The CCTP must meticulously monitor the inputs and outputs for the patient. The initial fluids administered should be limited to a 10 to 20 mL/kg bolus of 0.9% saline over the first 1 to 2 hours, repeated up to two times as necessary to maintain hemodynamic stability.

Subsequent fluid resuscitation using 0.45% to 0.9% saline or lactated Ringer solution should be titrated to replete total estimated fluid losses over the next 48 hours. Additionally, an insulin infusion should be initiated at a dose of 0.05 to 0.1 unit/kg/h after 1 to 2 hours of fluid resuscitation, with a goal of lowering the glucose at a rate of about 50 mg/dL/h.

Signs and Symptoms

Diabetic Ketoacidosis

- Polydipsia (excessive thirst)
- Polyuria (excessive urination)
- Polyphagia (excessive hunger)
- Nausea and vomiting
- Abdominal pain
- Deep, rapid (Kussmaul) respirations
- Dehydration
- Hypotension
- Tachycardia
- Warm, dry skin and mucous membranes
- Confusion
- Gradual deterioration of consciousness
- Fruity-smelling breath (rare)

Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS), also known as hyperosmolar hyperglycemic nonketotic syndrome (HHNS), is characterized by hyperglycemia and hyperosmolarity (serum osmolality exceeding 320 mmol/kg) without significant metabolic acidosis or ketonemia. Blood glucose levels in patients with HHS are commonly 600 mg/dL or greater and may exceed 1,000 mg/dL. The hyperglycemia and hyperosmolarity lead to osmotic diuresis and an osmotic shift of body fluid to the extracellular space, resulting in further intracellular dehydration. Unlike DKA, HHS is not characterized by significant ketoacidosis. However, in clinical practice, the syndromes associated with DKA and HHS often overlap, resulting in a mixed clinical picture. HHS can result in a significant mortality rate, as high as 20%, which is approximately tenfold higher than the mortality rate linked to DKA.

Although most patients diagnosed with HHS have a known history of diabetes mellitus (usually type 2), approximately 30% will have no previous diagnosis of diabetes. The onset of HHS is usually more insidious than the emergence of DKA. It is marked by **polydipsia** (excessive thirst), **polyuria** (excessive urination), and **polyphagia** (excessive hunger), which progress over several days before the patient seeks medical attention.

HHS often develops in patients with diabetes who have some secondary illness that leads to reduced fluid intake. Although infection (in particular, pneumonia and urinary tract infection) is the most common cause, many other conditions can lead to altered mentation or dehydration. The physiologic stress response to any acute illness tends to increase the levels of hormones that favor elevated glucose levels—cortisol, catecholamines (epinephrine and norepinephrine), glucagon, and many others.

Signs and Symptoms

Hyperosmolar Hyperglycemic State

- Severe dehydration
- Drowsiness
- Lethargy
- Delirium
- Coma
- Focal or generalized seizures
- Visual disturbances
- Hemiparesis
- Sensory deficits
- Acute myocardial infarction (AMI)

Assessment

Patients with diabetes mellitus may present with varied physical findings and vital signs on examination, depending on their current blood glucose concentration. The overall patient assessment, the history of present illness or injury, and a thorough review of the patient's medical history will help the CCTP determine whether a diabetes-related condition is influencing the patient's vital signs and symptoms.

Signs and Symptoms

The assessment of the patient with hypoglycemia may reveal fatigue, headache, altered mental status, lack of coordination, stroke like symptoms, and even seizures. Hypertension, tachycardia, diaphoresis, chest pain, upper abdominal pain, and anxiety may be present as well because of the release of epinephrine caused by stimulation of the sympathetic nervous system.

It is important to rule out the possibility of hypoglycemia in patients presenting with signs of intoxication, including slurred speech, lack of coordination, paranoia, confusion, and behavioral emergencies. These signs may be the direct result of cerebral hypoxia, rather than use of alcohol or drugs.

Hyperglycemia and DKA typically present with the three Ps: polyuria, polydipsia, and polyphagia. Polyuria results from osmotic diuresis, polydipsia is caused by dehydration, and polyphagia is believed to stem from the body's inefficient use of nutrients. Patients, especially young individuals, may also experience abdominal pain; vomiting, which increases the degree of dehydration and can even result in hypotension; tachycardia; warm, dry skin; and dry mucous membranes. The two hallmark signs of DKA are hyperglycemia and acidosis. Acidosis can be indirectly inferred using capnography; a lower than expected end-tidal carbon dioxide (ETCO_2) level—that is, respiratory alkalosis—may develop as a compensatory mechanism to significant metabolic acidosis.

Laboratory Assessment

Testing for hypoglycemia or hyperglycemia is a rapid, point-of-care procedure that a CCTP can perform during transport. Administration and/or titration of existing medications or fluids may then follow based on the results of this biochemical analysis.

Because glucose is one of the three major energy sources for the body, it is important to routinely monitor the patient's blood glucose level during transport. Most commonly, this is accomplished via a portable blood glucose monitor (glucometer) **FIGURE 18-5**, similar to the one the patient may use at home. Portable blood glucose monitors measure the glucose level in whole blood using either capillary or venous samples. In contrast, blood glucose testing performed in a laboratory measures the blood glucose concentration in the plasma, which is typically about 10 mg/dL higher than that in a whole blood sample.

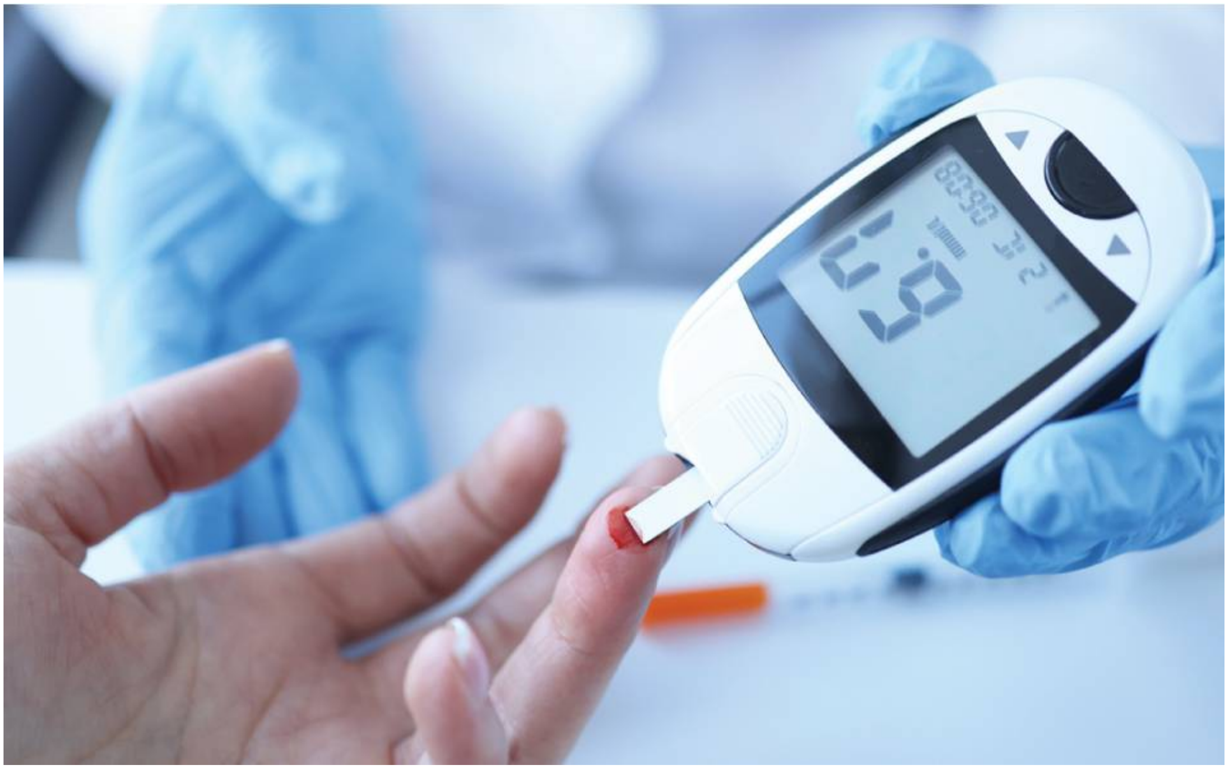


FIGURE 18-5 A portable glucometer used in the critical care transport environment.

© megaflopp/Shutterstock.

It is important to read and understand the operator's manual prior to using the glucometer because of differences in manufacturers' specifications. Some glucometers will read "Lo" when the glucose reading is less than 20 mg/dL, whereas others will display "Lo" when the reading is less than 30 mg/dL. The same variations may apply with a "Hi" reading; some glucometers read "Hi" at 550 mg/dL, and others read "Hi" at 600 mg/dL. Thus, it is important to know both the upper and lower ranges of the specific glucometer model.

The normal lab value for glucose in whole blood in nonfasting adults and children is 70 to 100 mg/dL. In a neonate, blood glucose levels should be maintained at greater than 65 mg/dL.

Venous blood gas monitoring should also be used in patients with DKA. Monitoring commonly reveals metabolic acidosis with a pH less than 7.30, a bicarbonate level less than 15 mEq/L, and a $\text{Pa}\textsc{co}_2$ level less than 30 mm Hg.

Laboratory testing for diabetes may also include urine and/or serum ketone tests, which can identify the presence of dehydration and DKA. Generally, blood chemistry analysis and blood testing for ketones are indicated to detect elevations in blood urea nitrogen (BUN) and creatinine that may result from significant dehydration, to detect electrolyte abnormalities (which can be profound), and to calculate the anion gap, which, in the presence of serum ketones (β-hydroxybutyrate), is used to diagnose DKA and guide ongoing insulin infusion therapy.

A person with diabetes may also have had a hemoglobin A1c (glycohemoglobin) test completed prior to transport—although this test is typically not performed during an acute emergency. When a person experiences prolonged hyperglycemia, the red blood cells become saturated with glucose. The percentage of saturation can then be measured in an attempt to estimate the patient's blood glucose level during the previous 3 to 4 months. Typically, patients *without* diabetes will have a hemoglobin A1c level between 4% and 6%.

Management

Patients presenting with hypoglycemia should be treated prior to initiating transport. However, if the CCTP is called to transport a patient with persistent hypoglycemia, then a continuous infusion of a dextrose-containing solution may be needed. If IV/IO access is not readily available, glucagon can be administered via the intramuscular, subcutaneous, or intranasal routes to rapidly correct severe hypoglycemia.

Hyperglycemic patients (with DKA and HHS) who present in hypovolemic shock from dehydration should receive an initial fluid bolus with an isotonic or 0.9% saline solution via an IV, IO, or central line at a volume of 20 mL/kg in an effort to restore intravascular volume. Following the initial fluid bolus, the optimal maintenance fluid rate and type of crystalloid solution will depend on the patient's clinical condition. Patients without evidence of heart failure, renal failure, advanced liver disease, or pulmonary edema should be rehydrated at 250 to 500 mL/h for several hours. The 0.9% saline should be changed to 0.45% saline or PlasmaLyte solution once the corrected serum sodium concentration has increased to normal or above normal. Proceed with fluid administration cautiously if the patient requires more than 50 mL/kg during the first 4 hours of rehydration.

As the intravascular volume is repleted, any potassium and magnesium deficits should be corrected. Insulin therapy should be withheld and 10 to 20 mEq/h of potassium chloride should be administered until the serum potassium is at least 3.3 mEq/L, due to the risk of iatrogenic hypokalemia and cardiac dysrhythmia. Once the serum potassium concentration is between 3.3 and 5.2 mEq/L, 20 to 40 mEq of potassium chloride should be added to each liter of subsequent IV fluid to maintain the serum potassium concentration between 4 and 5 mEq/L. If the serum potassium concentration is greater than 5.2 mEq/L, potassium supplementation should be withheld. Patients with end-stage renal disease are at particularly high risk for hyperkalemia; in these patients, potassium supplementation should not begin until serum concentrations are less than 3.3 mEq/L.

Regular IV insulin is less expensive and equally as effective as the more costly rapid-acting insulin analogs; hence, most experts and institutional protocols initiate continuous insulin infusions with an IV bolus of 0.1 unit/kg of regular insulin, followed immediately by a continuous infusion of 0.1 unit/kg/h. In both DKA and HHS, this rate of infusion is expected to decrease serum glucose by 50 to 70 mg/dL/h. Larger doses do not typically produce greater reductions in serum glucose, although CCTPs should be aware that volume replacement often results in an additional lowering of serum glucose by 35 to 70 mg/dL/h due to hemodilution and improved renal function. Once the serum glucose level reaches 200 to 250 mg/dL in a patient with DKA or 250 to 300 mg/dL in a patient with HHS, the IV fluids should be switched from 0.9% or 0.45% saline to a dextrose-containing solution, typically 5% dextrose with 0.45% sodium chloride, to maintain serum glucose between 150 and 200 mg/dL. The insulin infusion may need to be reduced to 0.02 to 0.05 unit/kg/h as well. Lowering serum glucose below 150 to 200 mg/dL with a continuous insulin infusion may increase the risk of severe hypoglycemic episodes and cerebral edema. In DKA, insulin infusions should be continued until the anion gap is 12 or lower and serum pH is greater than 7.3.

Considerable controversy surrounds the practice of administering bicarbonate to correct the metabolic acidosis often seen in DKA. Most experts suggest that bicarbonate administration is warranted when the arterial pH is less than 6.90. Typically, 100 mEq of bicarbonate is added to the IV fluids infusing to run over 2 hours; this treatment is repeated until the pH rises above 7.00. Little evidence of improved outcomes exists for correcting pH beyond 7.00, and the risks may outweigh any additional benefits. Of note, if the patient does not have an arterial line, then venous blood sampling can be used to measure pH: Venous pH is typically 0.03 lower than arterial pH.

Patients being treated for hyperglycemia should have continuous cardiac monitoring, with the CCTP watching for the development of cardiac arrhythmias and hypokalemia. Serum glucose should be checked at least hourly, and more often during resuscitation. Venous blood pH should be checked at least every 2 hours; if this capability is unavailable, $ETCO_2$ values should be trended continually. DKA is considered to be resolved when blood glucose is less than 200 mg/dL and either the anion gap is 12 or lower, pH is greater than 7.3, or serum bicarbonate level is greater than 15 mEq/L. Note that serum bicarbonate measurements can be affected by hyperchloremia resulting from fluid resuscitation with 0.9% saline infusions. HHS is considered to be resolved when serum osmolality has normalized and the patient's mental status has returned to baseline (if it was found to be altered during the initial assessment). Once DKA or HHS has resolved, subcutaneous insulin can be started and insulin infusions discontinued 1 to 2 hours later. Patients not previously taking insulin can be transitioned to subcutaneous insulin at 0.5 to 0.8 unit/kg/d.

In patients with uncomplicated hyperglycemia or mild DKA (awake and alert, tolerating oral fluids without vomiting, pH > 7, bicarbonate ≥ 10 mmol/L), subcutaneous short-acting insulin can be considered instead of IV infusions. The recommended subcutaneous dosing of short-acting insulin typically includes an initial bolus of 0.3 unit/kg, followed by 0.2 unit/kg every 2 hours until the blood glucose level reaches 250 mg/dL, then 0.05 to 0.1 unit/kg every 2 hours until the DKA has resolved. If the patient is already taking a long-acting basal insulin, it may be coadministered to prevent rebound hyperglycemia.

As with all patients whom the CCTP will encounter, definitive airway management and ventilatory assistance may be required for patients with hyperglycemia. Due to the potentially severe metabolic acidosis and risk of cardiac arrest resulting from the loss of respiratory compensation, extreme caution should be taken when performing endotracheal intubation or other airway management, should it become necessary. If aspiration is possible because of the patient's decreased level of consciousness, then consider inserting a nasogastric tube. If urine output must be monitored during transport and the patient is unresponsive, then insert an indwelling (Foley) catheter. Neurologic status should be continuously monitored as well. Correction of serum glucose that is too rapid can lead to cerebral edema, which has a mortality of 20% to 40% when it occurs during

DKA treatment. Early identification (headache and obtundation are the earliest signs) and aggressive treatment of this condition can improve outcomes.

Numerous studies in patients who have recently undergone cardiac surgery demonstrate that these patients have fewer infections and improved survival when tight glycemic control is achieved, yet data from the NICE-SUGAR study suggest these values cannot be applied to the rest of the critically ill patient population (ie, noncardiac surgery patients). This is not to say that insulin infusions are unhelpful in noncardiac surgical patients, but rather that standard guidelines for glycemic control can be used. Standard glucose management practices should not be abandoned in critically ill patients; in fact, CCTPs can expect to see continuous insulin infusions in many patients admitted to an intensive care unit who subsequently require transfer to another hospital. When insulin infusions are used in some critically ill patients, there appears to be a decrease in both mortality and morbidity.

CONTROVERSIES

The use of continuous insulin infusions in critically ill patients has been questioned and is becoming less frequent due to two largely unresolved issues:

- Whether the increased survival results from the insulin infusion or the control of the blood glucose level
- What the optimal blood glucose target is to ensure improved outcomes in critically ill patients

Most institutions have established their own protocols for insulin infusions. These protocols may differ substantially, as does the incidence of hypoglycemia associated with the various protocols. Research has shown that hypoglycemic episodes significantly increase morbidity and mortality, and may negate the benefits of the insulin infusion in some patient populations.

In summary, the CCTP should understand that insulin infusions are a routine part of care for many patients. They require vigilance in monitoring during transport, including frequent (hourly or more often) checks of blood glucose levels using a blood glucometer, and careful management of the insulin infusion rate to maintain blood glucose at the optimal level.

Transport Management

Hypoglycemia

- Test for hypoglycemia/hyperglycemia.
- Administer a continuous dextrose infusion, if required, and titrate the infusion to the patient's blood glucose level.
- If IV/IO access is not readily available, administer intramuscular, subcutaneous, or intranasal glucagon.

Transport Management

Hyperglycemia (DKA and HHS)

- Initiate fluid resuscitation with 0.9% saline via an IV, IO, or central line.
- Correct electrolyte derangements, including potassium and magnesium deficits.
- Administer a regular IV insulin bolus, followed immediately by a continuous insulin infusion.
- Administer sodium bicarbonate if pH is less than 6.90.
- Provide continuous cardiac and $ETCO_2$ monitoring.
- Provide airway management and ventilatory assistance if required.
- Insert an indwelling (Foley) catheter to measure urine output if the patient is critically ill or unresponsive.
- Check blood glucose at least hourly, and more often if the patient is receiving fluid resuscitation or insulin treatment.
- Measure the arterial or venous pH every 2 hours (if unable to do so, monitor the $ETCO_2$ trend).
- Monitor the patient's neurologic status for signs and symptoms of cerebral edema (eg, headaches, obtundation).

Pituitary Disorders

Pituitary disorders often present with signs and symptoms common to other disease processes, requiring the CCTP to perform a thorough medical history and physical exam to correctly identify the underlying pathology. Although these disorders are typically not acutely life threatening, they can result in significant morbidity and mortality if left untreated.

Pathophysiology

The pituitary gland, commonly referred to as the “master gland,” secretes hormones that regulate the secretions of other endocrine glands. Located at the base of the brain, and approximately the size of a grape, it is attached to the hypothalamus. The pituitary gland is divided into two lobes:

- The anterior pituitary, which produces and secretes six hormones: growth hormone (GH), thyroid-stimulating hormone (TSH), ACTH, and three gonadotropic hormones
- The posterior pituitary, which secretes two hormones—antidiuretic hormone (ADH; also known as vasopressin) and oxytocin—but does not produce them

Central Diabetes Insipidus

Central diabetes insipidus occurs when the posterior part of the pituitary gland no longer secretes ADH. This condition may result from a traumatic head injury, neurosurgery, or autoimmune disease, or it may be genetic. Because of the lack of ADH, patients with this disease frequently experience free water loss from the kidneys, leading to severe dehydration and hypernatremia.

Signs and Symptoms

Central Diabetes Insipidus

- Polyuria with dilute urine
- Polydipsia
- Dehydration

Pituitary Lesions

Pituitary lesions can be classified into two types: nonfunctioning adenomas and functioning adenomas. A **nonfunctioning adenoma** is a tumor that does not secrete hormones. A **functioning adenoma**, in contrast, does secrete hormones. Depending on the type of hormone and the amount produced by the lesion, different diseases may result:

- ACTH-secreting adenomas are responsible for Cushing disease. Cushing disease is the cause of Cushing syndrome (discussed later in this chapter).
- Growth hormone–secreting adenomas are responsible for acromegaly and gigantism.
- Prolactin-secreting adenomas are responsible for reproductive disorders.

The majority (approximately 70%) of pituitary lesions are functioning adenomas.

Acromegaly and Gigantism

Acromegaly is a syndrome that results from the secretion of excessive growth hormone by the pituitary gland *after* the epiphyseal plate has closed. Commonly affecting middle-aged adults, acromegaly can result in progressive enlargement of the face, hands, and feet; diabetes and hypertension; and ultimately, premature death if left untreated. Because of the slow progression of the syndrome, this condition often goes undiagnosed for many years.

Acromegaly is often associated with gigantism. **Gigantism** results from the secretion of excessive growth hormone by the pituitary gland *before* the epiphyseal plate has closed.

Regardless of the onset (childhood or adulthood), both acromegaly and gigantism are characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate. Acromegaly and gigantism are almost always caused by a benign pituitary tumor.

Signs and Symptoms

Acromegaly and Gigantism

- Abnormally fast growth of bones, muscles, and internal organs
- Onset of diabetes and hypertension

Assessment

Follow the same assessment steps for patients presenting with acromegaly or gigantism as you would for any other patient. Obtain a detailed medical history and information about weight gain as well as excessive and rapid growth.

Laboratory Assessment

Patients with acromegaly and gigantism typically present with elevated creatinine levels (greater than 1.2 mg/dL). Because acromegaly and gigantism are a result of excessive growth hormone production, GH levels will be elevated (more than 18 ng/mL).

Management

TABLE 18-1 lists medications used to treat acromegaly and gigantism. Bromocriptine (Parlodel), a dopaminergic agonist, is used to decrease growth hormone secretion. Octreotide (Sandostatin) and lanreotide (Somatuline), synthetic forms of the hormone somatostatin, stop growth hormone production entirely. Pegvisomant (Somavert), a growth hormone receptor antagonist, is used to treat acromegaly and gigantism. Pegvisomant can control acromegaly and gigantism in virtually all patients because of its ability to block the action of the endogenous growth hormone molecules.

TABLE 18-1 Medications Used to Treat Acromegaly and Gigantism

Medication Class	Examples
Dopaminergic agonist	Bromocriptine (Parlodel)
Somatostatin analog	Octreotide (Sandostatin) Lanreotide (Somatuline)
Growth hormone receptor antagonist	Pegvisomant (Somavert)

Adrenal Abnormalities

Many abnormalities of the adrenal glands are possible. Some are hereditary (familial adrenal hypoplasia syndromes), others involve steroid resistance and hypersensitivity abnormalities such as glucocorticoid resistance syndromes and states, and some are genetic in origin, such as adrenal insufficiency as a result of X-linked adrenoleukodystrophy.

Pathophysiology

Conditions associated with a **pseudo-Cushing state** are a mixed group of disorders related to increased cortisol production. The physiologic conditions that cause increased cortisol production include stress associated with a recent surgery, severe illness, emotional stress, intense aerobic exercise, and caloric restriction. Nonphysiologic conditions that may elevate cortisol production include chronic alcoholism and alcohol withdrawal syndrome, poorly controlled diabetes mellitus, and obesity.

Endocrine hypertension is a result of hormonal disorders that cause clinically significant hypertension. The most common causes of endocrine hypertension are excess production of mineralocorticoids, such as aldosterone; catecholamines, such as epinephrine, norepinephrine, and dopamine; and glucocorticoids, such as cortisol. The cause of endocrine hypertension often relates to excess hormone produced by a tumor. Endocrine hypertension can be treated with surgery or antihypertensive therapy.

Adrenal Insufficiency

Underproduction of cortisol and aldosterone caused by decreased functioning of the adrenal cortex is called **adrenal insufficiency (AI)**. When at least 90% of the adrenal cortex has been damaged, AI occurs. Cortisol helps the body respond to stress, including stress caused by surgery, illness, or infection. This hormone also aids in maintaining normal blood pressure and cardiovascular functions and regulating the metabolism of proteins, carbohydrates, and fats. AI may affect the adrenal gland (idiopathic AI) or other glands (polyendocrine deficiency syndrome).

Primary causes of AI include the following:

- Autoimmune disorders (eg, Hashimoto disease)
- Illness or increased stress
- Genetic disorders
- Renal injuries
- Radiation therapy
- Surgery
- Infections
- Pituitary and hypothalamic lesions

Adults of all ages are equally affected by AI. Causes of permanent AI include Addison disease, congenital adrenal hyperplasia, and complete surgical removal of the pituitary gland or the adrenal glands. Temporary AI can be caused by physical stress, infections, surgery, or medication noncompliance.

In the patient with chronic AI, signs and symptoms of **addisonian crisis** may appear suddenly as a result of an increased period of stress, trauma, recent surgery, or severe infection. The primary clinical manifestation of addisonian crisis is shock. Other symptoms include weakness, altered mental status, hyperthermia, and severe pain in the lower back, legs, or abdomen. Severe vomiting and diarrhea may precipitate dehydration in these patients.

The ACTH stimulation test is the most specific test for diagnosing AI; this test measures blood cortisol levels (normal range, 10 to 60 ng/L). When it goes undiagnosed, AI is a potentially fatal disease owing to hypotension or cardiac arrhythmias as a result of hyperkalemia. Acute AI may present in postsurgical or trauma patients.

Approximately 50% of patients with moderate or severe traumatic brain injury present with some form of AI. Patients with traumatic brain injury receiving high-dose pentobarbital or propofol as well as patients with vasopressors used to manage lower blood pressures should be carefully monitored for AI.

Signs and Symptoms

Addisonian Crisis

- Shock
- Weakness
- Altered mental status
- Hyperthermia
- Severe pain in the lower back, legs, or abdomen
- Severe vomiting and diarrhea
- Dehydration

Addison Disease

Addison disease is a chronic hormonal or endocrine disorder that occurs in patients of all age groups; it is caused by a deficiency in cortisol and/or aldosterone. Addison disease is characterized by weakness, fatigue, hypotension, unexplained weight loss, and darkening of the skin **FIGURE 18-6**. Although other AI conditions can occur acutely, Addison disease is chronic.

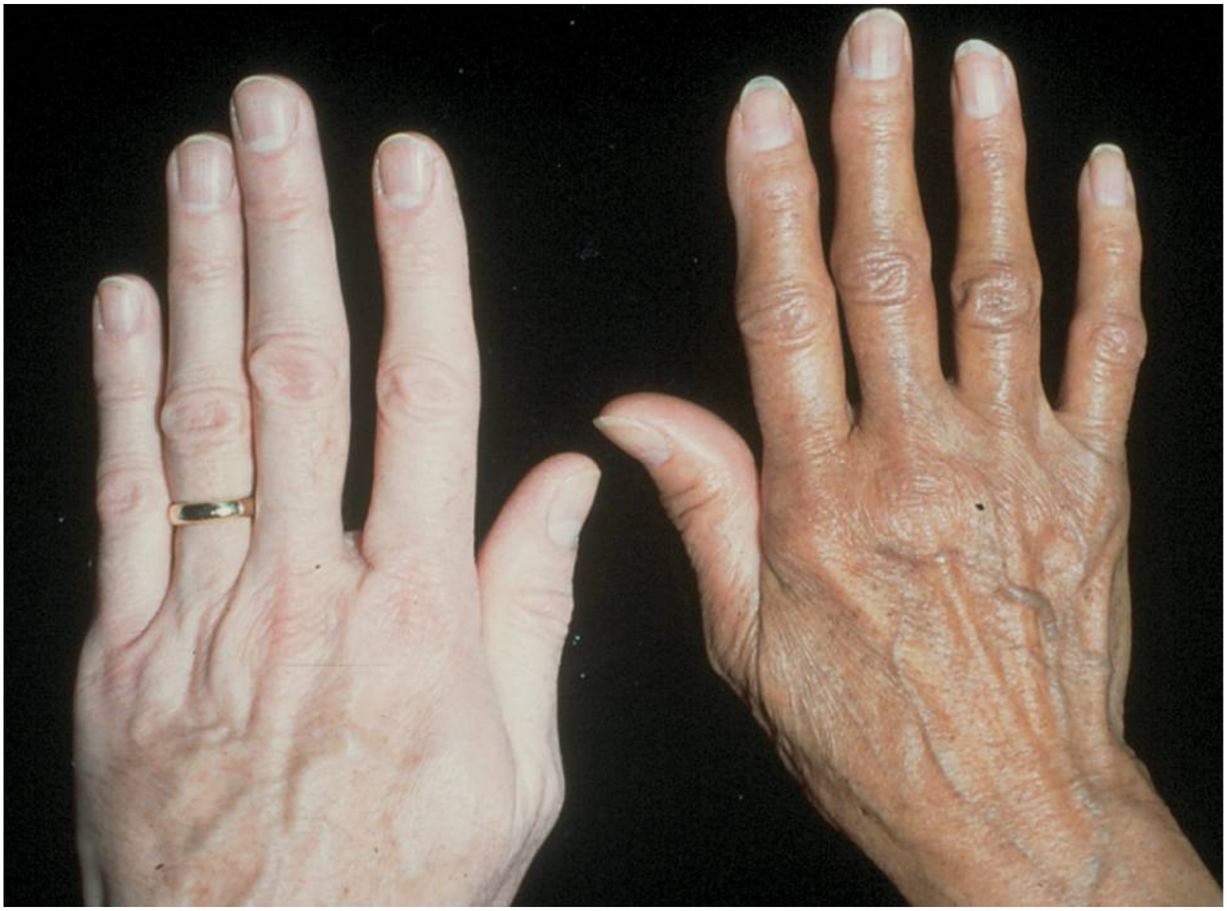

FIGURE 18-6 The hand of a patient with Addison disease (right) compared with the hand of a healthy patient (left).

Courtesy of Leonard V. Crowley, MD, Department of Laboratory Medicine and Pathology, University of Minnesota Medical School, Minneapolis, Minnesota.

Most cases of Addison disease are caused by the slow destruction of the adrenal cortex. Addison disease affects about 1 in 100,000 people.

Treatment of Addison disease is the same as that of acute AI conditions. The prognosis is good for well-managed adult-onset Addison disease, as these patients have a normal average mortality rate. In contrast, recent studies show that young patients with Addison disease are at risk for premature death. In patients diagnosed at a young age, Addison disease is still a potentially lethal condition, with excess mortality owing to acute adrenal failure, infection, and sudden death.

Signs and Symptoms

Addison Disease

- Weakness
- Fatigue
- Hypotension
- Unexplained weight loss
- Darkening of the skin

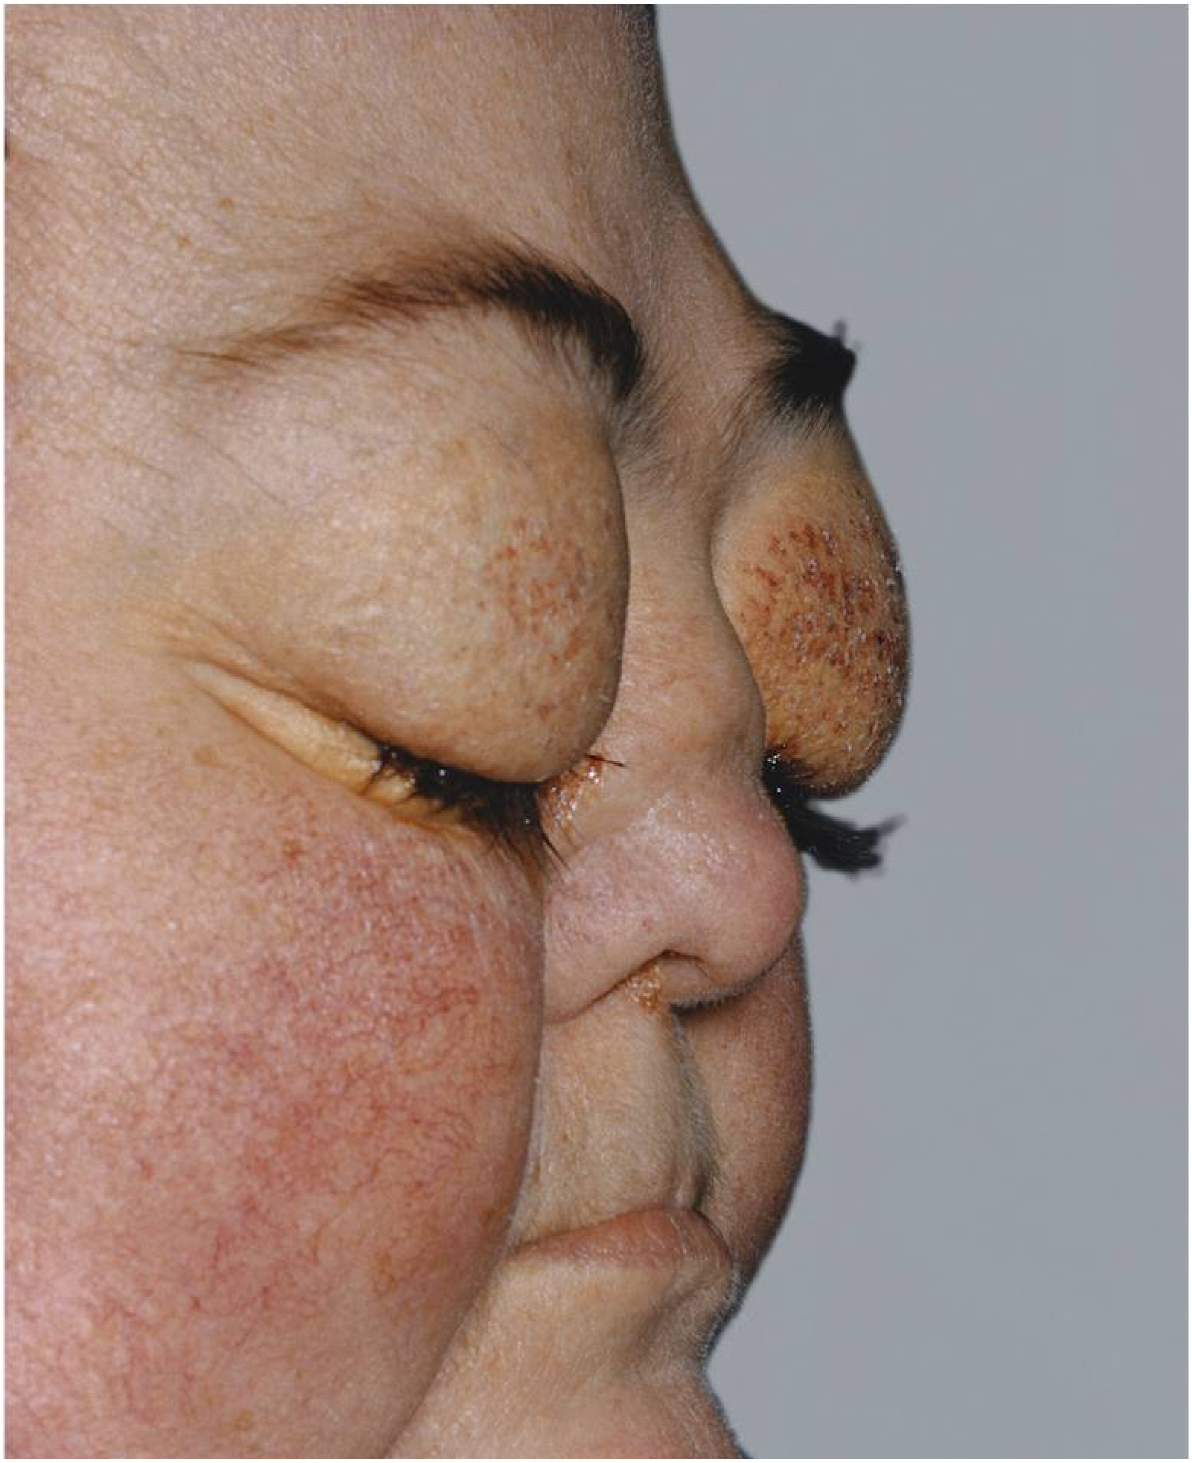
Cushing Syndrome

Cushing syndrome, also known as hypercortisolism, is caused by prolonged exposure to elevated levels of cortisol in the body. This syndrome, which is relatively rare, affects people between age 20 and 50 years. Risk factors for Cushing syndrome include obesity, poorly controlled type 2 diabetes, and hypertension. Patients taking glucocorticoids, such as prednisone for inflammatory diseases, are also at risk for developing Cushing syndrome.

Regardless of the cause, excess cortisol causes characteristic changes in many body systems. The metabolism of carbohydrates, protein, and fat is disturbed, causing hyperglycemia. Protein synthesis is impaired so that body proteins are broken down, which leads to a loss of muscle fibers and muscle weakness. Bones become weaker and more susceptible to fracture. Other common signs and symptoms include the following:

- Weakness and fatigue
- Depression and mood swings
- Increased thirst and urination
- Weight gain, especially on the abdomen, face (“moon face”) **FIGURE 18-7**, neck, and upper back (“buffalo hump”) **FIGURE 18-8**
- Thinning of the skin, with easy bruising and pink or purple stretch marks (striae) on the abdomen, thighs, breasts, and shoulders

- Increased acne, facial hair growth, and scalp hair loss; in women, menstrual irregularities
- Darkening of skin (acanthosis) on the neck
- Obesity and restricted growth in children



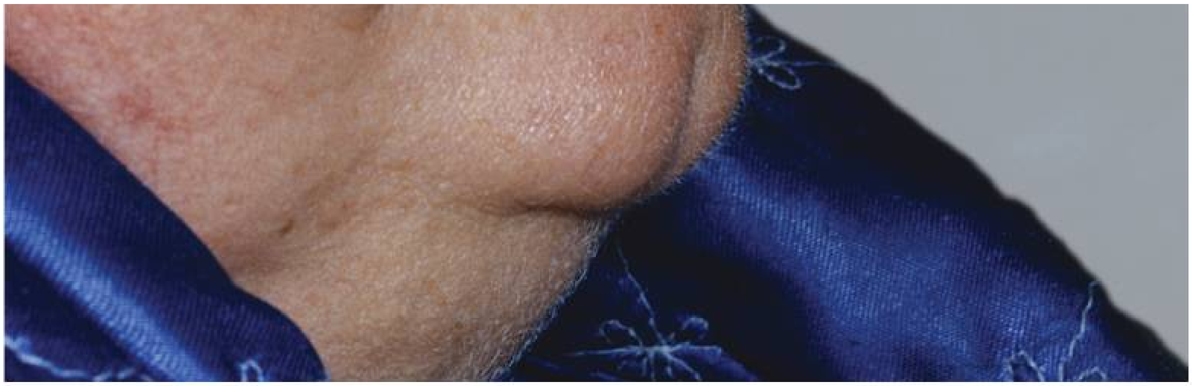


FIGURE 18-7 Weight gain in the face as a result of Cushing syndrome.

Signs and Symptoms

Cushing Syndrome

- Hyperglycemia
- Weakness and fatigue

- Depression and mood swings
- Increased thirst and urination
- Weight gain (especially on the abdomen, face, neck, and upper back)
- Thinning of the skin; easy bruising and pink or purple stretch marks on the abdomen, thighs, breasts, and shoulders
- Increased acne, facial hair growth, and scalp hair loss; in women, menstrual irregularities
- Darkening of skin on the neck
- Obesity and poor growth in height in children

Pheochromocytoma

A **pheochromocytoma** is a catecholamine-producing benign tumor of chromaffin cells, located in the center of the adrenal gland. The effects of such a tumor can manifest either sporadically or chronically. The catecholamines produced include epinephrine, norepinephrine, and occasionally dopamine. These catecholamines stimulate alpha-adrenergic receptors, resulting in severe hypertension, increased cardiac contractility, glycogenolysis, gluconeogenesis, and intestinal relaxation. Stimulation of the beta-adrenergic receptors increases the heart rate and contractility.

Although the majority of the pheochromocytomas are found in the adrenal glands, these tumors can arise anywhere there is chromaffin tissue. Approximately 95% occur in the abdomen, with the remaining 5% being found in other parts of the body.

Investigation of sustained hypertension leads to a diagnosis of pheochromocytomas in 0.05% to 0.2% of patients. Pheochromocytoma can be corrected in approximately 90% of cases if identified. If left untreated, fatal events such as catecholamine-induced malignant hypertension, heart failure, myocardial infarction (MI), stroke, or ventricular arrhythmias can occur.

Although patients may be temporarily treated with antihypertensive and cardiac rate-control medications, definitive treatment for pheochromocytoma consists of surgical removal of the tumor. Patients with pheochromocytoma should be treated with appropriate preoperative medical management to block the effects of released catecholamines.

Patients can experience a hypertensive crisis as a result of the rapid increase in catecholamines released from the tumor. They may present with varying symptoms, including severe headaches or diaphoresis, visual disturbances, palpitations, epistaxis, AMI, congestive heart failure, or stroke. Treatment of a hypertensive crisis triggered by a pheochromocytoma should be initiated immediately and commonly includes IV alpha blockers (phentolamine), beta blockers (esmolol or labetalol), and/or calcium channel blockers (nicardipine). Phentolamine is typically administered as a 5 mg IV bolus and may be repeated every 10 minutes to achieve target blood pressure. During the first hour, blood pressure targets are typically a systolic blood pressure of 140 mm Hg, not to exceed a 25% reduction in systolic blood pressure over the first hour.

Immediately following surgery for pheochromocytoma removal, some patients remain hypertensive, although the majority present with hypotension that requires treatment with fluids. Hypoglycemia is another postoperative complication that can be prevented by infusion of 5% dextrose started immediately after tumor removal and continuing for several hours thereafter. Postoperative hypoglycemia is transient, whereas hypotension may continue for several days or more after surgery.

The long-term prognosis of patients after pheochromocytoma excision is excellent. However, nearly one-half of these patients will experience resultant lifelong hypertension.

Signs and Symptoms

Pheochromocytoma

- Hypertension
- Increased heart rate
- Severe headache
- Diaphoresis
- Visual disturbances
- Palpitations
- Chest pain
- Upper abdominal pain

- Epistaxis
- Anxiety
- Acute myocardial infarction
- Congestive heart failure
- Stroke

Transport Management

Pheochromocytoma

- Administer IV boluses of phentolamine to achieve the target systolic blood pressure.

Aldosteronism

Aldosteronism is a syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone. Two main types of aldosteronism are distinguished: primary and secondary.

Primary aldosteronism (also known as Conn syndrome) is usually caused by a tumor of a single adrenal gland that overproduces aldosterone. More than 95% of such cases are benign. On rare occasions, however, these tumors may be malignant.

Secondary aldosteronism results from other conditions not associated with the adrenal gland. It can be caused by obstructive renal artery disease, renal vasoconstriction, and edematous disorders, and occurs as a result of reduced renal blood flow. The reduced blood flow stimulates hypersecretion of aldosterone.

Aldosteronism should be suspected in patients with hypertension and hypokalemia because aldosterone normally functions to increase sodium and fluid in the bloodstream as well as potassium excretion by the kidney. Elevated aldosterone levels can be measured via blood or urine chemistry. A special blood test that measures plasma renin activity is performed to distinguish between primary aldosteronism (low plasma renin activity) and secondary aldosteronism (high plasma renin activity). Once blood chemistry testing is completed, a computed tomography (CT) scan of the abdomen may be performed to confirm the location of the disease.

Surgery is the appropriate treatment for aldosteronism if the primary cause is a single adenoma. When the cause does not lie within the adrenal gland, treatment is to correct the underlying condition that led to the elevated aldosterone levels.

Signs and Symptoms

Aldosteronism

- Hypertension
- Low blood potassium levels
- Alkalosis
- Muscular weakness
- Polyuria
- Polydipsia
- Edema
- Heart failure
- Hepatic cirrhosis

Amyloidosis

Amyloidosis comprises a group of diseases that result from abnormal deposits of the protein amyloid in various tissues of the body. This protein can be deposited in a localized area, or it may affect tissues throughout the body in a systemic fashion. Systemic amyloidosis can lead to serious changes in virtually any organ of the body and can cause the affected organs to fail.

Primary amyloidosis—the most common form of amyloidosis—affects the heart, kidneys, tongue, nerves, and intestines. This condition is associated with multiple myeloma, a form of bone marrow cancer, in a minority of cases. The form of amyloid deposited in primary amyloidosis is classified as an apolipoprotein.

Secondary amyloidosis occurs as a result of another illness, such as multiple myeloma, chronic infection, or chronic inflammatory disease. The form of amyloid deposited in secondary amyloidosis is classified as an amyloid A protein. This disease mostly affects the kidneys, spleen, liver, and lymph nodes, although other organs may be involved. Treatment of the underlying disease may help mitigate this form of amyloidosis.

There is no known cure for amyloidosis. Therapies are directed at managing symptoms and limiting the production of amyloid protein.

Signs and Symptoms

Amyloidosis

- Pedal edema
- Weight loss
- Dyspnea
- Weakness
- Diarrhea
- Fatigue
- Cardiac arrhythmias

Assessment

Patients with adrenal abnormalities may present with variable physical findings and vital signs on examination. The patient assessment, the history of present illness or injury, and a thorough review of medical history will aid in determining whether adrenal abnormalities are influencing the patient's vital signs and symptoms. It is also important to be aware of the possibility of adrenal complications in a patient's differential diagnosis. Treatment of adrenal abnormalities may not be commonly recognized as necessary, contributing to increased morbidity and mortality for patients with these conditions.

Signs and Symptoms

In addition to the medical history and physical exam, diagnosis of Cushing syndrome or Cushing disease requires laboratory studies showing elevated levels of blood cortisol.

The assessment of the patient with pheochromocytoma may reveal hypertension and other symptoms associated with catecholamine release, such as tachycardia, diaphoresis, chest pain, upper abdominal pain, and anxiety.

Primary aldosteronism typically presents with hypokalemia, alkalosis, muscular weakness, polyuria, polydipsia, and hypertension. Secondary aldosteronism is commonly associated with edematous states, heart failure, hepatic cirrhosis, and malignant hypertension.

Signs and symptoms of amyloidosis depend on the organ system affected, but typically include pedal edema, weight loss, dyspnea, weakness, diarrhea, fatigue, and cardiac arrhythmias.

Laboratory Assessment

Laboratory testing is required to definitively diagnose these underlying health conditions and will vary with the disease process.

The ACTH stimulation test, along with the cortisol test, is the most specific combination of tests for diagnosing Addison disease. In these tests, a synthetic form of ACTH is injected into the patient, with blood and urine cortisol measurements obtained before and after the injection. In a healthy patient, blood and urine cortisol levels will rise after an injection of ACTH. In contrast, patients with AI will exhibit less of an increase or no increase at all. The normal range for cortisol levels in adults is 5 to 25 µg/dL; the normal range for aldosterone levels in adults is 2 to 9 ng/dL.

No increase in blood and urine cortisol levels after injection of ACTH indicates the pituitary gland is the likely origin of the condition, whereas a delayed increase indicates the hypothalamus is the likely source. Specifically, patients with primary AI have high ACTH levels but do not produce cortisol. Patients with secondary AI have decreased cortisol responses but absent or delayed ACTH responses.

Unlike adults, children are more likely to have absolute AI, defined by a basal cortisol level of less than 18 µg/dL and a peak ACTH-stimulated cortisol concentration of less than 18 µg/dL. Patients at risk of inadequate cortisol or aldosterone production in the setting of shock include those who previously received corticosteroid therapies for chronic illness, those with pituitary or AI, and children with purpura fulminans and Waterhouse-Friderichsen syndrome.

Management

Treatment of adrenal diseases usually involves replacing or substituting the deficient adrenal gland hormones. The details vary with the underlying cause, the clinical presentation, and the severity of symptoms.

The initial treatment of acute adrenal crisis focuses on correcting hypovolemic shock via fluid resuscitation. Fluid resuscitation (500 to 1,000 mL) with an isotonic crystalloid solution should be given by the IV or IO route. For a patient diagnosed with glucocorticoid deficiency, IV steroids such as dexamethasone or hydrocortisone may be administered. Dexamethasone has a long duration of action and does not interfere with serum or urinary steroid testing; therefore, it is preferred for this indication.

TABLE 18-2 lists medications used to treat adrenal conditions. Although treatment of patients with pituitary disorders in the acute setting is rare, the CCTP should appreciate the impact that these disease processes have on a patient's day-to-day life, and should maintain a high index of suspicion when encountering a patient who may be presenting with these signs and symptoms.

TABLE 18-2 Medications Used to Treat Adrenal Conditions

Medication Class	Examples
Adrenal Insufficiency Synthetic glucocorticoids	Fludrocortisone acetate (Florinef), taken once per day.
Cushing Syndrome Synthetic cortisol	Ketoconazole (Nizoral), mitotane (Lysodren), metyrapone (Metopirone), prednisone, hydrocortisone, dexamethasone; dosages depend on the cause of the syndrome and the treatment plan.

Medication Class	**Examples**
Pheochromocytoma Antihypertensives	Phentolamine: IV bolus of 5 mg; nicardipine: 5 mg/h IV, increase by 2.5 mg/h every 5 min to a maximum of 15 mg/h; esmolol (rate-control): IV bolus of 1 mg/kg over 30 seconds followed by 150 mcg/kg/min infusion to a maximum of 200 mcg/kg/min.
Aldosteronism	Treatment for primary aldosteronism depends on the underlying cause.
Amyloidosis	Treatment is directed at managing symptoms and limiting the production of amyloid protein; it includes melphalan (Alkeran or Alkeran IV), a chemotherapy agent, and dexamethasone. New drugs being tested for use in amyloidosis include bortezomib (Velcade), thalidomide (Thalomid), and lenalidomide (Revlimid).

© Jones & Bartlett Learning.

Thyroid Abnormalities

Although transport of a patient with a life-threatening thyroid condition may be uncommon, a CCTP with a high index of suspicion and understanding of laboratory studies may be in a position to appreciate and better manage these conditions.

Pathophysiology

The thyroid gland, which serves as the primary controller of the body's metabolism, produces the hormones T_3 (triiodothyronine) and T_4 (thyroxine). These hormones stimulate an increase in organ function in all organs that are exposed to them.

Hypothyroidism

Hypothyroidism is caused by a deficiency of T_3 and T_4, both of which are secreted by the thyroid gland. Because of the decreased production of these hormones, the body's organ function slows, causing the patient to feel a decrease in body temperature, to have gradual weight gain, and to have an increased risk for AMI and stroke. In the critical care patient, a careful history will help with the diagnosis of hypothyroidism.

Signs and Symptoms

Hypothyroidism

- Decrease in body temperature
- Gradual weight gain
- Lethargy
- Constipation
- Muscle aches and weakness
- Joint pain, stiffness, or swelling
- Facial swelling

- Pale, dry skin
- Brittle fingernails and hair
- Hoarse voice
- Depression

Hyperthyroidism

Hyperthyroidism is caused by increased production of T_3 and T_4. Because the excess hormones increase the body's metabolism, patients with hyperthyroidism experience an increase in body temperature and gradual weight loss, even if they are eating the same amounts of food as they did before this condition occurred. Other side effects of hyperthyroidism include increased and/or irregular heart rate, sweating, and irritability.

Signs and Symptoms

Hyperthyroidism

- Increase in body temperature
- Gradual weight loss
- Increased and/or irregular heart rate
- Hypertension
- Sweating
- Irritability

Thyrotoxicosis and Thyroid Storm

Thyrotoxicosis and **thyroid storm** are rare but severe, life-threatening conditions that can occur in patients with long-term, untreated or undertreated hyperthyroidism. However, they are most commonly precipitated by an acute physiologic stressor such as a surgical procedure, trauma, infection, administration of large doses of iodine such as in the cardiac catheterization lab, or abrupt discontinuation of thyroid medications. Thyrotoxicosis is sometimes referred to as "impending thyroid storm," while severe thyrotoxicosis is considered "thyroid storm," although there are no universally accepted criteria defining either condition.

Even a minor trauma, such as a laceration, can cause a patient with hyperthyroidism to experience thyrotoxicosis. It is unclear why thyroid storm develops, but the mortality from this condition is high, ranging from 10% to 20%. Patients typically exhibit severe symptoms of hyperthyroidism, including hyperpyrexia (body temperature greater than 103°F [39°C], often ranging from 104°F to 106°F [40°C to 41°C]), altered mental status, and myocardial depression. Significant tachycardias and atrial fibrillation are common as well. Treatment includes the use of beta blockers, thionamides (ie, propylthiouracil or methimazole), iodine, glucocorticoids, and, in some patients, bile acid sequestrants.

Myxedema Coma

Myxedema coma is a rare, life-threatening clinical condition in patients with long-standing, severe, untreated hypothyroidism. Most commonly seen in older adult female patients, this condition has an extremely high mortality rate if left untreated. Myxedema coma is characterized by three key features:

- Altered mental status and lethargy (including lengthy sleeping patterns)
- Failure of the thermoregulatory system (hypothermia or the absence of fever despite infectious disease)
- A precipitating event (eg, cold exposure, infection, drugs [diuretics, tranquilizers, sedatives, or analgesics], trauma, stroke, heart failure, or gastrointestinal bleeding)

A person who initially presents with myxedema coma is usually hypothermic and may be experiencing both auditory and visual hallucinations, seizures, or depressed mental status.

Signs and Symptoms

Myxedema Coma

- Hypothermia
- Auditory and visual hallucinations
- Seizures
- Depressed mental status

Hashimoto Disease

Hashimoto disease, also known as chronic lymphocytic thyroiditis, occurs when the immune system attacks the patient’s thyroid gland. The resulting inflammation leads to hypothyroidism. In fact, Hashimoto disease is the leading cause of hypothyroidism, most commonly affecting women between ages 30 and 50 years.

Assessment

A patient with a thyroid-related condition may present with signs and symptoms of hypothyroidism (general weakness, cold intolerance, altered mental status, abdominal pain, and lethargy) or hyperthyroidism (heart-related complications that can include rapid heart rate, congestive heart failure, atrial fibrillation, and hypertension). The physical exam may reveal thyroid enlargement (goiter) **FIGURE 18-9**. In cases of hyperthyroidism, thyrotoxicosis may occur. Although hypothyroid emergencies are rare, they require urgent evaluation and treatment.

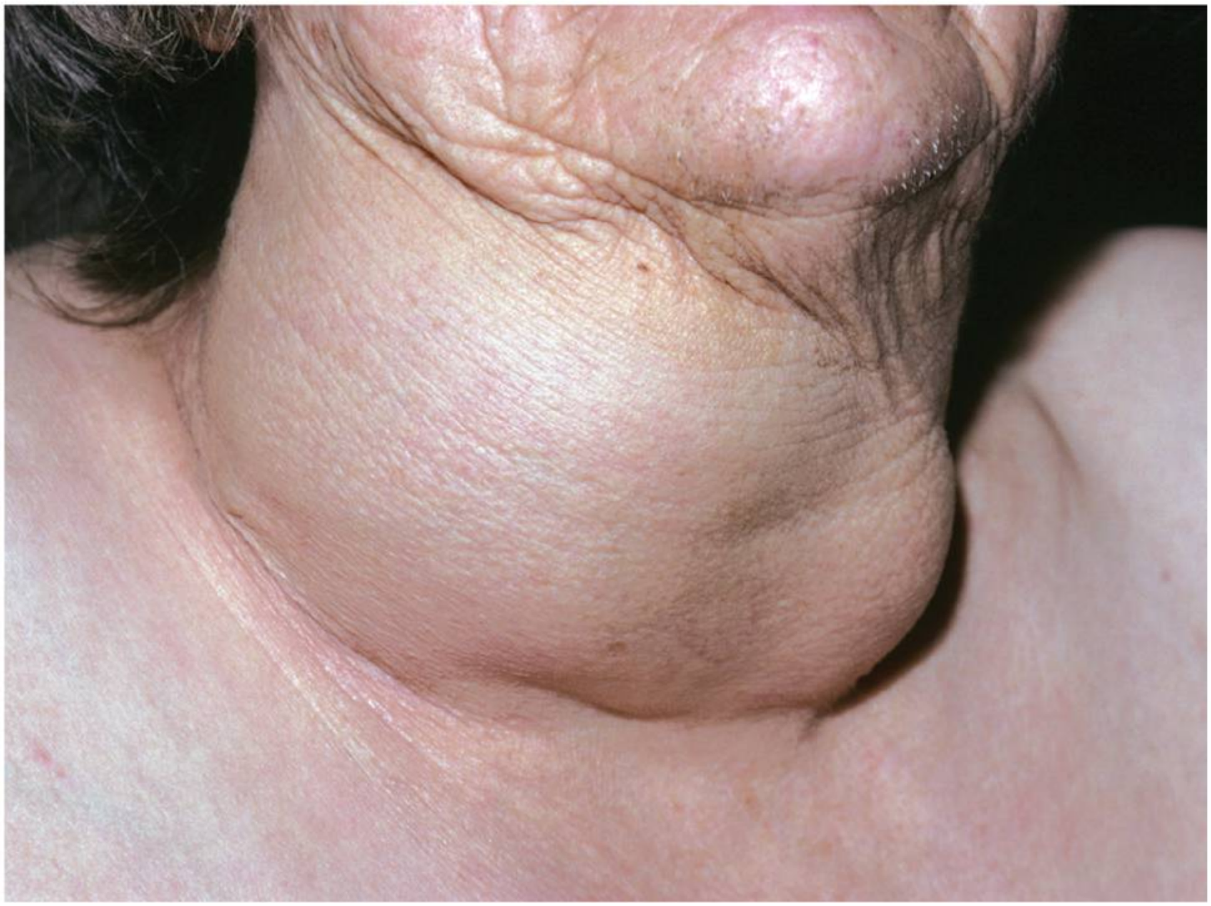

FIGURE 18-9 Thyroid enlargement.

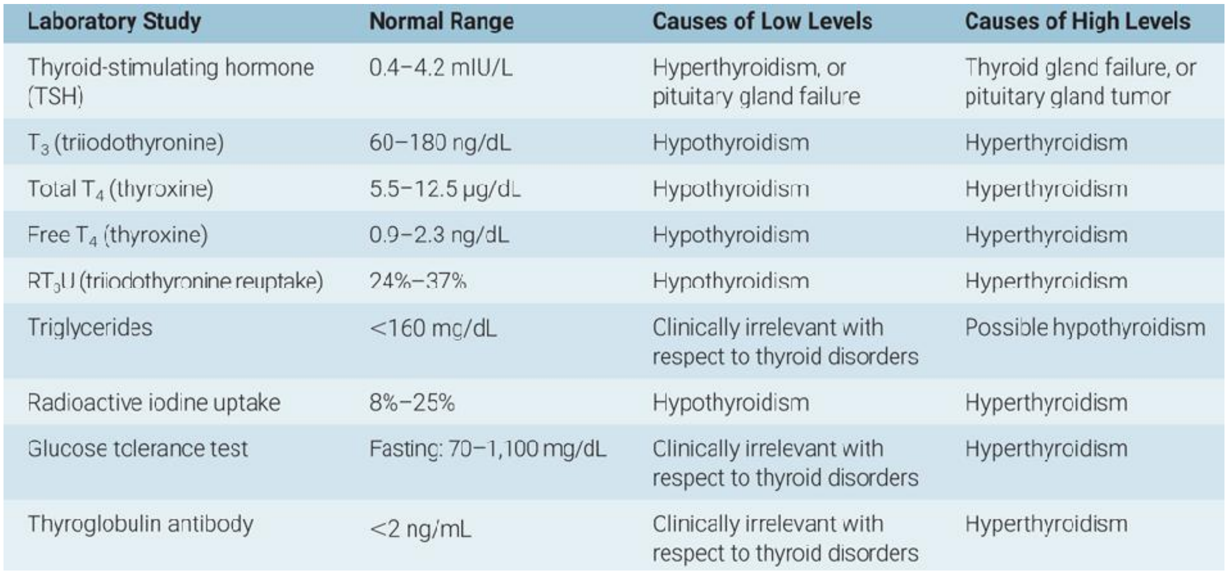
© Dr. P. Marazzi/Science Source.

Laboratory Assessment

Laboratory tests that evaluate thyroid function include serum TSH, T_3, and T_4. The normal range of serum TSH is 0.4 to 4.2 mIU/L for persons with no symptoms of abnormal thyroid function. However, people without signs or symptoms of hypothyroidism who have a TSH value greater than 2.0 mIU/L but normal T_4 levels may experience hypothyroidism in the future; this condition is called subclinical hypothyroidism (mildly underactive thyroid) or early-stage hypothyroidism. Patients being treated for a thyroid disorder should have a TSH level between 0.5 and 3.0 mIU/L. Low levels of TSH indicate possible hyperthyroidism or pituitary gland failure, and above-normal values indicate thyroid gland failure or a pituitary gland tumor.

TABLE 18-3 describes common laboratory studies for thyroid-related conditions.

TABLE 18-3 Common Laboratory Studies for Thyroid-Related Conditions



Laboratory Study	Normal Range	Causes of Low Levels	Causes of High Levels
Thyroid-stimulating hormone (TSH)	0.4–4.2 mIU/L	Hyperthyroidism, or pituitary gland failure	Thyroid gland failure, or pituitary gland tumor
T_3 (triiodothyronine)	60–180 ng/dL	Hypothyroidism	Hyperthyroidism
Total T_4 (thyroxine)	5.5–12.5 μg/dL	Hypothyroidism	Hyperthyroidism
Free T_4 (thyroxine)	0.9–2.3 ng/dL	Hypothyroidism	Hyperthyroidism
RT_3U (triiodothyronine reuptake)	24%–37%	Hypothyroidism	Hyperthyroidism
Triglycerides	<160 mg/dL	Clinically irrelevant with respect to thyroid disorders	Possible hypothyroidism
Radioactive iodine uptake	8%–25%	Hypothyroidism	Hyperthyroidism
Glucose tolerance test	Fasting: 70–1,100 mg/dL	Clinically irrelevant with respect to thyroid disorders	Hyperthyroidism
Thyroglobulin antibody	<2 ng/mL	Clinically irrelevant with respect to thyroid disorders	Hyperthyroidism

Description

Management

Treatment of thyroid conditions depends on the cause of the condition and the severity of symptoms. As with most conditions discussed in this chapter, transport management is mainly supportive.

Hypothyroidism is typically treated with hormone replacement therapy. Complications may sometimes arise related to replacement of the thyroid hormones. If too little hormone is given, then symptoms of hypothyroidism can occur, including fatigue, increased cholesterol levels, mild weight gain, depression, and slowing of mental and physical activity. If too much hormone is given, then the symptoms of hyperthyroidism will occur.

Hyperthyroidism is usually treated with antithyroid medications, radioactive iodine (which destroys the thyroid and stops the excess production of hormones), or surgical removal of the thyroid. Beta blockers, such as propranolol, are indicated to treat the resultant tachycardia, and anxiety may be treated with diazepam, lorazepam, or midazolam until the hyperthyroidism can be controlled. If the thyroid must be removed through radiation therapy or surgery, then replacement thyroid hormones must be taken for the rest of the person’s life.

Thyroid storm is a life-threatening condition with extremely high mortality if it is not promptly recognized and treated. Initial treatment consists of a beta blocker, which blocks the increased adrenergic tone that is caused by excessive thyroid hormone secretion and that results in tachycardia, tremor, hyperthermia, and arrhythmias such as atrial fibrillation. Propranolol is the most commonly used beta blocker for this purpose, as it can be given intravenously or orally and is widely available. Initial dosing is 0.5 to 1.0 mg IV over 10 minutes, followed by 1 to 2 mg IV every 15 minutes. Alternatively, 60 to 80 mg can be given orally every 4 hours.

Once adequate beta blockade is achieved, a thionamide, such as propylthiouracil or methimazole, is administered. These agents block synthesis of new thyroid hormone, and propylthiouracil also inhibits conversion of T_4 to T_3. Typical doses are a 500 to 1,000 mg loading dose of propylthiouracil, followed by 250 mg every 4 hours, or 60 to 80 mg of methimazole per day. Next, iodine is administered at least 1 hour after a thionamide is given to block thyroid hormone conversion. Additionally, glucocorticoids can be given to prevent adrenal suppression and help decrease conversion of T_4 to T_3. Ultimately, the patient will require thyroidectomy.

Myxedema coma is a rare, life-threatening condition marked by severe hypothyroidism. It requires aggressive treatment, as mortality may otherwise approach 40%. Initial therapy consists of IV T_4 (levothyroxine) and T_3 (triiodothyronine). This therapy must be administered carefully and in a closely monitored setting (such as an intensive care unit), as side effects may include arrhythmia and MI. Additional treatments consist of supportive measures including management of hypothermia, fluid resuscitation and electrolyte repletion, and empiric antibiotics for an underlying precipitant infection.

TABLE 18-4 lists medications used to treat thyroid conditions.

TABLE 18-4 Medications Used to Treat Thyroid Conditions

Medication Class	Examples
Antithyroid medications	Methimazole (Tapazole) or propylthiouracil
Thyroid hormone	Levothyroxine (L-Thyroxin, Levolet, Levo-T, Levothroid, Levoxyl, Novothyrox, Synthroid, Thyro-Tabs, or Unithroid), liothyronine (Cytomel), or liotrix (Euthroid or Thyrolar)
Beta blockers	Acebutolol (Sectral), atenolol (Tenormin), betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), carvedilol (Coreg), labetalol (Normodyne or Trandate), metoprolol (Lopressor or Toprol-XL), nadolol (Corgard), nebivolol (Bystolic), penbutolol (Levatol), pindolol (Visken), propranolol (Inderal), sotalol (Betapace), or timolol (Blocadren)

© Jones & Bartlett Learning.

Lipid Disorders

Lipid disorders cause a change in the production or use of cholesterol. They may also alter the way cholesterol is circulated or processed in the body. As a result, patients with lipid disorders experience very high total cholesterol levels; very low high-density lipoprotein (HDL), or “good,” cholesterol levels; or high triglyceride levels.

A lipid disorder increases the patient’s risk for atherosclerosis and heart disease, but is rarely a true medical emergency.

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) is an autoimmune disorder in which antibodies block certain phospholipid-binding proteins that normally protect the body from excessive coagulation. It was first recognized in patients with systemic lupus erythematosus (SLE), as the lupus anticoagulant is an antiphospholipid autoantibody. Now, however, APS is more commonly recognized as a primary condition. Patients with APS may experience venous or arterial thrombosis or fetal demise during pregnancy, and have laboratory evidence of antiphospholipid antibodies. Treatment focuses on preventing thrombotic events through the use of anticoagulants.

Metabolic Syndrome

Metabolic syndrome is a group of risk factors (hypertension, dyslipidemia, insulin resistance, hyperinsulinemia, glucose intolerance, and obesity, particularly central obesity) that together may lead to coronary artery disease, stroke, and type 2 diabetes. Although this syndrome is not widely understood, patients display the risk factors and predisposition for lipid disorders and, consequently, for heart disease.

Flight Considerations

Patients experiencing endocrine-related disorders require the same management in flight as during ground transport. No special management considerations apply when flying at altitude.

Summary

Although endocrine disorders are not a common cause for a critical care transport, an understanding of endocrine-related conditions and their pathophysiology will help the CCTP care for patients with these conditions. As always, it is important to ensure patients maintain appropriate blood glucose levels and hemodynamic parameters. An appreciation of AI, in particular, can help prevent patient death.

CASE STUDY

You are just finishing up your dinner after a relatively quiet shift when your dispatch center advises that you are being dispatched to Pondera Medical Center, approximately 95 miles (183 km) away. A patient there has been diagnosed with DKA and requires transport to your base hospital, Northern Rockies Medical Center, for further treatment in the intensive care unit. You and your partner, an EMT, depart for the rural hospital.

When you arrive at Pondera Medical Center, you are met by the attending physician. He advises you that the patient is a 28-year-old, 84-kg man who had been complaining of general malaise and increasing thirst for the past 3 to 4 days. The patient's family called 9-1-1 this morning when they found him with altered mental status. He was subsequently transported to Pondera Medical Center via BLS ambulance with a Glasgow Coma Scale (GCS) score of 8 (eye-opening score, 2; verbal score, 2; motor score, 4). On arrival, the patient's GCS score had increased to 12 (eye-opening score, 3; verbal score, 3; motor score, 6) and he was able to answer some questions appropriately but with difficulty. According to the family members, the patient is generally healthy, has no medical conditions, takes no medications, and has no allergies. They tell you it seems as if he has been drinking "a lot" of water over the past couple of days and has had to urinate excessively.

Treatment in the emergency department included a bedside glucose test that revealed high serum glucose concentration, laboratory studies including a complete blood cell count and comprehensive metabolic panel, and an electrocardiogram that was unremarkable. The patient has a 16-gauge IV catheter in his left forearm, currently running normal saline to keep the vein open. The patient has received two boluses of normal saline, with each bolus based on a rate of 20 mL/kg, and 10 units of IV regular human insulin, which decreased the blood glucose level to 580 mg/dL on recheck.

On admission, vital signs included the following: blood pressure, 89/42 mm Hg; heart rate, 132 beats/min; sinus tachycardia with no ectopy; clear respirations, 36 breaths/min with a Kussmaul respiration pattern; and oxygen saturation as measured by pulse oximetry, 96% on room air. Laboratory studies revealed the following abnormalities: glucose, 789 mg/dL; blood urea nitrogen, 60 mg/dL; creatinine, 2.0 mg/dL; chloride, 116 mEq/L; potassium, 5.5 mEq/L; and sodium, 151 mEq/L. A urinalysis was positive for ketones and glucose. Venous blood gases showed metabolic acidosis with a pH of 7.04; $PaCO_2$, 19 mm Hg; bicarbonate, 4 mEq/L; and base deficit of 12.

As your partner is securing the patient onto the stretcher and connecting him to your transport monitoring equipment for the return transport, you contact your base hospital physician to advise her of the patient's status, obtain any additional orders, and give an estimated time of arrival. The receiving intensivist has requested a continuous insulin infusion be initiated at 8.4 units/h, which she expects will decrease the blood glucose level by 50 mg/dL/h.

Once en route back to Northern Rockies Medical Center, you prepare an insulin infusion by adding 100 units of regular insulin to a 100-mL bag of normal saline and begin the infusion at 8.4 units/h, based on a rate of 0.1 unit/kg/h. Because of the patient's altered mental status, you elect to administer 4 mg of ondansetron IV as prophylaxis against vomiting and insert a 16 F nasogastric tube in the left nare. After approximately 20 minutes, you recheck the patient's blood glucose level using your glucometer and obtain a reading of 550 mg/dL. Once you arrive at Northern Rockies Medical Center, the patient is taken directly to the intensive care unit for continuing treatment.

1. How was the diagnosis of DKA determined?
2. Why was the patient given 3,360 mL of normal saline?
3. What are the potential complications that you may experience while en route with this patient?

Analysis

Because of your critical care training, you are able to recognize that this patient is experiencing DKA based on the presence of Kussmaul respirations, an elevated blood glucose reading, and arterial blood gas abnormalities. Symptoms of DKA include an elevated blood glucose level, acidosis, and an altered mental status. Signs include polydipsia, polyphagia, polyuria, and Kussmaul respirations.

This patient was given 3,360 mL of normal saline (20 mL/kg) in an attempt to hydrate him because of excessive fluid losses; the hypovolemia led to his tachycardia and hypotension. Short-acting insulin was administered in an attempt to decrease the blood glucose level. It is imperative not to decrease glucose levels too quickly in cases of DKA because of the possibility of cerebral edema. In an attempt to gradually decrease the glucose level, a continuous infusion of insulin was initiated, allowing the CCTP to accurately titrate the amount of insulin based on glucose level.

Ondansetron (Zofran) was given prophylactically to minimize the risk of aspiration resulting from decreased mental status.

This patient has the potential to experience several complications en route. The ground transport was 95 miles (183 km); with the patient’s decreased level of consciousness, the possibility of aspiration must be considered. Insertion of a nasogastric tube minimizes this risk, but the CCTP must still carefully monitor the patient’s airway. With any patient presenting with an altered mental status in the transport environment, CCTPs need to be aware of the possible need to perform definitive airway management, which is often difficult in the confined space of an ambulance. Furthermore, with continued administration of insulin, the possibility of inadvertent hypoglycemia may develop. Hypoglycemia can be recognized through vigilant monitoring of the patient’s blood glucose level and subsequently corrected by reducing the insulin infusion and administering dextrose-containing fluid based on local protocols. Close monitoring of the ECG, capnography, and pulse oximetry also provides rapid and early warning of changes in the patient’s condition.

PREP KIT

Ready for Review

- CCTPs should be familiar with the endocrine system and its function.
- The thyroid gland secretes thyroxine to regulate the body's metabolism and calcitonin to maintain normal calcium levels in the blood.
- The adrenal glands consist of the adrenal cortex, which produces corticosteroids, and the adrenal medulla, which produces catecholamines (the hormones epinephrine and norepinephrine).
- During stress, adrenocorticotropic hormone causes the adrenal cortex to secrete cortisol, which stimulates the body's cells to increase energy production.
- The adrenal cortex secretes aldosterone if blood pressure or volume drops, sodium level decreases, or potassium level increases. The aldosterone increases the reabsorption of sodium and water and releases potassium into the kidneys, thereby increasing circulating blood volume and, in turn, blood pressure.
- During the "fight-or-flight" response, the adrenal medulla secretes small amounts of norepinephrine and large amounts of epinephrine to enable the body to respond to a short-term emergency.
- The pancreas is both an endocrine gland and an exocrine gland. The exocrine component secretes digestive enzymes; the endocrine component comprises the islets of Langerhans.
- The main hormones secreted by the pancreas are glucagon and insulin, which regulate blood glucose levels. Insulin is the only hormone that decreases blood glucose levels; it is essential for glucose to enter and nourish the cells.
- Diabetes is a metabolic disorder in which the body's ability to metabolize glucose is impaired as a result of either insufficient production or inadequate utilization of insulin.

- There are two major types of diabetes mellitus: type 1 and type 2. Type 1 diabetes generally occurs in children, whereas type 2 diabetes commonly occurs in adults.
- Most patients with type 1 diabetes do not produce enough insulin. In patients with type 2 diabetes, the pancreas produces adequate insulin, but the body is not able to use it—a condition known as insulin resistance. Type 2 diabetes can also be caused by a deficiency in insulin production.
- Hypoglycemia, a drop in the blood glucose level, can develop rapidly in patients with diabetes, with alcoholism, following an ingested poison or certain drugs, or with other medical conditions such as cancer, liver disease, or kidney disease. If hypoglycemia persists, it can lead to seizure, coma, and death.
- Hyperglycemia, an increase in the blood glucose level to above the normal range, can have either a rapid or gradual onset. If left untreated, hyperglycemia may progress to diabetic ketoacidosis (DKA) or hyperosmolar hyperglycemic state (HHS), both of which are life-threatening conditions.
- Patients with DKA tend to be young—teenagers to young adults. The development of DKA usually progresses slowly, over a period of 12 to 48 hours, and can lead to dehydration and shock.
- HHS occurs principally in patients with type 2 diabetes. It is characterized by hyperglycemia, hyperosmolarity, and an absence of significant ketones.
- Signs of hypoglycemia may mimic those associated with intoxication. Patients presenting with signs of intoxication, such as slurred speech and lack of coordination, should be evaluated for hypoglycemia.
- Hyperglycemia and DKA typically present with the three Ps: polyuria, polydipsia, and polyphagia. The two hallmark signs of DKA are Kussmaul respirations and fruity-smelling breath.
- Signs of HHS are similar to those of DKA, except that patients with HHS do not typically present with Kussmaul respirations or fruity-smelling breath.

- CCTPs may test for hypoglycemia or hyperglycemia during transport. Knowledge of the glucometer being used is important for accurately interpreting the readings.
- Insulin infusions are routinely used in critically ill patients. The CCTP should check the patient’s blood glucose levels frequently using a blood glucometer and adjust the insulin infusion rate to maintain the blood glucose targets prescribed for the patient.
- Signs and symptoms of pituitary disorders commonly mirror those associated with other disease processes; a careful medical history and physical exam are key to identifying an underlying condition.
- The pituitary gland is divided into two lobes: the anterior pituitary and the posterior pituitary. The anterior pituitary produces and secretes six hormones; the posterior pituitary secretes two hormones, which it does not produce.
- Central diabetes insipidus, caused by a decrease in ADH secretion from the posterior pituitary gland, is characterized by polyuria and polydipsia, which lead to dehydration.
- Pituitary lesions are classified into two types: nonfunctioning adenomas and functioning adenomas. Nonfunctioning adenomas do not secrete hormones; with functioning adenomas, overproduction of hormones may occur.
- Acromegaly results from excessive secretion of growth hormone by the pituitary gland after the epiphyseal plate has closed. Gigantism results from excessive secretion of growth hormone by the pituitary gland before the epiphyseal plate has closed. Both conditions are characterized by growth of bones, muscles, and many internal organs at an abnormally fast rate, and both are usually caused by a benign pituitary tumor.
- Acromegaly and gigantism are managed with medications.
- Disorders of the adrenal glands may stem from genetic disorders, corticosteroid resistance, or hypersensitivity abnormalities.
- Pseudo-Cushing states comprise a mixed group of disorders related to increased cortisol production. They may be caused by

physiologic conditions, such as severe illness or intense aerobic exercise, or by nonphysiologic conditions, such as chronic alcoholism and obesity.

- Endocrine hypertension is a result of hormonal disorders that cause clinically significant hypertension. This condition is often related to overproduction of hormones by a tumor.
- Adrenal insufficiency (AI) is characterized by underproduction of cortisol and aldosterone, caused by decreased functioning of the adrenal cortex. This condition may be temporary or permanent, and it affects adults of all ages.
- In patients with chronic AI, signs and symptoms of addisonian crisis may appear suddenly as a result of an increased period of stress, trauma, surgery, or severe infection. If it goes undiagnosed, AI is potentially fatal.
- Addison disease is a chronic disorder caused by a deficiency in cortisol and/or aldosterone. Although it occurs in all age groups, young patients with Addison disease are at higher risk for premature death from this condition.
- Cushing syndrome is caused by prolonged exposure to elevated levels of cortisol in the body. A relatively rare condition, it typically affects patients ages 20 to 50 years. Excess cortisol affects many body systems, leading to hyperglycemia, muscle weakness, and bone weakness, among other signs and symptoms.
- A pheochromocytoma is a catecholamine-producing benign tumor of chromaffin cells. Most (95%) arise in the abdomen; the remaining 5% are found in other parts of the body. Most pheochromocytomas can be treated successfully by surgery to remove the tumor; if untreated, they can be fatal.
- Aldosteronism is a syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone. Two types are distinguished: primary and secondary.
- Primary aldosteronism (Conn syndrome) is caused by a tumor; most cases are benign. Secondary aldosteronism occurs as a

result of reduced renal blood flow, which stimulates hypersecretion of aldosterone.

- A low plasma renin activity blood test indicates primary aldosteronism; high plasma renin activity indicates secondary aldosteronism. Treatment for either condition consists of surgery or treatment of the underlying condition.
- Amyloidosis results from abnormal deposits of the protein amyloid in various tissues of the body. Primary amyloidosis is the most common form; secondary amyloidosis occurs as the result of another illness. There is no cure for amyloidosis, so treatments focus on managing the symptoms and limiting production of the amyloid protein.
- Transport of patients with a life-threatening disorder resulting from a thyroid abnormality is rare. Transport management for patients with thyroid conditions is mainly supportive.
- The thyroid gland is the primary controller of the body's metabolism; it produces the hormones T_3 and T_4.
- Hypothyroidism is caused by a deficiency of the hormones T_3 and T_4. Patients with hypothyroidism are at increased risk for acute myocardial infarction and stroke.
- Hyperthyroidism is caused by increased production of the hormones T_3 and T_4, or ingestion of exogenous thyroid replacement medication. Abnormal vital signs will commonly be more pronounced in the hyperthyroid patient compared to the hypothyroid patient, including tachycardia and hypertension.
- Thyrotoxicosis and thyroid storm are rare but severe, life-threatening events that can occur in patients with long-term, untreated hyperthyroidism. However, they are more commonly precipitated in hyperthyroid patients by an acute physiologic stressor.
- Myxedema coma is a rare, life-threatening clinical condition in patients with long-standing, severe, untreated hypothyroidism. It occurs most often in older female patients and can be fatal if untreated.

- Hashimoto disease, the leading cause of hypothyroidism, arises when the immune system attacks the patient’s thyroid gland. It most commonly affects women ages 30 to 50 years.
- Laboratory tests that evaluate thyroid function include serum thyroid-stimulating hormone, T_3, and T_4.
- Lipid disorders cause a change in the production or use of cholesterol. Such disorders rarely cause a true medical emergency, but do increase the patient’s risk for atherosclerosis and heart disease.
- Antiphospholipid syndrome (APS) is an autoimmune disorder in which antibodies block certain phospholipid-binding proteins that normally prevent excessive coagulation. Patients with APS may experience venous or arterial thrombosis, or fetal demise during pregnancy.
- Metabolic syndrome is a group of risk factors (hypertension, dyslipidemia, insulin resistance, hyperinsulinemia, glucose intolerance, and obesity, particularly central obesity) that together may lead to coronary artery disease, stroke, and type 2 diabetes.

Vital Vocabulary

ascromegaly A syndrome that results from excessive secretion of growth hormone by the pituitary gland after the epiphyseal plate has closed; characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate.

Addison disease A chronic hormonal or endocrine disorder caused by a deficiency of cortisol and/or aldosterone; characterized by weakness, fatigue, hypotension, unexplained weight loss, and darkening of the skin.

addisonian crisis The sudden appearance of symptoms, especially shock, in a patient with chronic adrenal insufficiency; it may appear suddenly as a result of an increased period of stress, trauma, surgery, or severe infection. Other symptoms include weakness, altered mental status, hyperthermia, and severe pain in the lower back, legs, or abdomen.

adrenal insufficiency (AI) Underproduction of cortisol and aldosterone caused by a decreased function of the adrenal cortex; it occurs when at least 90% of the adrenal cortex has been damaged.

aldosterone The main hormone responsible for adjustments to the final composition of urine; it increases the rate of active resorption of sodium and chloride ions into the blood and decreases the resorption of potassium.

aldosteronism A syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone; there are two main types—primary and secondary.

amyloidosis A group of diseases that result from abnormal deposits of the protein amyloid in various tissues of the body; can occur in a localized area or may be systemic.

antiphospholipid syndrome (APS) An autoimmune disorder in which antibodies block certain phospholipid-binding proteins that normally protect the body from excessive coagulation.

central diabetes insipidus A condition caused by a decrease in ADH secretion from the posterior pituitary gland; characterized by polyuria and polydipsia, which lead to dehydration.

Cushing syndrome A condition caused by overproduction of cortisol by the adrenal glands or by excessive use of cortisol or other similar steroid (glucocorticoid) hormones; also known as hypercortisolism.

diabetes mellitus A metabolic disorder in which the pancreas's ability to metabolize simple carbohydrates (glucose) is impaired because of either inadequate production of insulin or insensitivity to circulating insulin.

diabetic ketoacidosis (DKA) A form of acidosis in uncontrolled diabetes in which certain acids accumulate in the body when insulin is not available.

endocrine hypertension Significant high blood pressure caused by a hormonal disorder; often related to excess hormone produced by a tumor.

functioning adenoma A type of pituitary lesion in which overproduction of hormones occurs.

gigantism A syndrome that results from excessive secretion of growth hormone by the pituitary gland before the epiphyseal plate has closed; characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate.

Hashimoto disease A condition that occurs when the immune system attacks the patient's thyroid gland and that is the leading cause of hypothyroidism; also known as chronic lymphocytic thyroiditis.

hyperglycemia A condition in which the blood glucose concentration exceeds the normal range (70 to 100 mg/dL).

hyperosmolar hyperglycemic state (HHS) A metabolic disorder that occurs principally in patients with type 2 diabetes, and is characterized by hyperglycemia, hyperosmolarity, and the absence of significant ketosis; also known as hyperosmolar hyperglycemic nonketotic syndrome (HHNS).

hyperthyroidism A condition caused by increased production of T_3 (triiodothyronine) and T4 (thyroxine) from the thyroid gland, resulting in an increase in the body's organ function; characterized by an increase in body temperature, gradual weight loss, increased and/or irregular heart rate, sweating, and irritability.

hypoglycemia A condition in which blood glucose drops below the normal range (70 to 100 mg/dL) and, in people without diabetes, is accompanied by signs and symptoms.

hypothyroidism A condition caused by a deficiency of T_3 (triiodothyronine) and T_4 (thyroxine) from the thyroid gland, resulting in a slowing of the body's organ function; characterized by a decrease in body temperature, gradual weight gain, and increased risk for acute myocardial infarction and stroke.

insulin resistance A condition in which the pancreas produces enough insulin but the body cannot effectively use it.

lipid disorders A group of disorders that cause a change in the production or use of cholesterol and may also alter the way cholesterol circulates or is processed in the body.

metabolic syndrome A group of risk factors that together may lead to coronary artery disease, stroke, and type 2 diabetes; usually related to a predisposition to a lipid disorder.

myxedema coma A rare, life-threatening condition that can occur in patients who have severe, untreated hypothyroidism, and that is characterized by altered mental status and lethargy, failure of the thermoregulatory system, and a precipitating event; may be accompanied by auditory and visual hallucinations, seizures, or unresponsiveness.

nonfunctioning adenoma A type of pituitary lesion in which the tumor does not secrete any hormones.

pheochromocytoma A catecholamine-producing benign tumor of chromaffin cells located in the center of the adrenal gland, which can occur either sporadically or chronically as a result of genetic risk factors; it causes stimulation of alpha-adrenergic and beta-adrenergic receptors, resulting in hypertension, increased cardiac contractility, glycogenolysis, gluconeogenesis, intestinal relaxation, and increased heart rate.

polydipsia Excessive thirst, resulting in excessive intake of fluid.

polyphagia Excessive desire to eat, resulting in overconsumption of food.

polyuria Frequent and plentiful urination.

primary aldosteronism A type of aldosteronism usually caused by a tumor on a single adrenal gland that overproduces aldosterone; also known as Conn syndrome.

primary amyloidosis The most common form of amyloidosis, affecting the heart, kidneys, tongue, nerves, and intestines; the form of amyloid deposited in this disease is classified as apolipoprotein.

pseudo-Cushing state A condition in which a person has higher cortisol levels from a cause other than actual Cushing syndrome—for example, depression, alcoholism, malnutrition, or panic attack.

secondary aldosteronism A type of aldosteronism that occurs as a result of reduced renal blood flow, which stimulates hypersecretion of aldosterone; it can be caused by obstructive renal artery disease, renal vasoconstriction, and edematous disorders.

secondary amyloidosis A form of amyloidosis that occurs as a result of another illness, and that primarily affects the kidneys, spleen, liver, and lymph nodes; the form of amyloid deposited in this disease is classified as amyloid A protein.

thyroid storm A rare but severe, life-threatening form of thyrotoxicosis that can occur in patients with long-term, untreated hyperthyroidism, but is more commonly precipitated in hyperthyroid patients by an acute physiologic stressor such as a recent surgery, trauma, infection, administration of large doses of iodine, or abrupt discontinuation of thyroid medications.

thyrotoxicosis An excess of thyroid hormones resulting in a hypermetabolic crisis, including tachycardia, hyperthermia (sometimes with a body temperature greater than 103.9°F [39.9°C]), coma with agitation, nausea, vomiting, diarrhea, unexplained jaundice, pulmonary edema, and elevated thyroxine level; severe cases are known as thyroid storm.

type 1 diabetes An endocrine disease that usually starts in childhood and requires daily injections of supplemental insulin to control blood glucose; sometimes called juvenile or juvenile-onset diabetes.

type 2 diabetes An endocrine disease that usually starts later in life and often can be controlled through diet and oral medications; sometimes called adult-onset diabetes.

CHAPTER 19

Environmental Emergencies

David Fifer, MS, NRP, FAWM
Michael Murphy, RN, CEN, EMT-P

OBJECTIVES

After completing this chapter, you will be able to:

1. Discuss risk factors for environmental emergencies (p 1012).
2. Describe the process of thermoregulation, including the concepts of thermogenesis and thermolysis (p 1012).
3. Explain the process of heat transfer, including radiation, conduction, convection, evaporation, and absorption (p 1014).
4. Discuss signs, symptoms, and transport management of heat cramps (p 1016).
5. Discuss signs, symptoms, and transport management of heat syncope (p 1018).
6. Discuss signs, symptoms, and transport management of heat exhaustion (p 1019).
7. Discuss signs, symptoms, and transport management of heatstroke (p 1020).
8. Discuss signs, symptoms, and transport management of frostbite (p 1024).
9. Discuss signs, symptoms, and transport management of hypothermia (p 1026).
10. Discuss signs, symptoms, and transport management of drowning (p 1028).
11. Discuss signs, symptoms, and transport management of diving injuries (p 1029).
12. Explain the purpose of hyperbaric therapy and when it might be used (p 1030).
13. Discuss signs, symptoms, and transport management of altitude illness (p 1032).
14. List flight considerations relating to environmental emergencies (p 1034).

Introduction

Environmental emergencies are medical conditions caused or worsened by the weather, terrain, or unique atmospheric conditions. People may experience severe illness from environmental conditions in a vast array of locations and situations. Heat, cold, submersion, and decompression illnesses can occur in remote wilderness locations, major urban metropolitan areas, and any place in between. People who are used to harsh environmental conditions frequently survive environmental extremes far better than at-risk people (such as older adults, homeless individuals, and people with substance use disorders). The list of potential scenarios creating an environmental emergency is seemingly endless, regardless of geographic region.

The critical care transport professional (CCTP) often sees patients who have experienced environmental emergencies during critical care transports between facilities. Many preexisting medical and social factors predispose patients to critical illness created or exacerbated by environmental stressors. The challenge for CCTPs is to recognize those patients who are more susceptible to environmental exposure in unexpected conditions. To provide patients with the optimal chance for recovery, it is essential that CCTPs continue or initiate many critical interventions during patient transport.

Risk Factors

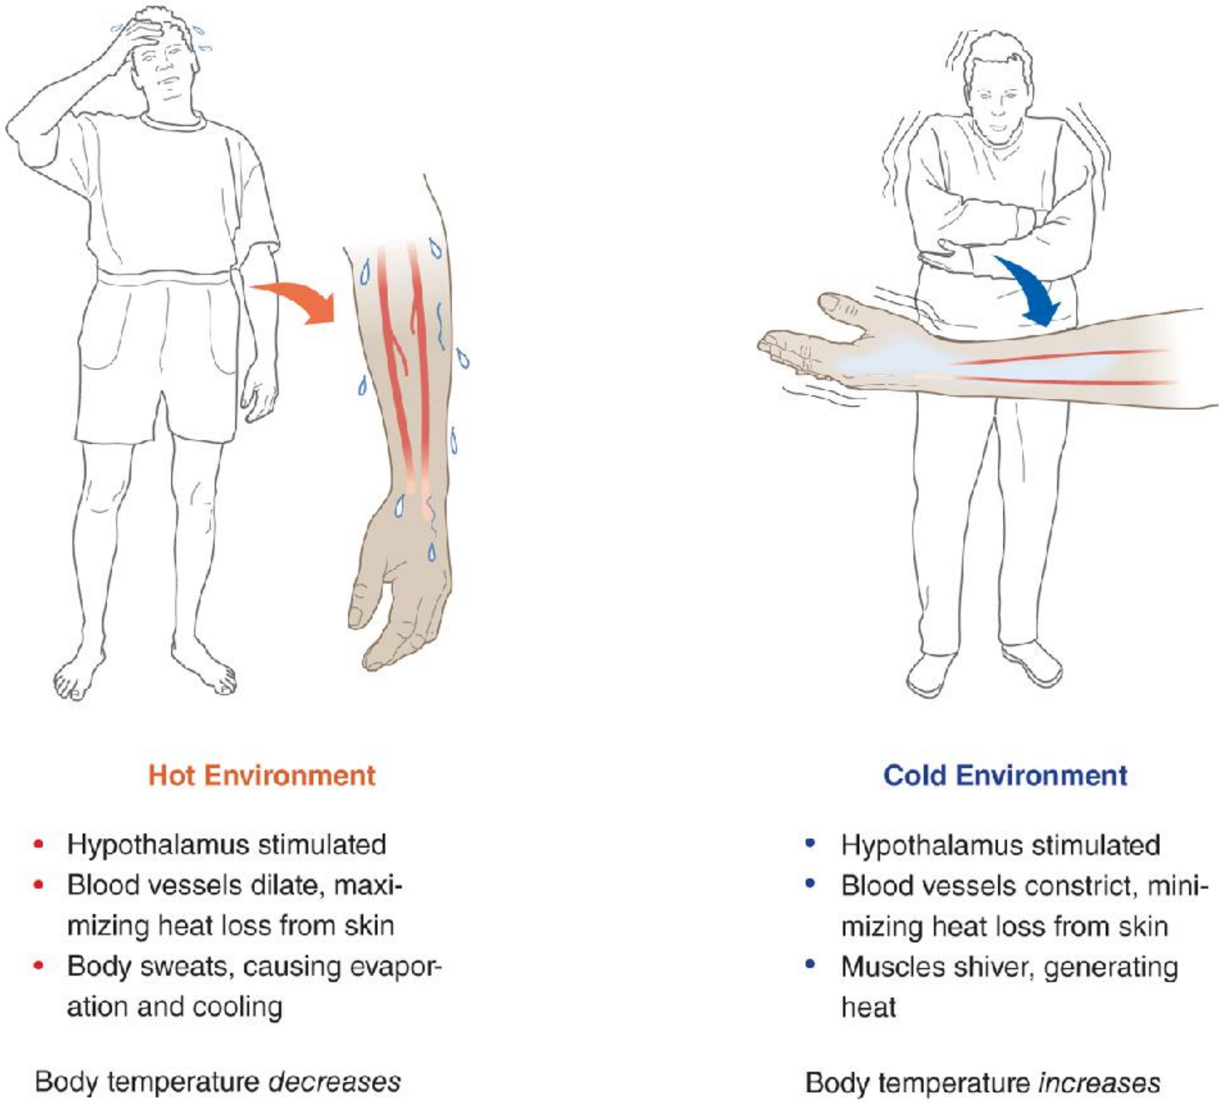
Risk factors that predispose people to environmental emergencies include extremes of age (young and old), taking certain medications, and being in a poor state of health. Specifically, environmental factors can be worsened in people with diabetes, cardiovascular disease, restrictive lung disease, thyroid disease, and psychiatric illnesses.

Thermoregulation

The body's ability to acclimatize—that is, to adjust to a changing environment—is part of the homeostatic process. **Thermoregulation** refers to the body's natural ability to ensure and maintain a balance between heat production (**thermogenesis**) and heat elimination (**thermolysis**). This process is governed by the brain.

The **hypothalamus** is located in the most inferior portion of the diencephalon, making up the portion of the brain between the cerebrum and the brainstem. Through the **hypothalamo-hypophysial portal system**, the hypothalamus sends stimulating or inhibiting factors to the pituitary gland. This interaction, which is referred to as the **hypothalamic-pituitary axis**, results in, respectively, an increase or a decrease in metabolism throughout the body.

The hypothalamus serves as the body's "master thermostat" through negative feedback control. A rise in the core body temperature elicits signals to shut off thermogenesis pathways and increase the activity of heat loss mechanisms; a fall in the core body temperature prompts heat production and limits the actions of thermolysis mechanisms **FIGURE 19-1**. In the preoptic area of the hypothalamus, heat-sensitive neurons fire more rapidly when the body senses an increase in temperature. In the posterior hypothalamus, signals from the preoptic area combine with signals from the remainder of the body to cause a compensating heat loss, which seeks to restore the body's temperature to a tolerable range.



Hot Environment
Hypothalamus stimulated
Blood vessels dilate, maximizing heat loss from skin
Body sweats, causing evaporation and cooling
Body temperature *decreases*
Cold Environment
Hypothalamus stimulated
Blood vessels constrict, minimizing heat loss from skin
Muscles shiver, generating heat
Body temperature *increases*

FIGURE 19-1 The hypothalamus notes a rise or fall in core body temperature and elicits responses to regulate it.

© Jones & Bartlett Learning.

Description

This hypothalamus-driven negative feedback system cannot work properly without input from a network of complementary detectors that are sensitive to temperature changes. Cold sensors are located predominantly in the skin, spinal cord, and other areas that are sensitive to the cold end of the temperature spectrum. They respond to excess cooling by transmitting neural action potentials to the hypothalamus; these halt the heat-reducing signals. The goal is to maintain a constant core body temperature within one degree of 98.6°F (37°C).

The negative feedback system has three major components:

- Temperature receptors
- Effector organ systems
- Integrator or controller

The majority of temperature receptors are found in the papillary layer of the dermis, throughout widespread areas of the body. These exteroceptors respond to external stimuli affecting the skin directly. Areas populated by nerves (spots) respond to hot or cold stimuli, with cold spots being more numerous. Receptors are nerve endings that act as transducers, converting one form of energy into nerve impulses. These impulses are then sent along afferent nerves, including the lateral spinothalamic tract, to the diencephalon. The subsequent neural processing stimulates motor nerves and peripheral pathways to activate the effector organ systems. Based on the types of messages they receive, muscles may then contract or relax, blood vessels may constrict or dilate, and glands may secrete hormones. These impulses are coordinated as necessary by the specific integrator or controller based on information already stored in that integrator or controller (such as the “normal” body temperature of 98.6°F [37°C]).

Through these collective actions, the hypothalamic “thermostat” reduces excesses in body heat. Three major mechanisms play key roles in the heat-reducing process:

- Blood vessels in the skin dilate, resulting in eight times as much heat transfer to the skin’s surface.
- Perspiration is increased at a ratio of 10 times the normal perspiration for each degree of temperature increase.
- Increases in muscle activity, including shivering, are inhibited.

In contrast, in response to cold, three other regulatory processes increase body heat:

- Stimulation of the posterior hypothalamus causes a constriction of blood vessels.
- Hypothalamic stimulation of the primary motor center in the posterior hypothalamus stimulates the brainstem, spinal cord, and motor neurons to ultimately cause muscle activity, including shivering.
- The hypothalamic stimulation of piloerector muscles causes minimal production of heat and the visible sign of goosebumps and prompts the body hair to “stand on end.”

CCTPs should consider the specific needs of their patients and how the dynamics of the transport environment, such as flight altitudes, may impact thermodynamics. Neonates and pediatric patients in particular pose unique challenges, as discussed in Chapter 23, *Neonatal Emergencies*, and Chapter 24, *Pediatric Emergencies*.

Basal Metabolic Rate

At rest, the body’s chief source of heat production is the metabolism of nutrients. The heat produced at rest from normal metabolic reactions, including breathing, circulation, and digestion, is referred to as the **basal metabolic rate (BMR)**. It represents the number of calories metabolized per square inch of body surface area per hour and can be thought of as the minimal requirement to sit still all day long. In fact, BMR represents nearly 70% of the energy demands of a sedentary individual. Calculation of the BMR requires fairly sophisticated laboratory equipment. This rate provides useful information in specialized clinical settings, such as studies in endocrinology and metabolism. The average BMR of a 154-lb (70-kg) adult is approximately 60 to 70 kcal/h. A brisk walk can increase this rate to 300 kcal/h.

The largest determination of BMR is the individual's **fat-free mass (FFM)**. The FFM is the proportion of body mass that consists of tissues other than adipose tissue, and that therefore consume calories. The BMR can also be greatly affected by age, sex, stress, hormones, underlying conditions, pharmaceuticals, supplements, and body surface area. As the ratio of body surface area to body volume increases, heat loss increases. Thus, the shorter of two persons with the same weight will lose heat at a faster rate. This relationship is most relevant to pediatric patients, who have a very high surface area to body volume ratio and are most susceptible to heat loss.

Heat Transfer

Heat produced by metabolism and glycogen breakdown is used to warm the body and maintain the core body temperature. Excess heat must be eliminated. Usually this elimination is accomplished through the temperature gradient between the body and the immediate surrounding environment. The body transfers heat to the surrounding environment through five primary mechanisms:

- **Radiation**—the transfer of heat through electromagnetic waves
- **Conduction**—the transfer of heat through direct contact with a cooler object
- **Convection**—the loss of heat carried away from the body by currents of air or water
- **Evaporation**—the loss of heat carried away as a liquid is converted to a gas
- **Respiration**—the loss of heat as warm air in the lungs is exhaled into the atmosphere and cooler air is inhaled

If the surrounding environment is hotter than the body, the body gains heat through **absorption**. Convection and radiation cease as ambient temperatures reach or exceed skin temperatures. The humidity of the immediate environment can affect thermoregulation as well. A healthy adult can sweat up to about 1 L/h (although not for very long), but if the humidity in the surrounding air is more than 75% to 80%, the evaporative process is impaired.

When placed in a cold environment, the body shifts to thermogenesis. This process is mainly controlled by increases in BMR and can be enhanced through physical exertion. The sympathetic nervous system increases muscle tone and initiates shivering to produce more kilocalories per hour for the immediate needs of the body. The thyroid is stimulated to meet the increased heat-production needs. The hypothalamus stimulates peripheral vasoconstriction, sweating stops, and blood is shunted toward the core.

In very cold temperatures, heat loss occurs through the process of respiration. When cold air is inhaled, it is warmed by the body and then exhaled, causing heat loss.

Expecting the Unexpected

A patient need not be found in the desert or a snowbank to have a temperature-related emergency. For example, patients with a spinal cord injury may have a disruption in the negative feedback loop and, therefore, a disruption of thermoregulation. CCTPs must be cognizant of these patients’ inability to self-regulate body temperature and take the necessary external steps to maintain warmth or prevent overheating.

Heat Emergencies

Heat illness occurs when core body temperature increases as a result of inadequate thermolysis. According to the US Centers for Disease Control and Prevention, heat-related illness is a major public health concern, with the United States averaging more than 700 heat-related deaths each year from 2004 to 2018. CCTPs in all geographic regions should be prepared to transport patients experiencing heat-related illnesses.

Risk Factors

Factors that contribute to how heat affects the body **TABLE 19-1** include the person's general state of health, age, use of certain medications **TABLE 19-2**, amount of clothing, mobility, and surroundings.

TABLE 19-1 **Factors That Predispose Individuals to Heat Illness**

Factors That Increase Internal Heat Production	Factors That Interfere With Heat Dissipation

Factors That Increase Internal Heat Production	Factors That Interfere With Heat Dissipation
Physical exertion Response to infection (fever) Hyperthyroidism Agitated and tremulous states (eg, Parkinson disease, psychosis, mania, drug withdrawal—opiate and alcohol) Drug overdoses (eg, sympathomimetics, cocaine, caffeine, lysergic acid diethylamide, phencyclidine hydrochloride, methamphetamine, and 3,4-methylenedioxy-amphetamine)	High ambient temperature High humidity Obesity (insulation effect, and less efficient dissipation) Impaired vasodilatation Diabetes Alcoholism Drugs: diuretics, tranquilizers, beta blockers, antihistamines, and phenothiazines Impaired ability to sweat (as in cystic fibrosis, skin diseases, and healed burns) Heavy or tight clothing
Factors That Increase Heat Absorption	**Factors That Impair the Body's Response to Heat Stress**
Confined, unventilated, hot living quarters Working in hot conditions (eg, bakeries, steel mills, and construction sites) Being in parked motor vehicles in the summer	Dehydration Prior heatstroke Hypokalemia Cardiovascular disease Previous stroke or other central nervous system lesion

© Jones & Bartlett Learning.

TABLE 19-2 Substances That Contribute to Heat Illness

Alcohol
Alpha agonists
Amphetamines

Anticholinergic medications (eg, atropine sulfate, scopolamine, benztropine mesylate, belladonna, and synthetic alkaloids)
Antihistamines
Antiparkinsonian agents
Antipsychotics (such as haloperidol)
Beta blockers
Calcium channel blockers
Cocaine
Diuretics (eg, furosemide, hydrochlorothiazide, and bumetanide)
Heroin
Laxatives
Lithium
Lysergic acid diethylamide
Monoamine oxidase inhibitors
Phencyclidine hydrochloride
Phenothiazines (eg, prochlorperazine, chlorpromazine, and promethazine)
Sympathomimetic medicines (eg, amphetamines, epinephrine, ephedrine, cocaine, and norepinephrine)
Thyroid agonists (eg, levothyroxine)
Tricyclic antidepressants (eg, amitriptyline, imipramine, nortriptyline, and protriptyline)

© Jones & Bartlett Learning.

Medications can cause or contribute to heat illness through a variety of mechanisms. Medications that depress the central nervous system (CNS), such as alcohol and barbiturates, impair a person's ability to properly dissipate heat generated within the body. Many CNS depressant medications can cause heat illness or hyperthermia.

Stimulant medications promote increased muscle activity and metabolism, causing increased thermogenesis. Cocaine, amphetamines, and other sympathomimetic medications may lead to hyperthermia through this mechanism. When heat dissipation mechanisms cannot compensate for the increase in heat production, the result will be hyperthermia.

Any medication that interferes with cardiovascular performance will undermine the body's ability to dissipate heat. Beta blockers, calcium channel blockers, and diuretics all interfere with heat loss, causing or worsening hyperthermia. Diuretics further complicate heat illness by limiting the fluid volume available for evaporative cooling (sweating).

Medications that impair sweating, such as antihistamines, tricyclic antidepressants, and other anticholinergics, compromise this essential thermoregulatory mechanism—another factor leading to heat illness. Other specific medication-related causes of hyperthermia or heat illness include neuroleptic malignant syndrome and malignant hyperthermia, which are discussed further in Chapter 21, *Toxicologic Emergencies*.

If thermoregulation mechanisms fail or become taxed beyond their limits, the core body temperature will rise dramatically and quickly. Indeed, it can rise to 106°F (41.1°C) or more in less than 15 minutes. Older persons are particularly at risk for rapid increases in body temperature. As a result of underlying illness and other metabolic changes, they often do not acclimatize well. Specifically, they may perspire less, feel thirst more slowly, have difficulty swallowing, and have decreased mobility (making it more difficult just to reach a glass of water). They are also more likely to be taking medications that can alter or impede thermoregulation.

Among young and healthy populations, children exposed to hot environments are most vulnerable to heat stressors. Compared with adults, children have higher rates of metabolism and do not dissipate heat as well. Infants and young children are completely dependent on others to provide the proper thermal environment. Covering them with excessive blankets or bedding, prolonged confinement in hot vehicles, and other lapses in environmental control place infants and young children at serious risk for heat-related injury.

Physical exertion in a warm environment can lead to hyperthermia, including a serious thermoregulatory emergency called **exertional heatstroke**. Exertional heatstroke is influenced by exercise intensity, environmental conditions, clothing, equipment, and individual health factors. It is normal for body temperature to rise during exercise when muscle-generated heat accumulates faster than heat dissipates. Heat production during intense exercise is 15 to 20 times greater than at rest, and can raise core body temperature by 1.8°F (1°C) every 5 minutes if no heat is removed from the body. Exertional heatstroke is a life-threatening condition with a high mortality rate if not promptly recognized and treated with aggressive whole-body cooling.

Adolescent athletes are at high risk for heat-related illness, and exertional heatstroke is a leading cause of death among high school athletes in the United States. Older children may elect to continue strenuous activities in hot or humid environments without understanding the risks or symptoms of heat-related illness or the importance of adequate hydration.

Heat Cramps

Heat cramps are involuntary muscle pains, usually in the abdomen, lower extremities, or both. Although the cause is not well understood, they are thought to result from electrolyte depletion caused by profuse sweating. They usually affect healthy persons who are overexerting their bodies in a hot environment. Generally, people recognize this problem and instinctively move to a cooler place and replenish fluids. However, if the person sweats profusely and drinks only water, the electrolyte loss has not been resolved, and cramps may continue. In addition, a person may attempt to quench thirst by drinking excessive amounts of water without appropriate sodium replacement, leading to dilutional hyponatremia.

Heat cramps result from an imbalance of water and sodium, and may not always be accompanied by hyperthermia. If a patient also has some degree of heat exhaustion, heatstroke, or significant hyperthermia, additional cooling measures may be required.

Treatment

The treatment for heat cramps is largely supportive: Patients should be removed from the hot environment, lie supine if they feel faint, and be instructed to drink a salt-containing liquid or electrolyte drink (if not at risk for aspiration) **FIGURE 19-2**. As the patient’s salt balance is restored, the symptoms will abate. If symptoms continue, the underlying cause should be sought, and the patient should be rapidly transported to the emergency department (ED). It is unlikely that patients will require critical care transport for heat cramps unless they have a significant degree of hyponatremia or some form of hyperthermia accompanies the heat cramps. Significant heat cramps, refractory to oral electrolyte replacement, may be managed with the administration of 1 to 2 L of intravenous (IV) isotonic fluid. To avoid contributing to hyponatremia, CCTPs should use caution before administering large volumes of IV fluids in these patients, especially in the absence of thorough patient evaluation or laboratory studies.

FIGURE 19-2 Give the patient experiencing heat cramps one or two glasses of a salt-containing solution if the person is not nauseated and there is no risk of aspiration.

Courtesy of Rhonda Hunt.

Signs and Symptoms

Heat Cramps

- Involuntary muscle pain, usually in the abdomen or lower extremities
- Profuse sweating

Differential Diagnosis

Heat Cramps

- Heat exhaustion
- Heatstroke
- Musculoskeletal trauma (such as sprains or strains)
- Electrolyte abnormality
- Autoimmune disease
- Medication side effect or medication withdrawal symptoms

Transport Management

Heat Cramps

- Remove the patient from the hot environment.
- Place the patient in a supine position.
- If there is no risk of aspiration, give the patient a drink containing salt.
- Consider administering 1 to 2 L of IV isotonic fluid; use caution if there is a possibility of hyponatremia.

Dilutional Hyponatremia

The normal process of homeostasis enables the body to balance intake against output. In general, an average adult takes in about 0.5 to 1 gallon (2 to 3 L) of fluid, from both food and beverages, throughout an average day. Human kidneys can excrete up to 15 to 20 L of **free water** (water that is not bound to molecules in the body) each day or up to 800 to 1,000 mL/h. When a euvolemic patient (one with normal blood volume) consumes or receives more hypotonic free water than the kidneys can excrete, the conditions for hyponatremia (abnormally low serum sodium) are present.

Dilutional hyponatremia—sometimes called overhydration or, colloquially, **water intoxication**—occurs when the normal osmotic balance of sodium in the body is pushed outside of safe limits by overconsumption of hypotonic free water. Due to its hypotonicity, the excessive quantity of water diffuses across the cellular membrane in tissues throughout the body, causing cells to swell as sodium levels are diluted.

Of particular concern is **exercise-associated hyponatremia (EAH)**, which is defined clinically as a serum sodium concentration of less than 135 mmol/L occurring within 24 hours of sustained physical activity, typically lasting 4 hours or longer. This condition is commonly experienced by participants in physically demanding activities, often in combination with an environmental factor, such as endurance competitions, hiking, or climbing. For example, various studies have found that the incidence of EAH among marathon runners is as high as 28%, and as high as 38% among triathletes.

While much more common in hot weather, EAH can also occur in cold climates, as its primary mechanism is simply fluid consumption that exceeds fluids lost. It can occur during cooler weather and short durations of activity as individuals drink to quench thirst while not necessarily losing significant amounts of fluid through perspiration or exhalation.

The secretion of arginine vasopressin, also known as antidiuretic hormone (ADH), is believed to play a role in EAH. Stimuli resulting from exertion (eg, pain), psychological stress, hypoglycemia, and elevated temperatures can all trigger the secretion of ADH, which inhibits urination, leading to retention of water. Nonsteroidal anti-inflammatory drugs such as aspirin, ibuprofen, and naproxen also stimulate ADH production and are often consumed by individuals who engage in physical activities. The loss of sodium through sweat may play a role in EAH as well, though this mechanism is controversial.

Fortunately, most cases of EAH are asymptomatic. Generally, individuals do not exhibit significant signs or symptoms until serum sodium concentration falls below 130 mmol/L, or decreases 7% from their normal baseline. Symptoms, when they occur, are typically mild and include weakness, dizziness, peripheral edema, headache, lethargy, and nausea and vomiting. A key sign of EAH in the context of extended endurance activities is a significant weight gain (ie, typically exceeding 6.6 pounds [3 kg]) from the start of the event until its completion. Severe signs and symptoms may include mental status changes and seizures stemming from cerebral edema, as well as pulmonary edema. Deaths are rare but do occur.

Treatment

Patients suffering from mild hyponatremia are generally treated with restriction of hypotonic fluids and consumption of salty oral solutions. Patients with moderate to severe hyponatremia typically receive infusions of IV hypertonic saline, such as 3% sodium chloride. In some instances, 8.5% sodium bicarbonate may be used. For severe hyponatremia, 3% hypertonic saline is typically administered in 100-mL aliquots bolused over 10 minutes and titrated to clinical improvement (up to 300 mL total), because overcorrection of serum sodium can itself have devastating effects on the brain. For moderate hyponatremia, an infusion of 3% sodium chloride at 0.5 to 3 mL/kg/h may be administered. Generally, an increase of only 4 to 6 mmol/L serum sodium will correct symptoms.

CCTPs may be involved in the maintenance or administration of these fluids. They may also need to administer benzodiazepines to patients experiencing seizures secondary to EAH or provide supportive care to patients in a coma resulting from especially profound cases. In addition, CCTPs may be called on to obtain point-of-care blood samples using i-STAT or similar devices to determine treatment end points.

Signs and Symptoms

Dilutional Hyponatremia

- Weakness
- Dizziness
- Peripheral edema
- Headache
- Lethargy
- Nausea and vomiting
- Mental status changes
- Seizures
- Pulmonary edema

- Weight gain

Differential Diagnosis

Dilutional Hyponatremia

- Heat exhaustion
- Hyperglycemia
- Mannitol overdose
- Hyperlipidemia
- Hyperproteinemia

Transport Management

Dilutional Hyponatremia

- Restrict hypotonic fluids and encourage consumption of salty oral solutions.
- For more severe hyponatremia, consider administration of IV hypertonic saline.

Heat Syncope

Heat syncope is an episode of collapse or near collapse, followed by immediate return to complete consciousness, that typically occurs in a non-acclimatized person. It is often seen at outdoor events where crowds are standing for long periods. Heat syncope is also common in outdoor settings when a person stands suddenly after sitting or lying on the ground for an extended period. Peripheral vasodilation, possibly exacerbated by some degree of dehydration, is theorized to be the cause of this condition.

To treat a person with heat syncope, place the patient supine and elevate the legs to auto-transfuse blood volume from the lower extremities; this effect is brief and transient, but effective if the person's volume status is normal. Move the patient to a cooler environment and allow fluid intake. If the patient does not recover rapidly, suspect heat exhaustion. If the patient exhibits CNS dysfunction, suspect heatstroke. Many other conditions can cause syncope, so the CCTP should consider a wide range of differential diagnoses and rule out underlying conditions such as cardiac arrhythmias.

Signs and Symptoms

Heat Syncope

- Postural hypotension from vasodilation
- Volume depletion
- Syncopal episode
- Subjective or documented hyperthermia

Differential Diagnosis

Heat Syncope

- Heat exhaustion
- Heatstroke
- Vasovagal syncope
- Cardiovascular dysfunction
- Psychogenic syncope
- Seizure
- Dehydration
- Pseudosyncope

Transport Management

Heat Syncope

- Place the patient supine and elevate the legs.
- Provide fluids.
- Remove the patient from the hot environment.

- Manage the ABCs (airway, breathing, and circulation) as clinically indicated.

Heat Exhaustion

Heat exhaustion is a clinical syndrome representing a moderate form of heat illness on the heat emergencies continuum. Two classic forms of this syndrome are recognized: water depleted and sodium depleted.

Water-depleted heat exhaustion primarily occurs in older adults. Age-related immobility, decreased thirst sensitivity, and medications that contribute to dehydration are suspected culprits. This condition may also occur in active younger workers and in athletes who do not adequately replenish fluids during activities in a hot environment.

Sodium-depleted heat exhaustion results from excessive losses of sodium through sweating and may take hours to days to develop. When a person sweats but replenishes their internal fluids only with water, the sodium is not replaced. This condition shares many characteristics with dilutional hyponatremia but is associated with excessive consumption of hypotonic water in a short time.

Symptoms of heat exhaustion include weakness, headache, fatigue, dizziness, nausea, vomiting, and abdominal cramps. Transient syncope may also be present, but any true alteration in neurologic status would be considered heatstroke. Profuse sweating and pale, clammy skin are generally seen. Heart rate and respirations are typically elevated. Tachypnea may lead to signs of hyperventilation syndrome: carpopedal spasm, perioral numbness, and a lowered end-tidal carbon dioxide ($ETCO_2$) level. In heat exhaustion, the patient's core body temperature typically ranges from 100.4°F (38°C) to 104°F (40°C), although it is also possible for core body temperatures to remain normal. The blood pressure (BP) may be low owing to peripheral pooling or volume depletion. Orthostatic hypotension will generally be present. The patient may report having darker, brown urine, which suggests rhabdomyolysis. If left untreated, heat exhaustion may completely compromise a patient's thermoregulatory ability and may progress to heatstroke.

Treatment

Treatment of heat exhaustion is aimed at rehydrating the patient, replacing electrolytes, and, most importantly, facilitating physical rest and heat dissipation. Move the patient to a cooler environment, remove excess clothing, and place the patient supine with the legs elevated. Oral rehydration with sports drinks may be appropriate if nausea is not present.

Consider obtaining blood samples for electrolyte analysis, as well as administering IV fluids to patients who appear volume depleted and who cannot tolerate oral rehydration due to nausea or vomiting. As cooling occurs, fluids distributed throughout the body may return to the intravascular space, improving intravascular fluid volume. Administer fluids based on measurable signs of volume status, such as BP, heart rate, skin turgor, and urine output.

Closely monitor the electrocardiogram (ECG) for signs of electrolyte-induced arrhythmia. Heat illness can cause multiple electrolyte disturbances, including hyponatremia, hypocalcemia, and hypomagnesemia, which may result in ECG changes. Rhabdomyolysis, if present, may cause the release of excess potassium as muscle tissue is destroyed. Hyperkalemia may result in tall, peaked T waves on the ECG. Exertional hyponatremia may lead to a relative increase in the calcium level. Finally, monitor vital signs, body temperature, and $ETCO_2$.

Techniques such as misting the patient with water, covering the patient with sheets soaked in ice water, and immersing the patient in cold water can effectively dissipate heat (to varying extents) but are not necessary unless the patient is experiencing CNS impairment. If such signs are present, the condition is more likely to be heatstroke, not heat exhaustion, and aggressive whole-body cooling would then be indicated. In general, simply allowing patients with heat exhaustion to rest and cool down, using intuitive methods while rehydrating orally, is sufficient.

Signs and Symptoms

Heat Exhaustion

- Headache
- Fatigue
- Dizziness
- Nausea
- Vomiting
- Abdominal cramps
- Profuse sweating
- Pale, clammy skin
- Elevated heart rate and respirations
- Carpopedal spasm
- Perioral numbness
- Lowered $ETCO_2$ level
- Normal or elevated skin temperature
- Low BP
- Darker, brown urine

Differential Diagnosis

Heat Exhaustion

- Cardiac insufficiency
- Influenza
- Heatstroke

Transport Management

Heat Exhaustion

- Move the patient to a cooler environment.
- Remove excess clothing.
- Place the patient in a supine position with the legs elevated.
- Rehydrate the patient with sports drinks if nausea is not present.
- Obtain blood samples for electrolyte analysis, and consider IV administration of isotonic fluids.
- Administer fluid based on assessment of volume depletion.

- Monitor the ECG, vital signs, temperature, and $ETCO_2$.
- Consider external cooling measures.
- Care for patients receiving specialized cooling techniques initiated prior to the CCTP’s arrival, such as cooling blankets; cold-water peritoneal, rectal, thoracic, or gastric lavage; cold IV fluids; or cold humidified oxygen. Determine if these measures are still necessary.
- Avoid giving antipyretic medications, which may cause severe complications in patients with heat exhaustion and which have no role in treating environmental heat stress.

Heatstroke

Heatstroke is the least common but most deadly of the heat illnesses. It is a severe disturbance in the body’s thermoregulation, defined as a core body temperature of 104°F (40°C) or higher (typically, but not always) and associated CNS dysfunction. Only core body temperatures are reliable in diagnosing heatstroke; oral, axial, skin, and tympanic readings are not relevant. Heatstroke is a profound emergency, with mortality as high as 80% in untreated patients and significant sequelae and rates of morbidity among patients who initially survive the heatstroke: Two-year mortality is approximately 71%. Death occurs in as many as 10% of treated patients.

The critical thermal maximum is reached when the core body temperature exceeds 109.4°F (43°C). At this point, cellular respiration becomes impaired, cell membranes have increased permeability, denaturation of proteins begins, and tissue necrosis results. When heatstroke is suspected or confirmed, immediate and aggressive whole-body cooling is required.

Two distinct syndromes have been identified: classic and exertional **TABLE 19-3**.

TABLE 19-3 **Classic Versus Exertional Heatstroke**

Characteristic	**Classic Heatstroke**	**Exertional Heatstroke**
	Older	***Younger***
General health	Chronic diseases or schizophrenia	Healthy person
Medications	Beta blockers, diuretics, or anticholinergics	Often none; consider stimulant abuse
Activity	Very little to bedridden	Strenuous
Sweating	May be absent	Usually present
Skin	Hot, red, and possibly dry	Moist and pale
Blood glucose level	Normal	Hypoglycemic
Rhabdomyolysis	Rare	Common
Acute renal failure	Rare	Common

© Jones & Bartlett Learning.

- *Classic heatstroke* usually occurs during heat waves and is associated with prolonged time spent in hot dwellings with poor climate control and ventilation. Populations with poor physiologic compensatory mechanisms, such as persons who are very old, very young, or bedridden, are more vulnerable to this condition. Patients with chronic illnesses (eg, diabetes and heart disease), people taking certain medications (eg, anticholinergics, diuretics, and beta blockers), and people with alcoholism are also more susceptible, as these factors can impair normal thermoregulatory mechanisms. As high environmental temperatures elicit dissipation of body heat, the previously mentioned conditions impair heat loss and the core body temperature continues to rise unchecked.
- As discussed previously, *exertional heatstroke* typically affects younger healthy persons who are exposed to high heat and

> humidity during a period of strenuous activity. When the core body temperature matches the ambient temperature, radiation and convection are interrupted and heat dissipation is no longer effective. Evaporative cooling through sweating may be further impaired when the relative humidity is more than 75%. Note, however, that ambient air temperature does not have to be high for this form of heatstroke to occur; it can occur when endogenous heat production is sufficiently high or heat dissipation is sufficiently impaired. For example, heatstroke has been documented in marathon runners and firefighters despite mild ambient temperatures. As the body continues to generate heat without a mechanism for its removal, the core body temperature continues rising toward the critical thermal maximum. In addition to the heat emergency, patients may have depleted glucose and electrolytes. Their conditions may progress to rhabdomyolysis or acute renal failure. Temperature-mediated activation of the clotting cascade and damage to endothelium may contribute to coagulopathies.

Both types of heatstroke present with similar signs and symptoms, but the cardinal sign is neurologic dysfunction. The earliest signs of neurologic dysfunction may include mental status changes, such as irritability, bizarre behavior, or combativeness, or more subtle cues, such as slurred speech or altered gait. In other cases, the patient may appear briefly unwell and then suddenly collapse, or the patient may have a seizure. These symptoms often mislead bystanders, who may attribute the problem to causes other than the environment, such as substance abuse or psychiatric disorders. Notably, however, individuals who are intoxicated or who are experiencing a psychiatric crisis are especially susceptible to heatstroke. The presentation of extreme hyperthermia mimics vascular stroke or head injury, which should remain part of the initial differential diagnosis.

Dry skin from anhidrosis is often cited as an important sign of heatstroke, but this commonly taught presentation is actually an inconsistent finding and therefore diagnostically unreliable. Anhidrosis may be more common in the setting of classic heatstroke, as the patient's body temperature rises somewhat gradually and compensatory mechanisms fail, but many patients experiencing this form of heatstroke will continue to sweat. In case of exertional heatstroke, 50% of patients continue to sweat persistently. Thus, the patient's skin condition should not be used to arrive at a diagnosis of heatstroke.

Given these potentially misleading signs and symptoms, the CCTP must attend closely to the diagnostic signs of heatstroke: a markedly elevated core body temperature coupled with CNS disturbance. Tachycardia and tachypnea are common. $ETCO_2$ values may be less than 20 mm Hg as a result of hyperventilation. BP may be normal or decreased, depending on volume status and the degree of vasodilation that may be occurring as a compensatory mechanism. Most patients with exertional heatstroke, however, are euvolemic.

Heatstroke is an easy diagnosis to miss. CCTPs must keep the possibility of this condition constantly in mind during heat waves and in the context of exertional activities when presented with a patient exhibiting signs of neurologic impairment.

Treatment

Treatment of heatstroke focuses on lowering core body temperature as rapidly as possible. CCTPs should evaluate the patient's ABCs and consider controlling the airway. Immediate attempts to decrease the core body temperature begin with removing the patient's clothing and moving the patient to a cool environment.

Cold-water immersion, which involves covering the patient up to their neck in ice water, is the preferred method to treat heatstroke in all settings. If this method is unavailable or impractical based on the situation, then evaporative cooling can be started and continued during transport with relative ease. Sponging or spraying water over the patient and fanning to promote evaporation is key. Placing bags of ice or commercial ice packs at the nape of the neck, armpits, groin, and palms and soles further assists in cooling but is ineffective as a stand-alone treatment. In high-humidity environments, evaporative cooling methods are less effective.

Applying rubbing alcohol to the skin is not an effective way to reduce core body temperature. In the context of environmental etiologies, antipyretic medications also have no benefit in treating heatstroke.

Cooling should be continued until the core body temperature falls below 102°F (38.8°C) and should be sustained as a matter of priority. If this target is achieved within 30 minutes of heatstroke presentation, immediate mortality decreases dramatically. Shivering need not be a concern, as the thermogenesis it produces is insufficient to raise body temperature back to dangerous levels from the point at which it begins. Cooling promotes peripheral vasoconstriction and may raise the BP.

Treatment also includes the following steps:

- Initiate an IV line of isotonic fluid, and obtain blood samples for glucose and electrolyte analysis.
- Watch the patient closely for signs indicating development of pulmonary edema.
- Closely monitor the ECG, vital signs, and $ETCO_2$, and be prepared to treat a seizure with a benzodiazepine; keep a close eye on the ECG for indications of hyperkalemia and arrhythmia.

Monitor the patient for changes in central venous pressure, pulmonary wedge pressure, systemic vascular resistance, and cardiac index. If rhabdomyolysis is present, treatment should include aggressive hydration and administration of crystalloid fluid. Closely monitor the patient's fluid status and contact medical control about administration of additional medications (eg, mannitol and sodium bicarbonate) if the patient's condition continues to deteriorate. Additional efforts, such as dialysis, may be needed in patients with elevated potassium levels or uremia.

Signs and Symptoms

Heatstroke

- Altered mental status
- Confusion
- Irritability
- Bizarre behavior
- Combativeness
- Hallucinations
- Elevated core body temperature
- Tachycardia
- Tachypnea with $ETCO_2$ less than 20 mm Hg
- Hot, red skin
- Normal or decreased BP
- Seizure

Differential Diagnosis

Heatstroke

- Intracranial hemorrhage
- Ischemic stroke
- Diabetic ketoacidosis
- Malignant hyperthermia
- Neuroleptic malignant syndrome
- Sympathomimetic toxicity
- Salicylate toxicity
- Phencyclidine toxicity
- Encephalopathy
- Withdrawal syndrome

Expecting the Unexpected

A heat emergency can occur in any season of the year, especially in older adults who have difficulty acclimatizing, and who often have inadequate hydration and take multiple medications, which may affect the negative feedback loops in thermoregulation. CCTPs should give particular attention to signs of poor skin turgor during transport of older adults with an elevated temperature.

Transport Management

Heatstroke

- Evaluate the ABCs.
- Administer supplemental oxygen if the pulse oximetry reading is less than 92%.
- Consider endotracheal intubation.
- Remove the patient's clothing.
- Move the patient to a cooler environment.
- Prioritize cold-water immersion. Consider options to initiate or sustain cold-water immersion in transit, such as packaging the patient in a fluid-impervious material filled with ice water, such as a tarp, body bag, or MegaMover-like device.
- If cold-water immersion is not possible:
  - Sponge or spray water over the patient.
  - Fan the patient.
  - Place ice packs at the nape of the neck, armpits, groin, and palms and soles.
- Initiate an IV line of crystalloid fluid, and obtain blood samples for glucose and electrolyte analysis.
- Watch closely for signs of pulmonary edema.
- Closely monitor the ECG, vital signs, and $ETCO_2$.
- Be prepared to treat a seizure with antiepileptic drugs (eg, benzodiazepines).

Fever and other conditions may mimic heatstroke and, therefore, increase the challenge for clinicians. The patient's history may provide important clues as to the appropriate diagnosis. For example, a recent complaint of cough or dyspnea, an obvious skin rash, a change in urine color, and intermittent shaking "chills" are more likely to be associated with infection rather than with an environmental cause. When a patient has an infection, pyrogens (proteins excreted as the body fights an infection) act on the hypothalamus to increase the body temperature. Fever in children may result in seizure. Fever is most often treated with antipyretic medications, which can prove dangerous in patients who actually have heat-related illness because of their harmful effects on the kidneys and clotting process.

Anticholinergic and organophosphate exposure and poisoning can also cause hot, red, dry skin; mental status changes; and tachycardia. Exposure to these agents usually causes dilated pupils, whereas a heat emergency generally would not. In addition, **neuroleptic malignant syndrome** is caused by some antiemetic and antipsychotic medications, and **malignant hyperthermia** may occur with use of common anesthesia agents (most notably succinylcholine). These conditions may present with hyperthermia, a hyperdynamic state, and altered mentation.

Cold Emergencies

Most cold-related injuries are localized to exposed body parts, especially the face, where there are fewer cold receptors in the skin compared with areas of the body covered by clothing. The tip of the nose, ear lobes, fingers, and toes—all areas where peripheral circulation is weakest and body temperature is the lowest—are most susceptible to such injuries.

Frostbite

Frostbite is a form of cold injury that develops slowly and generally without a lot of pain. People with frostbite may be unaware of its occurrence, and its major signs and symptoms may not manifest until after the patient has been removed from the cold environment and the affected tissue warms.

Frostbite is classified similarly to burns, using four degrees of injury. The precise nature of the injury, and thus the degree of injury, may not be evident prior to warming. First-degree frostbite is characterized by numbness, erythema, and capillary leakage resulting in localized edema. Second-degree frostbite involves superficial blistering. Third-degree frostbite involves deep hemorrhagic blistering, and fourth-degree frostbite involves damage to deep subcutaneous tissues such as muscle and bone. In severe frostbite that is still frozen, tissue may appear white and waxy **FIGURE 19-3**. Paresthesia that results during warming may persist for weeks following the event.

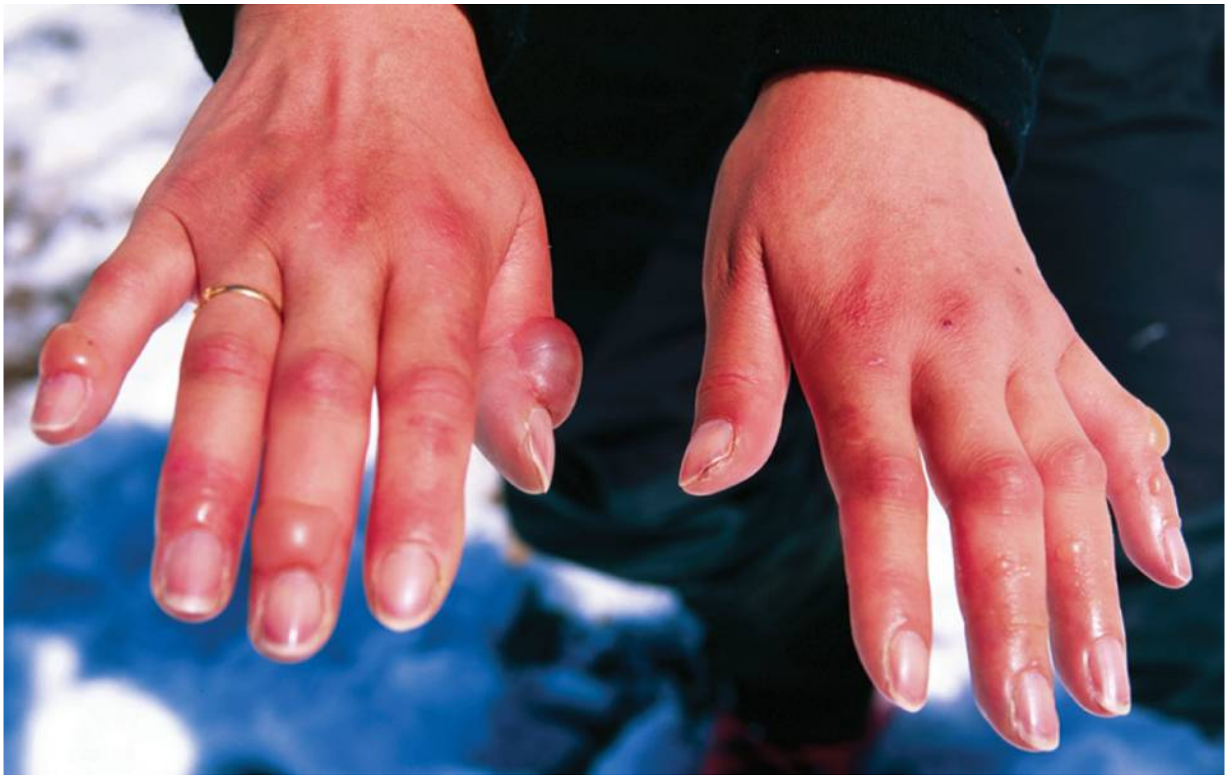


FIGURE 19-3 Frostbitten parts are hard and usually waxy to the touch.

Courtesy of Neil Malcom Winkelmann.

Frostnip

Frostnip has traditionally been classified as a form of mild frostbite. It is a nonfreezing, superficial cold injury easily treated by placing a warm hand over the chilled ear, nose, or fingers. The return of warmth to the affected part is accompanied by some degree of redness and tingling. For clinical classification purposes, frostnip is not included among the degrees of frostbite.

Severe frostbite involves the freezing of tissues exposed to temperatures below the freezing point (32°F [0°C]). When subjected to such low, freezing temperatures, the fluid within cells becomes ice crystals, which damage the cells. Rubbing these frozen tissues, which may be done in a well-intentioned attempt to improve circulation or to create warmth via friction, should be avoided because it will cause the frozen crystals to crack and lacerate surrounding tissue. This condition is further complicated by the “sludge” effect of cooled blood, which results in increased viscosity, poor flow, capillary leakage, poor perfusion, thrombus, and ischemia. Frozen tissues appear hard and cold, are without sensation, and take on a yellow-white or mottled blue-white appearance.

The most serious complication of frostbite is seen during gradual thawing or refreezing. When tissues thaw slowly, the residual effect of this tissue damage becomes apparent and profound edema and third spacing can occur. If thawing is not conducted mindfully, or is not sustained and the freezing conditions eliminated, partial refreezing may occur. Because the newer ice crystals formed at this point are larger (due to the presence of increased interstitial fluid), they cause greater tissue damage. During thawing, as circulation returns, the area becomes purple and excruciatingly painful. CCTPs should be prepared to provide generous pain management to these patients and to safely manage that analgesia by thoroughly understanding the drugs selected for administration. Gangrene, a result of permanent cell death, may set in within a few days, requiring amputation **FIGURE 19-4**.

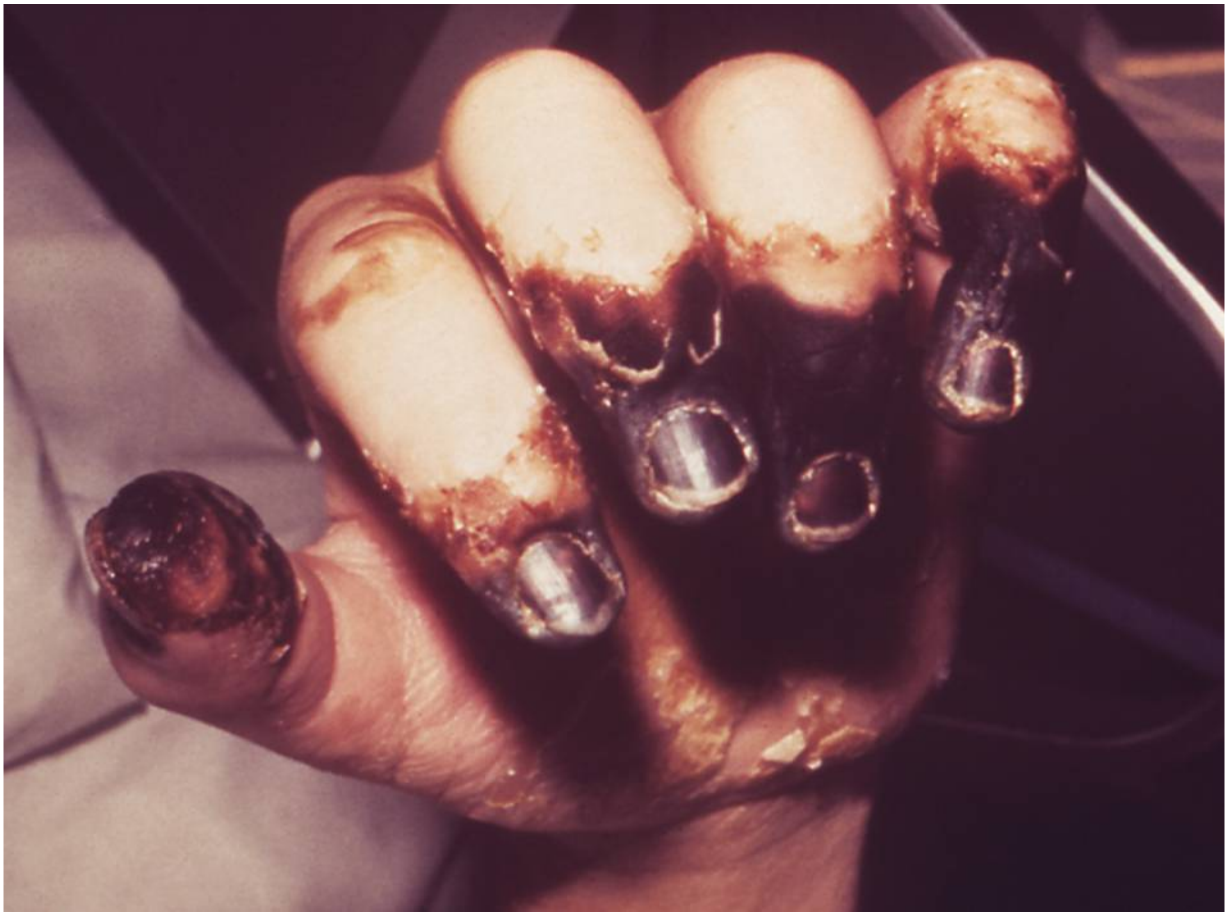

FIGURE 19-4 Gangrene can occur when tissue is frozen and permanent cell death occurs.

Courtesy of Dr. Jack Poland/CDC.

Treatment

Treatment of severe frostbite by the CCTP depends on two factors:

- The distance to the receiving hospital or burn center
- The degree of thawing before arrival at the hospital

If the part is still frozen or the transport time is less than 1 hour, do not attempt to warm the part, as rapid warming is difficult. Pad the part with dry dressings to protect it from further injury. Instruct the patient not to rub or massage the area because, as noted earlier, the ice crystals in the cells will lacerate delicate tissues.

If the tissue is partially thawed or transport will be prolonged, contact medical control for advice on field warming. Field warming can be difficult to accomplish in an effective and controlled manner, however, and the risk of incomplete thawing and refreezing may outweigh its benefits.

Should the CCTP be called to undertake this process, the general approach is to completely immerse the affected tissue in water between 98.6°F and 102.2°F (37°C and 39°C). The water must be maintained at this temperature. The frozen tissue will cool water that is not exchanged or that does not have an active heat source, so monitor the water temperature to maintain it in the therapeutic range. This treatment procedure typically takes 30 minutes or more. Establish an IV line for the administration of pain control medication (eg, fentanyl or ketamine). The patient should not consume nicotine products, because nicotine causes vasoconstriction that would further interfere with the thawing process. Once circulation has returned and the part is thawed, dry it thoroughly and apply a dry dressing to further protect the tissues during transport. Do not allow the tissues to refreeze.

Ibuprofen may be administered, chiefly to reduce inflammation. Tissue plasminogen activator may be initiated within 24 hours of thawing, typically as a 3-mg bolus followed by an infusion of 1 mg/mL at 10 mg/h. Heparin may be administered concurrently at 500 units as an adjunct treatment. Other vasodilators, such as iloprost, nitroglycerin, and nifedipine, may be infused under some protocols, although research on their efficacy is inconclusive.

Signs and Symptoms

Frostbite

- Hard, cold, waxy, and yellow-white or mottled blue-white skin

Differential Diagnosis

Frostbite

- Arterial or venous occlusion
- Hypoxia or cyanosis
- Dermal exposure to corrosive chemicals
- Vasospasm

Transport Management

Frostbite

- Do not warm, rub, or massage the area.
- If transport time is less than 1 hour, leave the part frozen.
- If transport time is expected to be prolonged, contact medical control to discuss field warming.
- If medical control advises field warming:
  - Immerse the affected tissue completely in water between 98.6°F and 102.2°F (37°C and 39°C). Monitor the water temperature to maintain it.
  - Establish an IV line; administer pain medication.
  - Dry the part thoroughly once it has thawed.
  - Apply a dressing.
- Take great care to prevent refreezing.

Hypothermia

Hypothermia is defined as a decrease in core body temperature to 95°F (35°C) or less. This condition may result from impaired thermogenesis, excessive heat loss, or excess environmental cold stress. Any environmental temperature below an individual's physiologic core body temperature can result in hypothermia, and this emergency may occur in any season. Alcohol use has been identified as a factor contributing to hypothermia. Likewise, hypothyroidism, liver disease, and malnutrition may predispose a person to this cold emergency. Trauma is the other most important factor contributing to hypothermia. Additionally, hypovolemia and hypotension interfere with normal thermoregulation.

The classification and treatment of hypothermia depend chiefly on the patient's mental status and motor function, including shivering. In general, hypothermia is considered more severe as mental status and motor function decline; this type of progression requires more assertive warming measures. Many patients exposed to cold may simply be experiencing cold stress, a nonhypothermic condition in which patients complain of being cold but remain conscious and completely alert and have mostly normal motor function, including shivering. Simple, intuitive warming methods, such as increasing the ambient temperature in the patient care environment and adding insulating layers to the patient, will likely remedy cold stress. Patients who are shivering, and therefore producing endogenous heat, often improve quickly once sources of heat loss are corrected and adequate insulation is applied.

Various methods of categorizing hypothermia exist. In the United States, a three-tiered scale of mild, moderate, and severe hypothermia is prevalent. In Europe, the five-tiered Swiss Staging System of hypothermia has gained acceptance and offers greater precision.

Mild hypothermia is defined as a core body temperature between 90°F and 95°F (32.2°C and 35°C). At these temperatures, the body usually compensates with increased thermogenesis and interrupted thermolysis. Shivering is in full force and will generally be an effective form of thermogenesis if adequate insulating layers are provided. The “umbles” (stumbles, mumbles, fumbles, and grumbles) are present, indicating impaired motor function and declining mental status. The heart rate, BP, and cardiac output may rise. These processes continue until either the core body temperature returns to normal or glycogen stores are exhausted and compensation begins to fail. If left unchecked, more serious conditions will result.

Moderate hypothermia is defined as a core body temperature between 82°F and 90°F (27.7°C and 32.2°C). Mental status is markedly decreased, although the patient is likely to still be conscious, in the absence of other contributing factors. Shivering may still be present but is less vigorous and unlikely to be an effective from of thermogenesis. Warming with an external heat source is necessary to correct this condition and prevent further deterioration.

Severe hypothermia begins as the core body temperature drops below 82°F (27.7°C). At these temperatures, the body reacts by slowing things down. This slowed metabolism decreases thermogenesis, and the heart rate, BP, and cardiac output decrease. Shivering ceases. As peripheral vasoconstriction occurs to shunt warm blood to the core, the volume receptors interpret this change as an increase in blood volume and stimulate the kidneys to produce more urine (cold diuresis). Simultaneously, a shift of fluids from the intravascular space to the extravascular space increases the blood's viscosity. Shivering ceases at a body temperature less than 91°F (32.7°C). Tracheobronchial secretions increase and bronchospasm may occur. At a core body temperature of less than 90°F (32.2°C), hypoventilation is profound.

The Swiss Staging System includes additional categories and relies more heavily on patient appearance. In stage 1, which correlates to mild hypothermia, the patient exhibits clear consciousness and shivering. In stage 2, which correlates to moderate hypothermia, the patient demonstrates decreased consciousness without shivering. In stages 3 and 4, which correlate to severe hypothermia, the patient is unconscious. In stage 4, however, the patient *appears* to be dead.

The relevance of stage 4 in the Swiss scale is that the patient may not be dead at all, despite having a core body temperature between 56.6°F and 75.2°F (13.7°C and 24°C). The oft-repeated mantra in medicine of "They're not dead until they're warm and dead," while crude, is an important reminder that severely hypothermic patients may survive even if vital signs cannot be detected, and resuscitation should be initiated unless it cannot physically be performed. ECG leads may have to be amplified for organized electrical activity to be detected in these patients. $ETCO_2$ monitoring is helpful in detecting the output of cellular respiration, even if chest rise and fall are not evident.

In stage 5 of the Swiss system, hypothermia is irreversible, and death is indeed imminent or has occurred. The core body temperature of these patients is less than 56.6°F (13.7°C).

In severe hypothermia (Swiss stages 3 and 4), the heart rate plummets, the cardiac cycle elongates, and the action potential threshold of the myocytes is greatly reduced. Bradycardia is common, and cardiac arrhythmia may be seen. An Osborn or J wave may be seen on the ECG tracing, indicating an uneven voltage gradient through the myocardium caused by the cooling of those tissues **FIGURE 19-5**. Abnormal cardiac conduction and hypothermia-induced arrhythmias may lead to ventricular fibrillation, especially as the core body temperature falls below 82.5°F (28°C). When Osborn or J waves are seen, the risk of ventricular fibrillation or pulseless ventricular tachycardia is very high. Repeated defibrillation may not be effective until the patient has been warmed to a core body temperature of more than 86°F (30°C). When giving shocks to these patients, the defibrillator's maximum energy should be used. If defibrillation of a patient with a core body temperature less than 86°F (30°C) is not successful, further shocks should not be attempted until the core body temperature rises.

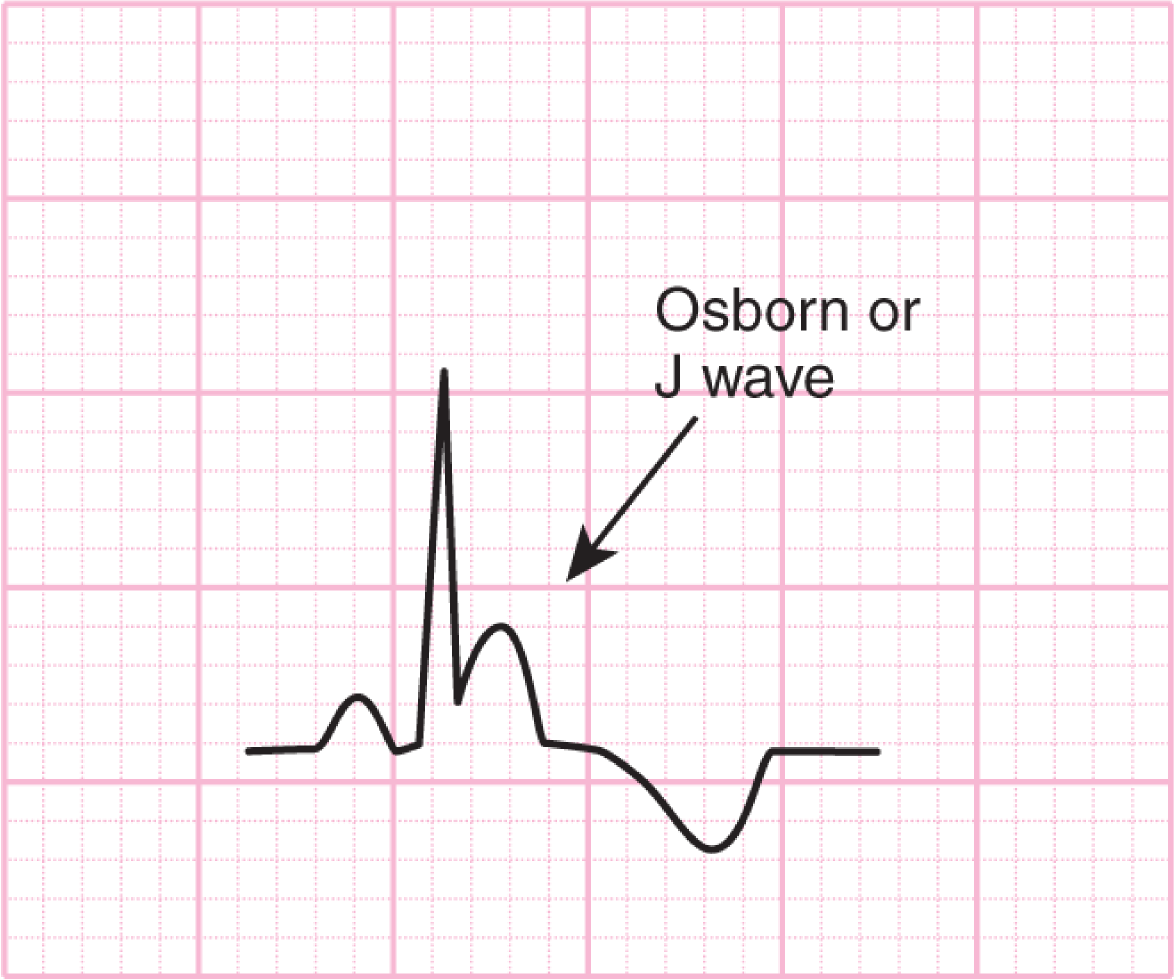

FIGURE 19-5 Osborn or J wave as it appears on electrocardiogram.

© Jones & Bartlett Learning.

Many of the usual advanced cardiac life support (ACLS) medications may be less effective in patients with severe hypothermia. Although the American Heart Association guidelines do not recommend departure from the normal ACLS regimen, the Wilderness Medical Society's Clinical Practice Guidelines for hypothermia recommend administering ACLS medications at twice the normal intervals (ie, waiting twice as long between doses) in patients with core body temperatures less than 35°C (95°F) and withholding them entirely if the core body temperature is less than 30°C (86°F).

Treatment

Treatment is based on warming the patient, which involves removing cold, wet clothing; drying the patient if necessary; and wrapping the patient in layers that retain radiant heat, minimize conductive heat loss, and protect the patient from ambient moisture such as rain or snow. This form of warming, known as **passive warming** because it does not involve the introduction of exogenous heat sources, will generally be effective if the patient is still shivering vigorously. Typically, this patient package, sometimes called a "hypothermia wrap," should be constructed beginning with the outermost layer (the moisture barrier), followed by insulating layers, and then a reflective inner layer. The CCTP can use materials such as tarp, cloth, or Mylar blankets for this purpose, but many lightweight, highly effective commercial products are also available that achieve the same result. In addition, the patient should be placed in a warmed environment.

Active warming involves the introduction of exogenous heat sources to the patient. This method is necessary when the patient is not shivering adequately or has ceased to shiver. Active warming may involve infusing warmed IV fluid (102°F to 105°F [38.8°C to 48.5°C]); delivering warm, humidified oxygen; or administering a peritoneal lavage of a potassium chloride–free solution or nasogastric/orogastric lavage with warmed fluids. When placing heat sources (such as heat packs) into the patient package to actively warm the person, place them around the trunk rather than along the extremities. This placement helps to avoid core afterdrop, a warming-related phenomenon in which vasodilation in the extremities returns relatively cooler blood to the warmed core of the body, causing a rebound hypothermic effect. Warm the patient compartment of ambulances or aircraft to a temperature 28°C (82.4°F) if possible, and if tolerable to the transport crew. Administration of IV dextrose may be required to treat depleted glucose stores in patients who have experienced prolonged shivering or who are no longer shivering.

Severely hypothermic patients should be handled gently to avoid inducing cardiac arrest; these patients may be experiencing a prolonged relative cardiac refractory period, predisposing the heart to rhythm irregularities if physically jolted. ECG leads should be placed to assess for Osborn or J waves and arrhythmias, and the CCTP should consider placing defibrillation/pacing pads during transport.

Special Populations

Older adult patients are more susceptible to hypothermia compared to their younger adult counterparts. Even in warm weather or inside a heated transport unit, older patients are susceptible to significant heat losses. Monitoring temperature is as important in the older population as it is in neonates.

Signs and Symptoms

Hypothermia

- Decrease in core body temperature to less than 95°F (35°C)
- Shivering or lack of shivering
- The “umbles”: stumbling, mumbling, fumbling, and grumbling
- Increased or decreased heart rate
- Increased or decreased BP
- Increased or decreased cardiac output
- Cardiac arrhythmias
- Osborn or J waves on the ECG

Differential Diagnosis

Hypothermia

- Drowning
- Profound shock
- Cardiac arrest
- Toxic chemical exposure
- Overdose

Transport Management

Hypothermia

- Remove cold, wet clothing.
- Dry the patient.
- Apply patient packaging that insulates and retains warmth.
- Move the patient to a warmed environment.
- Consider administration of warmed IV fluid, dextrose, humidified oxygen, or peritoneal lavage of a potassium chloride–free solution or nasogastric/orogastric lavage with warmed fluids.
- Monitor the ECG for arrhythmias and Osborn or J waves, and be prepared to defibrillate.
- Consult with medical direction and consider modifications to standard ACLS regimens as appropriate based on the patient's core body temperature.

Expecting the Unexpected

Hypothermia can occur in any season of the year, especially in older adults who have difficulty acclimatizing and are often prescribed multiple medications that affect the negative feedback loops of thermoregulation. CCTPs should pay particular attention during transport of both older and very young people. The transport environment creates numerous opportunities to cause or worsen preexisting hypothermia. Even brief episodes of exposure to cold temperatures while moving to or from a transport vehicle can significantly undermine warming efforts. Even when the ambient temperature is room temperature, young or older patients can be hypothermic. Although CCTPs may be sweating on a hot summer day, a patient may be too cold. It is essential that CCTPs sacrifice their personal comfort by creating an adequately warm environment for the resuscitation or transport of patients with hypothermia.

Drowning

Every day in the United States, approximately 10 people die from unintentional drowning. Drowning is the leading cause of unintentional injury-related death for children 1 to 4 years of age. More than 50% of drowning patients treated in EDs require hospitalization or transfer for further care (compared with a hospitalization rate of 6% for all unintentional injuries).

Treatment

Treatment begins with spinal motion restriction of patients witnessed diving into the water and when alcohol use is suspected. Initiate ventilation immediately if warranted, and advanced airway management where necessary. Widespread **atelectasis** and pulmonary shunt may be present in a drowning patient. The use of 10 cm H_2O of positive end-expiratory pressure (PEEP) may aid in keeping the alveoli open and driving fluid into the interstitial or capillary spaces. A nasogastric tube may be used, after airway control, to decompress the stomach. Bronchospasm and tracheobronchial irritation may be treated with a beta-2 adrenergic agonist.

Acute respiratory distress syndrome is a common complication of submersion incidents. Chemical or bacterial pneumonitis and renal failure are other complications that can occur days after resuscitation.

Transport Management

Drowning

- Provide spinal motion restriction for patients witnessed to have dived into the water and when alcohol use is suspected.
- Provide supplemental oxygen.
- Consider endotracheal intubation.

- Provide PEEP.
- Consider inserting a nasogastric or orogastric tube to decompress the stomach.
- Consider administering a beta-2 adrenergic agonist to treat bronchospasm and tracheobronchial irritation.

Diving Injuries and Decompression Sickness

Injuries associated with recreational and professional scuba diving activities can occur regardless of the diver's level of experience. All divers are subject to pressure effects. For each 33.9 feet (10.3 m) of depth, the pressure on the body increases by 1 atmosphere (atm), or 14.7 lb/in^2 ($1\ kg/cm^2$).

The most common effect of increasing depth relates to the amount of nitrogen present within the body. Nitrogen dissolves from the gas inhaled by divers into the body's fatty tissues. It readily displaces oxygen in the brain, resulting in feelings of euphoria and disorientation known as **nitrogen narcosis**. The effects of nitrogen narcosis vary among divers. Some divers are affected at 30 meters, but all divers are significantly impaired at depths of 60 to 70 meters. The effects do not develop in proportion to time at a particular depth; rather, symptoms progress and new symptoms develop as a diver descends deeper to greater pressures. If the nitrogen forms gas bubbles in the blood, a condition known as decompression sickness, the person may experience excruciating pain when the bubbles become trapped in body cavities such as joints or in the folds of the intestinal tract; the resulting pain is often referred to as the "bends" **FIGURE 19-6**. In addition to the bends, patients with decompression sickness may experience respiratory disturbances (the "chokes"; discussed later), neurologic impairment (the "staggers"), and skin sensation abnormalities (the "creeps" or "skin bends").

FIGURE 19-6 Decompression sickness affects divers who ascend to the surface too quickly.

Courtesy of Mass Communication Specialist 2nd Class Rebecca J. Moat/US Navy.

Barotrauma may occur during either ascent or descent in a dive, depending on the situation. With changes in elevation, gases stored in confined spaces within the body may either expand or contract. As the diver travels to a higher elevation, trapped gases attempt to expand, causing increased pressure within a particular body cavity. As the diver descends, the pressure of the outside environment exceeds the pressure of various gases within the body, resulting in inward pressure. The patient’s lungs, ears, and gastrointestinal tract are susceptible to injury from barotrauma.

Rapid ascent is also responsible for **pulmonary overpressurization syndrome (POPS)**, in which gases in the lungs expand rapidly as the pressure decreases, leading to pneumothorax or mediastinal or subcutaneous emphysema. Simply holding one’s breath during the last 6 feet (2 m) of the ascent is sufficient to cause these injuries. Arterial gas embolism may occur when air bubbles escape from ruptured alveoli, enter the pulmonary capillaries, and travel through the pulmonary veins to the heart. If the air bubbles end up in the coronary arteries or cerebral vasculature, they will result in acute myocardial infarction or stroke. The vast majority proceed to the cerebral arteries, resulting in a stroke.

Treatment

Treatment for decompression sickness in the prehospital setting includes rapid transport and oxygenation. Providers should administer 100% oxygen to promote nitrogen washout from the lungs. PEEP and continuous positive airway pressure (CPAP) should not be applied to patients with pressure-related diving injuries or decompression sickness unless necessary to maintain oxygenation.

A valuable resource when managing dive-related injuries is the Divers Alert Network (DAN), which provides a 24-hour hotline (919-

684-9111). The DAN staff can guide CCTPs through a variety of complex decisions about treatment, transport, and patient disposition.

CCTPs should closely monitor patients with decompression sickness, even if they begin to show signs of improvement or recovery. Relapses of symptoms are possible and may be associated with an overall deterioration in the patient’s condition.

The use of a pure Trendelenburg position or the combination of a head-down with left lateral decubitus (Durant) position is not currently recommended for arterial air embolisms (as seen in decompression sickness) because these positions increase intracranial pressure. Instead, transport patients in a supine position and, in aircraft, at the lowest cabin altitude pressure possible. Depending on the topography of the transport route, even ground ambulance transport may subject patients to increased physiologic stressors and worsen their conditions. Trendelenburg or Durant positioning continues to be recommended for venous air embolisms (as may be seen during central line insertion or removal).

Other potential interventions for decompression sickness may include the following: (1) administering aspirin to prevent thrombus formation, (2) managing tension or simple pneumothorax with a thoracostomy (chest) tube, (3) aggressively administering IV fluid resuscitation, and (4) following ACLS protocols for profound cardiopulmonary dysfunction. Patients with decompression sickness are likely to require analgesics, sedatives or anxiolytics, and antiemetics during transport. These patients may also have other medical concerns, such as trauma or hypothermia, that require additional resuscitative measures. In particular, hyperbaric oxygen therapy is often necessary to minimize the morbidity and mortality from decompression sickness.

Transport Management

Diving Injuries

- Provide rapid transport.
- Provide oxygenation.

- Do not use PEEP or CPAP.
- Consider hyperbaric therapy.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy (HBOT) is generally accomplished by placing the patient in a specially constructed chamber designed to withstand high internal pressures, well in excess of normal atmospheric pressures **FIGURE 19-7**. The chamber is filled with compressed air to a desired level, typically expressed in units of atmospheres or feet of seawater. The patient receives pure or blended oxygen via a mask or endotracheal tube.

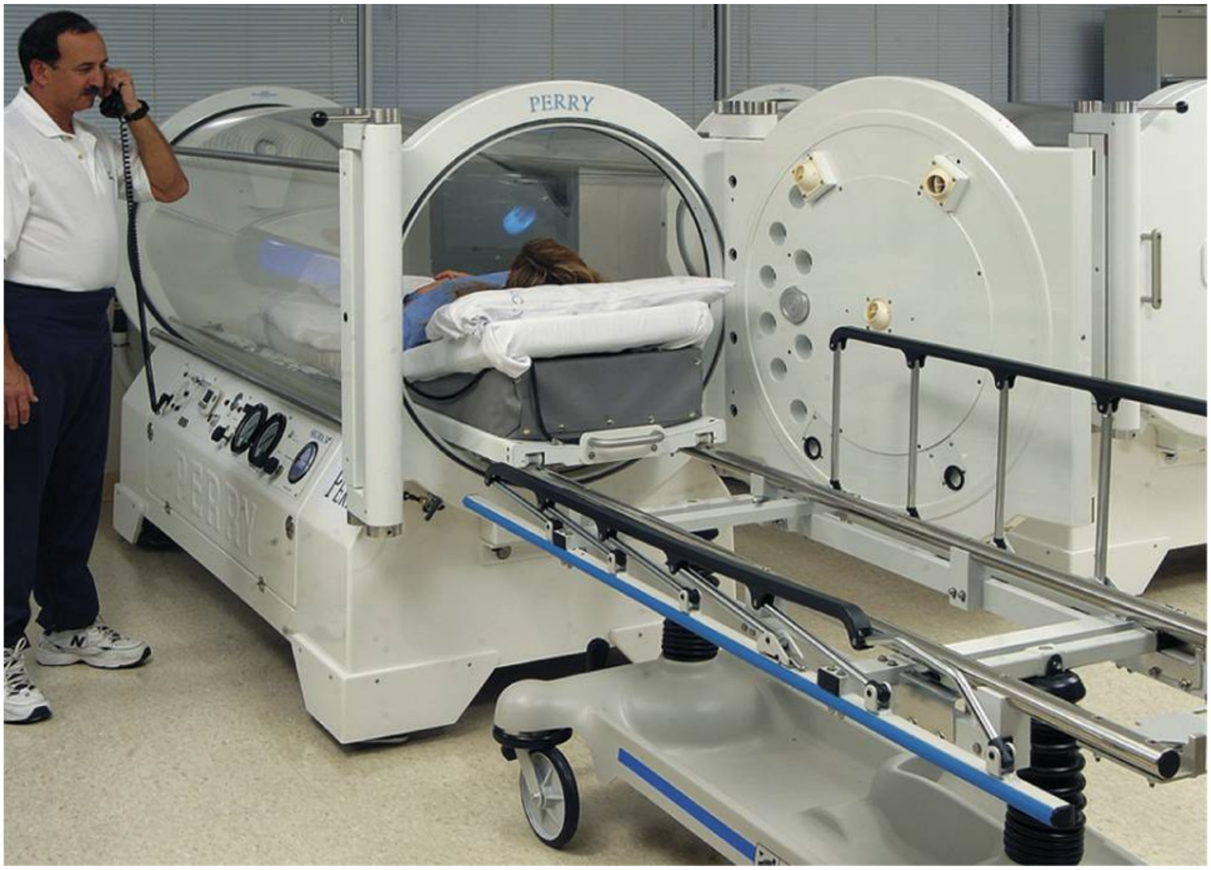

FIGURE 19-7 A hyperbaric chamber, usually a small room, is pressurized to more than atmospheric pressure. It is used in the treatment of decompression sickness and air embolism.

Courtesy of Perry Baromedical.

Chambers are configured to handle one patient or multiple patients. In larger chambers, a trained medical provider typically accompanies the patient into the chamber to monitor equipment and intervene if the patient's condition begins to deteriorate.

Most patients will receive 100% inspired oxygen while undergoing HBOT. In addition to saturating the blood hemoglobin, this oxygen, which is under greater than atmospheric pressure, becomes dissolved into the circulating plasma.

HBOT produces a number of interesting effects that can benefit a variety of patients. An example, the localized vasoconstriction that results from hyperoxygenation decreases tissue edema following crush injuries, burns, and other types of trauma. This vasoconstriction is offset by improved blood flow at the capillary level. HBOT also creates oxygen free radicals and alters other components of a patient's inflammatory response, leading to enhanced wound healing and improvement of a pathologic inflammatory response. In specific situations, nitrogen and helium can be blended into the inspired oxygen. The Committee on Hyperbaric Oxygenation of the Undersea and Hyperbaric Medical Society established the indications for HBOT **TABLE 19-4**.

TABLE 19-4	**Indications for Hyperbaric Oxygen Therapy**
	Air or gas embolism
	Carbon monoxide poisoning
	Carbon monoxide poisoning complicated by cyanide poisoning
	Clostridial myositis and myonecrosis (gas gangrene)
	Crush injury, compartment syndrome, and other acute traumatic ischemias
	Decompression sickness
	Enhancement of healing in selected problem wounds
	Exceptional blood loss (anemia)
	Intracranial abscess
	Necrotizing soft-tissue infections
	Osteomyelitis (refractory)
	Delayed radiation injury (soft-tissue and bony necrosis)
	Skin grafts and flaps (compromised)
	Thermal burns

Reprinted with permission from the Undersea and Hyperbaric Medical Society (www.uhms.org).

Treatment tables are used to determine the length of HBOT and treatment steps. In case of decompression sickness, these tables take into account the depth of the dive, the duration of the dive, decompression stops, and previous dives performed. A hyperbaric specialist can recommend which table to use. Patients with severe illness often require several HBOT sessions. HBOT may prove beneficial even several days or longer after the incident in selected situations, such as for patients with carbon monoxide poisoning. Whenever HBOT is considered, CCTPs or medical providers should seek consultation with a specialist in hyperbaric medicine.

Hyperbaric chambers can be facilities in a fixed location, or they may be portable units that are transported to be near high-risk diving activities. To identify HBOT facilities in North America and the Caribbean, contact the DAN at Duke University at 919-684-9111. The Undersea and Hyperbaric Medical Society also maintains a database of US and international hyperbaric chambers. Given the wide variety of indications for HBOT, it is quite possible that hyperbaric chambers may be found in locations not typically associated with underwater activities.

Transport to these special facilities often requires air medical evacuation. In cases of barotrauma, the flight should be planned to take place at low-level altitude (the lowest altitude safely possible) or in a pressurized aircraft cabin set to 1 atm or 1 ata (total ambient pressure). The sending medical providers, in conjunction with CCTPs, must carefully weigh the risks and potential benefits to the patient when selecting the appropriate transport vehicle for a patient requiring transfer to an HBOT facility. The DAN recommends that cabin altitude not exceed 800 feet (244 m) for aircraft transport of patients with decompression sickness. This altitude limit may not always be possible owing to terrain or topography, weather, aircraft limitations, or other factors.

Flight Considerations

As just noted, according to the DAN, if air evacuation is used for patients requiring treatment of decompression sickness, cabin pressure must remain near sea level and the aircraft should not travel at an elevation greater than 800 feet (244 m) unless the captain is required to do so for safety precautions. The patient should be placed in the lateral recumbent position, or the recovery position: with the patient on their side, the head supported at a low angle, and the upper leg bent at the knee. Gravity will help to keep the patient's airway clear. Other experts recommend that patients be transported in a supine position. Additional discussion of this subject is found in the Controversies box.

CONTROVERSIES

Although many training materials may not reflect the evolution of thinking regarding the ideal position for an injured diver, the trends have shifted over the years. Currently, use of the Trendelenburg position is not believed to provide the best outcomes for these patients. Research suggests that a head-down position creates limitations when performing resuscitation, increased cephalic venous volumes, and compromised subsequent middle ear equalization, as well as difficulty in distinguishing cerebral arterial gas embolism from cerebral decompression sickness. Likewise, significant arterial gas emboli most likely form in decompression sickness through the arterialization of venous bubbles. In the Trendelenburg position, venous return is increased, sending these bubbles back to the heart. Finally, studies show that brain function recovery time is longer for patients who are placed in a head-down position.

Ultimately, although there may occasionally be some benefit to placing specific patients in a head-down position, many practitioners prefer keeping these patients supine.

Altitude Illness

High altitude can affect the body negatively, usually owing to a lack of acclimatization. Hypoxia from low atmospheric pressure is the main culprit in altitude sickness. In the most dramatic examples, extremes of altitude pose life-threatening hazards for experienced mountain climbers who are pushing the limits of human exploration on remote peaks throughout the world. More prosaically, scores of other people experience similar, potentially catastrophic effects of altitude illness when they travel from lower elevations to higher elevations in the course of everyday life. People with preexisting medical conditions, extremes of age, sedentary lifestyles, and poor health choices are at increased risk of altitude-related illness following even modest changes in elevation. The severity of altitude-related illness can range from mild symptoms, such as imperceptible tachypnea or sleep disturbances, to life-threatening manifestations, such as pulmonary edema, cerebral edema, and hypoxia.

Altitude sickness is most commonly associated with mountain climbing and alpine skiing, in which case it is often called acute mountain sickness. Acute mountain sickness can occur at altitude changes of 3,000 feet to 6,000 feet (914 to 1,800 m), but generally occurs at elevations of 8,000 feet (2,438 m) or higher. The Lake Louise criteria are useful for identifying acute mountain sickness **TABLE 19-5**.

TABLE 19-5 | **Lake Louise Criteria for Identifying Acute Mountain Sickness (AMS)**

- Headache
    - 0—No headache
    - 1—Mild headache
    - 2—Moderate headache
    - 3—Severe, incapacitating headache

- Gastrointestinal symptoms
  - 0—Good appetite
  - 1—Poor appetite or nausea
  - 2—Moderate nausea or vomiting
  - 3—Severe, incapacitating nausea and vomiting
- Fatigue/weakness
  - 0—Not tired or weak
  - 1—Mild fatigue/weakness
  - 2—Moderate fatigue/weakness
  - 3—Severe, incapacitating fatigue/weakness
- Dizziness/light-headedness
  - 0—No dizziness/light-headedness
  - 1—Mild dizziness/light-headedness
  - 2—Moderate dizziness/light-headedness
  - 3—Severe, incapacitating dizziness/light-headedness
- AMS clinical functional score (how did symptoms affect person's activities)
  - 0—Not at all
  - 1—Did not force change in activities
  - 2—Forced to stop ascent or to descend under own power
  - 3—Required evacuation to lower altitude

Suggested interpretation:

- Mild AMS: 3–5 points
- Moderate AMS: 6–9 points
- Severe AMS: 10–12 points

Data from Ho M, Siu AY. High altitude medicine. *Hong Kong Med Diary.* 2010;15(6):32-34. http://www.fmshk.org/database/articles/05sa.pdf.

More serious conditions, known as **high-altitude pulmonary edema (HAPE)** and **high-altitude cerebral edema (HACE)**, are likely to occur at higher elevations.

Treatment of Altitude Illnesses

The best and most effective treatment for all forms of altitude illnesses is descent.

High-Altitude Pulmonary Edema

HAPE is a noncardiogenic form of pulmonary edema that develops within 24 to 72 hours of reaching higher altitudes. Patients may demonstrate a variety of symptoms, including cough, respiratory distress, chest tightness, fatigue, and fever. The presence of fever may mislead clinicians and delay diagnosis.

The pathophysiologic features of HAPE are poorly understood. Pulmonary hypertension from alveolar hypoxia, localized inflammation, and capillary or arterial thromboses are implicated in patients with this condition. People who make frequent changes in altitude are at increased risk of HAPE.

Rapid descent is the preferred treatment for HAPE. Patients should also receive supplemental oxygen during the descent. Nifedipine, salmeterol, and portable hyperbaric bags are effective for this indication, and should be used, if available, for the management of HAPE. CPAP may also play a role in the care of these patients.

High-Altitude Cerebral Edema

HACE is a life-threatening emergency that should prompt immediate descent when recognized. Any patient who has recently experienced a significant increase in altitude and who now has mental status changes or ataxia should be evaluated for HACE. Either of these symptoms is presumed to be diagnostic for HACE if the person already has signs or symptoms of acute mountain sickness. If ataxia *and* mental status changes are present, HACE is presumed even if other signs or symptoms of acute mountain sickness are not present.

HACE is thought to result from cerebral vasodilation brought on by hypoxia, although the precise mechanism has not been identified. This enhanced blood flow produces cerebral edema, leading to the previously mentioned mental status changes and ataxia.

Once HACE is recognized, initiate immediate descent while providing the patient with supplemental oxygen. In addition, administer dexamethasone. Diuretic medications are not indicated and have the potential to produce harmful alterations in fluid volume.

Signs and Symptoms

Altitude Illness

- Hypoxia
- Fatigue
- Weakness
- Near-syncope
- Headache
- Dyspnea
- Cough
- Pulmonary edema
- Chest tightness
- Tachycardia

Differential Diagnosis

Altitude Illness

- Any other possible cause of respiratory distress (eg, asthma, chronic obstructive pulmonary disease, pneumonia, and bronchitis)
- Any other possible cause of altered mental status or ataxia (eg, stroke, toxic exposure, encephalitis, and traumatic brain injury)
- Unrelated cardiovascular dysfunction (eg, cardiogenic shock, cardiogenic pulmonary edema, and acute myocardial infarction)
- Unrelated gastrointestinal condition (eg, gastroenteritis, gastritis, and pancreatitis)
- Labyrinthitis
- Electrolyte or hematologic abnormality

Transport Management

Altitude Illness

- Provide oxygenation.
- Evacuate the patient and begin descent.
- Consider hyperbaric therapy.

Flight Considerations

Patients with various altitude-related illnesses pose a significant challenge for CCTPs. It is quite conceivable that CCTPs may be asked to perform a rescue or evacuation from a remote area with a high elevation. These locations are particularly hazardous for ground transport vehicles and aircraft. When requested to perform a rescue or evacuation mission, CCTPs should carefully consider safety issues, such as training and experience of the personnel, capabilities of the particular transport vehicle, and weather and environmental concerns, as well as the severity of illness and capabilities of a potential patient. Numerous emergency responders have been killed or severely injured while attempting rescue or evacuation of a patient from mountainous terrain.

During the transport, CCTPs must minimize the effect of environmental conditions on the patient. For patients with altitude-related illnesses, CCTPs must balance capabilities and safety concerns related to the particular transport vehicle employed with the patient’s clinical needs. Ideally, descent should occur rapidly for patients with severe manifestations of altitude illness. Rapid or prompt descent may not be possible when weather, topography, and terrain complicate the transport.

Indwelling devices with inflated balloons, such as endotracheal tubes and laryngeal mask airways, are also affected by changes in altitude. CCTPs should closely monitor these devices during ascent and descent.

Patients with altitude illness may have other issues, such as hypothermia, dehydration, trauma, or a preexisting medical condition that requires additional interventions. CCTPs must balance their needs for warmth, privacy, and protection against patient care needs such as exposure, thorough assessment, and patient access for monitoring or procedures. It may be advisable in many situations to defer a thorough visual assessment or invasive interventions in the interest of keeping a patient clothed, covered, and warm during extreme environmental conditions.

Prolonged evacuation of a patient with altitude illness may also exceed the supplies, equipment, and capabilities of a particular transport team. When performing such transports, CCTPs should be mindful of critical supplies, such as oxygen, that may become rapidly depleted during the patient’s care. Monitoring equipment, ventilator, and infusion pump batteries may not have the longevity to continue functioning during a prolonged evacuation or transport from remote locations.

Summary

Patients with medical conditions related to environmental emergencies can pose a significant challenge to CCTPs. These conditions are often difficult to diagnose and manage while in the transport environment, so there is a risk of further deterioration in the patient's condition during movement from one location or facility to another. CCTPs need to keep these conditions in mind when caring for patients in a coma or those who have collapsed suddenly as a result of unknown causes. Knowing the risk factors that predispose a patient to environmental emergencies can aid in recognizing these conditions early in the patient encounter.

CASE STUDY

You have just arrived for your regularly scheduled rotor-wing shift, when your dispatch center advises that you are being dispatched to the Rocky Mountain Rural Clinic, situated at 8,200 feet (2,500 m) above sea level, for a patient diagnosed as having probable HAPE. The patient needs to be transported to Mercy Hospital for HBOT. After your flight team (the pilot, flight nurse, and you, a critical care paramedic) completes the safety briefing, you depart for the rural clinic.

On arrival, the attending physician meets your flight team. She advises you that the patient is a 42-year-old, 233-lb (106-kg) man who had been climbing in the local national park for the past 2 or 3 days with three other people when he started to report fatigue and severe dyspnea. The party began its descent from approximately 12,000 feet (3,700 m), which took approximately 9 hours, and then drove a vehicle to the local clinic. On arrival, the patient's dyspnea was mildly resolved; however, he had a decreasing level of consciousness.

Treatment in the clinic included oxygen via nonrebreathing mask at 15 L/min to treat central cyanosis, a chest radiograph that showed patchy bilateral infiltrates, and an ECG that indicated a right-side heart strain pattern. The patient has an IV line with an 18-gauge needle in his left wrist running normal saline to keep the vein open; he also has an indwelling urinary catheter, with minimal urine output. Medications that were given at the clinic include 10 mg of nifedipine (Procardia) by mouth and 80 mg of furosemide (Lasix) IV. The patient is presently resting but is in moderate distress and has a Glasgow Coma Scale score of 13 (eye opening score, 3; verbal score, 4; motor score, 6). Vital signs are a BP of 142/81 mm Hg, a heart rate of 132 beats/min, sinus tachycardia with no ectopy, respirations of 28 breaths/min with rales bilaterally, and an SpO_2 of 86% despite aggressive oxygen therapy. After a positive Allen test result, an arterial line was inserted into the right radial artery. Arterial blood gas readings show acute respiratory alkalosis with a pH of 7.49; $PaCO_2$, 30 mm Hg; PaO_2, 88 mm Hg; HCO_3^-, 22 mEq/L; and base excess, 1. All available laboratory values are unremarkable.

As you are preparing to secure the patient onto your litter for the flight, he coughs up a small amount of blood-tinged sputum. Rather than electively intubating the patient for the flight, you decide to apply CPAP in an effort to decrease his work of breathing. CPAP is applied initially at 5 cm H_2O, which seems to have no effect. You subsequently titrate the CPAP up to 7.5 cm H_2O, which decreases his work of breathing and decreases his anxiety level. Your partner contacts your base hospital physician to advise of the patient's status, obtain any additional orders, and give an estimated time of arrival. The base hospital physician requests that 8 mg of dexamethasone (Decadron) and 250 mg of acetazolamide (Diamox) be administered en route. As your partner transfers the patient's IV line to your pump and calibrates the arterial line to your monitor, you speak to the pilot and advise him that owing to the patient's condition, it is imperative to fly at a lower altitude to minimize the effects of altitude on the patient.

Once airborne, 8 mg of dexamethasone and 250 mg of acetazolamide are given IV, and all hemodynamic parameters are monitored throughout the 48-minute flight. When you arrive at the Mercy Hospital helipad, the patient is taken directly to the hyperbaric chamber for definitive treatment.

1. How was the diagnosis of HAPE determined?
2. Why was the patient given nifedipine, furosemide, dexamethasone, and acetazolamide?
3. What are the potential problems that you may experience en route with this patient?

Analysis

Because of your critical care training, you are able to recognize that this patient is experiencing severe HAPE based on the Lake Louise acute mountain sickness criteria (described in Table 19-5).

Although you realize that HAPE usually resolves with descent from altitude, this patient was experiencing a severe case that did not resolve. In fact, the patient's condition appeared to be deteriorating.

Nifedipine is given to patients with HAPE to promote vasodilation of the pulmonary vessels, and furosemide is given to promote diuresis. Acetazolamide is administered to increase the amount of bicarbonate excreted in the urine, making the blood slightly acidic; this effect, in turn, stimulates ventilation, increasing the amount of oxygen in the bloodstream. Dexamethasone is given to treat pulmonary edema and to minimize cerebral edema.

This patient has the potential to experience several problems en route. Owing to the 48-minute flight to the receiving hospital and the fact that the patient is receiving CPAP, there is a risk that the crew might run out of oxygen; however, during your thorough preflight check of the aircraft, oxygen cylinders that are almost depleted should have been noted and replaced before the mission began. In any patient with an altered mental status in the flight environment, CCTPs need to be aware of the possible need to perform definitive airway management, which is often difficult to achieve in the confined space of a helicopter. Finally, this patient was experiencing an acute case of HAPE, and, depending on the altitude required during the flight, his pulmonary edema could progressively worsen. Good communication between the crew and the pilot will help to minimize the effects of pressurization, thereby minimizing the risk of complications en route.

PREP KIT

Ready for Review

- Very young and very old people, people taking certain medications, and people in a poor state of health are predisposed to environmental emergencies. The challenge for CCTPs is to recognize patients who are susceptible to environmental exposure in conditions that are not extremely hot or cold. CCTPs must also initiate or continue critical interventions during transport of these patients.
- The hypothalamus acts as the body's master thermostat, using negative feedback control. The three major components of the negative feedback system are temperature receptors, effector organ systems, and an integrator or controller.
- To reduce excess body heat, blood vessels in the skin dilate, perspiration increases, and muscle activity is inhibited.
- To increase body heat, the posterior hypothalamus is stimulated to constrict blood vessels, increase muscle activity (shivering), and activate the piloerector muscles.
- The heat produced at rest by normal metabolic reactions is referred to as the basal metabolic rate (BMR). Fat-free mass, age, sex, stress, hormones, and body surface area can all affect the BMR.
- Heat produced by metabolism and glycogen breakdown warms the body and maintains the core body temperature.
- The body transfers excess heat to the environment through radiation, conduction, convection, and evaporation. If the environment is hotter than the body, the body gains heat through absorption. Humidity can affect thermoregulation by impairing the evaporative process.
- The body shifts to thermogenesis when the environment is cold. In very cold temperatures, a fair amount of heat loss occurs through

respiration, and the BMR and physical exertion are increased to produce more kilocalories per hour.

- Heat illness occurs when core body temperature increases to a point that exceeds the body’s ability to dissipate the excess heat. CCTPs in all geographic regions of the United States should be prepared to transport patients with heat-related illnesses.
- CCTPs should be familiar with medications that contribute to heat illness, as well as medication-related causes of hyperthermia or heat illness such as neuroleptic malignant syndrome and malignant hyperthermia.
- Older adults are particularly at risk of heat illness as a result of underlying illness and other metabolic changes. Specifically, they may perspire less, feel thirst more slowly, have difficulty swallowing, have decreased mobility, or take medications that can alter or impede thermoregulation.
- Among the young and healthy population, children exposed to hot environments are most vulnerable to heat stressors. Compared with adults, children have higher rates of metabolism and do not dissipate heat as well.
- Prolonged hyperthermia, such as may occur during athletic or recreational activity, may lead to exertional heatstroke. This life-threatening condition has a high mortality rate if not promptly recognized and treated with body cooling.
- Heat cramps are thought to result from an imbalance of water and sodium, and are often not accompanied by hyperthermia. The patient with heat cramps should be removed from the hot environment, lie supine if feeling faint, and be instructed to drink a salt-containing liquid or electrolyte drink. CCTPs should use caution when administering IV fluids to correct presumed hyponatremia.
- Dilutional hyponatremia may occur if the person tries to replenish fluids by drinking excessive amounts of free water in a very short time.

- Additional cooling measures may be needed if the person has heat exhaustion, heatstroke, or significant hyperthermia.
- Treatment of heat syncope—an episode of collapse or near collapse that typically occurs in a non-acclimatized person—focuses on placing the patient supine or in the recovery position and allowing fluid intake if mental status permits. If the patient does not recover quickly, suspect heat exhaustion or heatstroke.
- Two forms of heat exhaustion exist: water-depleted exhaustion, which primarily occurs in older adults, and sodium-depleted exhaustion, which results from excessive losses of sodium through sweating and may take hours to days to develop. If left untreated, heat exhaustion may progress to heatstroke.
- Heatstroke is a severe disturbance in the body’s thermoregulation, resulting in CNS dysfunction and a core body temperature of more than 104°F (40°C). The critical thermal maximum is reached when the core body temperature exceeds 109.4°F (43°C).
- CCTPs should be aware of the differences between classic and exertional heatstroke and remain alert for the possibility of heatstroke during heat waves, especially when caring for patients with coma of unknown origin.
- Treatment of heatstroke focuses on lowering the core body temperature as quickly as possible. Evaporative cooling can be started and continued during transport.
- Heat emergencies can occur at any time of year, especially in older adults. CCTPs should pay attention to signs of poor skin turgor and lack of sweating when transporting an older patient with a fever. The patient’s history is also an important source of information in diagnosing heatstroke.
- Most cold-related injuries are localized to exposed body parts. The most susceptible parts are the tip of the nose, the ear lobes, and the fingers and toes.
- Frostbite is classified similarly to burns, using four degrees of injury:

  - First-degree frostbite is characterized by numbness, erythema, and capillary leakage resulting in localized edema.
  - Second-degree frostbite involves superficial blistering.
  - Third-degree frostbite involves deep hemorrhagic blistering.
  - Fourth-degree frostbite involves damage to deep subcutaneous tissues such as muscle and bone.
- Hypothermia is a decrease in core body temperature to less than 95°F (35°C), which may result from impaired thermogenesis, excessive heat loss, or excess environmental cold stress.
- Mild hypothermia is defined by a core body temperature between 90°F and 95°F (32.2°C and 35°C). The body usually compensates for mild hypothermia with increased thermogenesis and interrupted thermolysis.
- Moderate hypothermia is defined by a core body temperature between 82°F and 90°F (27.7°C and 32.2°C).
- Severe hypothermia occurs when the core body temperature drops below 82°F (27.7°C). The body reacts by slowing metabolism, which decreases thermogenesis, heart rate, BP, and cardiac output and has many other effects. Treatment focuses on warming the patient.
- Hypothermia can occur at any time of year, particularly in older adults. CCTPs should sacrifice their personal comfort to create an adequately warm environment for the resuscitation or transport of patients with hypothermia.
- Treatment of drowning patients begins with spinal motion restriction of patients witnessed diving into the water and when alcohol use is suspected. Ventilation should be initiated immediately if warranted, and advanced airway management where necessary.
- Divers may experience nitrogen narcosis, caused by nitrogen dissolving from inhaled gas into fatty tissues. Nitrogen gas bubbles expanding rapidly on ascent from depth may cause the

“bends,” the “chokes,” the “staggers,” and the “creeps” or “skin bends.”

- Barotrauma may occur during either ascent or descent in a dive, as gases stored in confined spaces within the body either expand or contract during these changes in elevation. The patient’s lungs, ears, and gastrointestinal tract are susceptible to injury from barotrauma.
- Pulmonary overpressurization syndrome is caused by rapid ascent during a dive; it occurs when gases in the lungs expand rapidly as the pressure decreases and pneumothorax or mediastinal or subcutaneous emphysema results. Arterial gas embolism may occur, which can result in acute myocardial infarction or stroke.
- CCTPs can consult the Divers Alert Network (DAN) hotline for guidance on treatment, transport, and patient disposition in cases of diving injury and decompression sickness.
- CCTPs should closely monitor patients with decompression sickness, even if they show signs of improvement or recovery. Relapses are possible.
- Hyperbaric oxygen therapy may be indicated for patients with decompression sickness and some other conditions, such as tissue edema following crush injuries, burns, and other types of trauma.
- If air evacuation is used for an injured diver, cabin pressure must be kept near sea level and the aircraft should not fly above 800 feet (244 m) unless necessary for safety precautions. Many experts recommend that patients with diving injuries be transported in a supine position.
- Hypoxia from the low atmospheric pressure found at high altitude is the main culprit in altitude sickness, also called acute mountain sickness. The Lake Louise criteria are useful for identifying this condition.
- High-altitude pulmonary edema (HAPE) may develop within 24 to 72 hours of reaching higher altitudes. Symptoms include cough, respiratory distress, chest tightness, fatigue, and fever. Rapid

descent is the preferred treatment for HAPE, along with supplemental oxygen.

- High-altitude cerebral edema (HACE) is a life-threatening condition; when it is recognized, immediate descent should be initiated. Mental status changes and ataxia are symptoms of HACE.
- CCTPs may be asked to rescue or evacuate patients from remote areas at high elevation. These locations are very hazardous, and safety issues such as training and experience of personnel, capabilities of the transport vehicle, weather and environmental concerns, and the severity of illness and capabilities of the patient must be considered before accepting the assignment.
- Capabilities and safety concerns related to the transport vehicle must be balanced with the patient’s clinical needs. Although rapid descent is ideal for patients with severe altitude illness, it may not be possible owing to environmental factors. A thorough visual assessment or invasive interventions may have to be deferred because of environmental conditions. Critical supplies and equipment must be monitored closely.

Vital Vocabulary

Absorption Acquisition of additional heat, radiation, or other energy from the environment; or, movement of a substance’s molecules from the site of entry on the body into the systemic circulation.

active warming A method of warming a hypothermic patient that involves the introduction of exogenous heat sources to the patient; measures may include infusing warmed IV fluid, delivering warm, humidified oxygen, or administering a peritoneal lavage of a potassium chloride–free solution or nasogastric/orogastric lavage with warmed fluids.

atelectasis Collapse of all or part of a lung.

barotrauma Injury to tissues, organs, or structures within the body, resulting from rapid or significant changes in environmental air pressure.

basal metabolic rate (BMR) The heat energy produced at rest by normal body metabolic reactions, determined mostly by the liver and skeletal muscle.

conduction Transfer of heat to a solid object or a liquid by direct contact.

convection The mechanism by which heat (body heat, in the context of this chapter) is picked up and carried away by moving air currents.

dilutional hyponatremia A condition caused by excessive intake of fluids in which serum sodium concentration is less than 135 mmol/L; sometimes referred to as water intoxication.

evaporation The conversion of a liquid to a gas.

exercise-associated hyponatremia (EAH) A condition occurring within 24 hours of sustained physical activity in which fluid consumption exceeds fluids lost, resulting in dilution of serum sodium levels. Signs and symptoms may include nausea, vomiting, and, in severe cases, mental status changes and seizures.

exertional heatstroke A thermoregulatory emergency that occurs during activities that require physical exertion in warm environments. This condition is defined by an excessive core body temperature, typically greater than 104°F (40°C), and associated CNS impairment.

fat-free mass (FFM) The proportion of body mass that consists of tissues other than adipose tissue, and that therefore consumes calories; typically the largest determinant of the basal metabolic rate in a healthy person.

free water Water that is not bound to molecules in the body.

frostbite Localized damage to tissues resulting from prolonged exposure to extreme cold.

heat cramps Acute and involuntary muscle pains, usually in the lower extremities, the abdomen, or both, that occur because of profuse sweating and subsequent sodium loss in sweat.

heat exhaustion A clinical syndrome characterized by volume depletion and heat stress that is thought to be a milder form of heat illness on the continuum leading to heatstroke.

heatstroke The least common and most deadly heat illness, caused by a severe disturbance in thermoregulation, usually characterized by a core body temperature of more than 104°F (40°C) and altered mental status.

heat syncope An orthostatic or near-syncopal episode that typically occurs in non-acclimated people who may be under heat stress.

high-altitude cerebral edema (HACE) An altitude illness characterized by a change in mental status and/or ataxia in a person with acute mountain sickness, or the presence of mental status changes and ataxia in a person without acute mountain sickness.

high-altitude pulmonary edema (HAPE) An altitude illness characterized by dyspnea at rest, cough, severe weakness, and drowsiness that may eventually lead to central cyanosis, audible rales or wheezing, tachypnea, and tachycardia.

hyperbaric oxygen therapy (HBOT) A treatment for decompression sickness and certain other conditions that involves placing the patient in a specially constructed chamber designed to withstand high internal pressures, well in excess of normal atmospheric pressures.

hypothalamic-pituitary axis An interrelationship between the hypothalamus and the pituitary gland in which a releasing or inhibiting factor is sent from the hypothalamus to the pituitary, resulting in, respectively, an increase or decrease in metabolism and other functions throughout the body.

hypothalamo-hypophysial portal system The venules between the capillaries in the hypothalamus and pituitary gland by which the hypothalamus sends releasing or inhibiting factors to the pituitary gland, thereby increasing or decreasing metabolism, respectively.

hypothalamus The most inferior portion of the diencephalon; it is responsible for control of many body functions, including heart rate, digestion, sexual development, temperature regulation, emotion, hunger, thirst, and regulation of the sleep cycle.

hypothermia A condition in which the core body temperature decreases to less than 95°F (35°C).

malignant hyperthermia A condition that can result from commonly used anesthesia medications (notably succinylcholine); it presents with hyperthermia, muscular rigidity, altered mental status, and a hyperdynamic state.

mild hypothermia A condition in which the core body temperature is between 90°F and 95°F (32.2°C and 35°C); at this stage of hypothermia, the body usually compensates with increased thermogenesis and interrupted thermolysis.

moderate hypothermia A condition in which the core body temperature is between 82°F and 90°F (27.7°C and 32.2°C); mental status is markedly decreased, and shivering may still be present but is less vigorous and unlikely to be an effective from of thermogenesis.

neuroleptic malignant syndrome A condition caused by antipsychotic and antiemetic medications that presents with hyperthermia, muscular rigidity, altered mental status, and a hyperdynamic state.

nitrogen narcosis A state resembling alcohol intoxication, which is produced by nitrogen gas dissolved in the blood at high ambient pressure.

passive warming A method of warming a hypothermic patient without the introduction of exogenous heat sources. It involves removing cold, wet clothing; drying the patient if necessary; and wrapping the patient in layers that retain radiant heat, minimize conductive heat loss, and protect from ambient moisture such as rain or snow.

pulmonary overpressurization syndrome (POPS) A diving emergency that can occur during ascent and cause pneumothorax, mediastinal and subcutaneous emphysema, alveolar hemorrhage, and the lethal arterial gas embolism; also called burst lung.

radiation Emission of heat from an object into surrounding, colder air.

respiration The loss of heat as warm air in the lungs is exhaled into the atmosphere and cooler air is inhaled.

severe hypothermia A condition in which the core body temperature drops to less than 90°F (32.2°C).

thermogenesis The production of heat in the body.

thermolysis The liberation of heat from the body.

thermoregulation The process by which the body maintains temperature through a combination of heat gain by metabolic processes and muscular movement and heat loss through respiration, evaporation, conduction, convection, and perspiration.

water intoxication A condition in which the normal balance of electrolytes in the body is pushed outside safe limits by the overconsumption of water.

CHAPTER 20

Infectious and Communicable Diseases

Robert P. Holman, MD
Ryan B. Gerecht, MD

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the types of immunity and the components of humoral and cell-mediated immunity (pp 1048, 1050–1051).
2. Describe the types of anaphylaxis and the signs, symptoms, and treatment of anaphylaxis (pp 1052–1053).
3. Discuss the implications of transporting patients with immunodeficiencies (p 1054).
4. Discuss the differences between normal, opportunistic, and pathogenic organisms (p 1055).
5. Explain the virulence factors found in pathogenic organisms, including how they can spread from bacterial cell to bacterial cell (p 1055).
6. Describe the portals of entry for infectious organisms and the process of infection once entry is gained (p 1056).
7. Compare the effects of bacterial endotoxins and exotoxins (p 1056).
8. Describe viral pathogenesis (p 1057).
9. Discuss epidemiology, including reservoirs of infection and transmission of infectious disease (p 1057).
10. Discuss the etiologic agents, mode of transmission, signs and symptoms, and treatment of the following:
    - Meningitis (bacterial and viral)
    - Respiratory syncytial virus
    - Cellulitis
    - Necrotizing fasciitis
    - Epiglottitis
    - Tuberculosis
    - Pneumonia

- Fungal diseases
- Influenza
- Various herpesviruses
- Viral hepatitis
- Human immunodeficiency virus
- Rickettsial diseases such as Rocky Mountain spotted fever
- COVID-19 (caused by SARS-CoV-2)
- *Escherichia coli* O157:H7
- West Nile virus
- Methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *S aureus*
- Vancomycin-resistant enterococci
- Carbapenem-resistant gram negative bacilli (pp 1062–1095)

11. Understand acquired immunodeficiency syndrome–defining conditions (p 1082).
12. State the recommendations for use of standard precautions in all health care settings (p 1086).
13. Understand how the overuse and misuse of antimicrobials lead to resistant infectious organisms (p 1093).
14. Explain standard precautions, including situations in which they should be used (p 1099).
15. Explain isolation, airborne, and droplet precautions, including situations in which they should be used (pp 1099–1101).
16. Discuss the importance of handwashing and use of hand sanitizers and/or hand antiseptics in preventing contamination and transmission of infectious diseases (p 1101).
17. Discuss the appropriate and correct use of personal protective devices (both donning and doffing) (p 1101).
18. Identify the vaccinations needed for CCTPs and health care workers in general (p 1107).
19. Understand decontamination chemicals and techniques appropriate for cleanup after transporting patients harboring various infectious diseases. Include decontamination of equipment and vehicle surfaces as well as uniforms (clothing and shoes) and personal protective equipment (p 1106).
20. Discuss actions to take after blood exposure (p 1106).

Introduction

The word **immunity** comes from the Latin word *immunis* and the 14th-century French word *immunité*, referring to a person who has an exemption or inviolability from something. In the modern medical sense, this term retains some of this meaning, in that it refers to protection from infection. Immunity is provided by a complex system of substances, cells, and tissues that exist to protect the human body from infection. While the function of the immune system is to protect against infection, it is also capable of causing damage.

The relationship between humans and infectious disease is an important one to understand. Perhaps it is this relationship, more than anything else, that has determined where we are today as a species.

One example of the countless outbreaks of disease and pandemics that have afflicted humans is the Black Death of the 14th century. This outbreak of bubonic plague, caused by infection with the bacterium *Yersinia pestis*, was the deadliest pandemic recorded in human history. It spread through Europe, Asia, and North Africa, killing an estimated one-third of the European population. The Black Death created religious, social, and economic turmoil.

The social impacts of disease are sometimes more dangerous than the diseases themselves. The threat of disease instills fear, oftentimes leading to irrational behaviors. In our time, the COVID-19 pandemic, caused by the SARS-CoV-2 virus, has demonstrated the dramatic effects of a serious, worldwide contagious disease.

With each outbreak, we learn more about keeping ourselves safe. Better knowledge of diseases and how they spread, consistent use of personal protective equipment (PPE), and a mix of appropriate responder behaviors and organizational policies can all improve the safety of health care providers.

Medical professionals who are involved in critical care and transportation of patients are at high risk for exposure to a multitude of pathogens during the course of their work. An understanding of infectious disease, the ways in which the body responds to disease, and the methods used to reduce the spread of disease will help critical care transport professionals (CCTPs) keep themselves—and consequently their families, coworkers, and communities—safe.

Fundamental Principles of Infectious Disease

Complexity of the Spread of Disease

The spread of infectious disease is a complex process that results from interactions between the host, the infectious agent, and the environment. It is important that all health care professionals know and understand that the spread of disease is dynamic and does not adhere to the strict models used to describe how pathogens are spread—for example, “airborne” or “airborne droplet.” Additionally, the ecology of each pathogen is not always completely understood.

As an example, consider the 2004 outbreak of Nipah virus (NiV) in Siliguri, India, near the border of India and Bangladesh. People within the community started to become ill from an unknown disease. It was later discovered that their illness was somehow connected to a popular drink made from date palm sap. Further investigation revealed that fruit bats were contaminating the sap with NiV. This virus, like many zoonoses, causes disease in both humans and animals. While the natural reservoir for NiV is a type of fruit bat, this virus, like many diseases, can also exist in intermediate hosts such as pigs, cows, and goats. NiV was first recognized as a disease in humans in Malaysia in 1998. During that and other outbreaks, there were no documented cases of human-to-human spread. During the 2004 Bangladeshi outbreak, however, human-to-human spread was well documented. This factor is important because human-to-human transmission significantly increases the threat that a disease poses to a population.

NiV infection can be asymptomatic in some people, yet cause acute respiratory failure or fatal encephalitis in others. Some human-to-human spread of the disease has occurred through contact with an infected person’s saliva, urine, or other body fluids. Spread throughout hospitals has occurred even when the index patient was previously unrecognized. Researchers have estimated the mortality rate to be 40% to 75% depending on local capabilities for surveillance and disease response.

Pinpointing the nature of disease spread can be complex. During the Bangladeshi outbreak, most people who became ill had contact with another ill person, yet two of the people who were infected had no known contact with other people who became ill. Adding to the puzzle, one study revealed that 57 environmental specimens were taken from the residences of people who became ill, but none tested positive for the virus. Additionally, while significant spread occurred within the hospital (although no health care workers became ill), only 11 of 498 environmental samples from that venue tested positive for the disease. This was true despite the aggressive spread and course of the disease, which often killed people.

The Nipah virus outbreaks provide an excellent example of the emergence of a deadly disease and the dynamic spread of disease that does not adhere strictly to common models.

Classification

A formal classification scheme for microorganisms was developed in the late 1960s, when Carl Woese devised a system that classified microorganisms according to their physical properties and cellular components. **TABLE 20-1** lists the major classes of microorganisms and their properties.

TABLE 20-1 **Classification of Organisms**

Organism	General Information	Cell Wall/Cell Membrane Components	Drug Classes, Groups of Actions (Use)	Medications
Bacteria	Prokaryote versus eukaryote bacteria: prokaryotes Cellularity: unicellular Reproduction: binary fission	Peptidoglycan cell wall No sterols in the membrane (except *Mycoplasma*) Mycolic acid in the cell wall of mycobacteria	Cell wall synthesis inhibitors	
			• Beta-lactams	Penicillins and cephalosporins
			• Glycopeptides	Vancomycin
			Protein synthesis inhibitors	
			• Tetracyclines	Doxycycline
			• Aminoglycosides	Amikacin and gentamicin
			• Macrolides	Erythromycin (many brand names)
			DNA/RNA synthesis inhibitors	
			• Quinolones or fluoroquinolones	Ciprofloxacin Polymyxin B
			Alter cell membrane permeability	
			Antimetabolites	
			• Sulfonamides	Sulfamethoxazole
Viruses	Prokaryote versus eukaryote: neither Cellularity: acellular Reproduction: N/A	None (lack cells)	Viral attachment inhibitor	Enfuvirtide
			Viral uncoating inhibitor (influenza)	Amantadine (Symmetrel) and rimantadine
			Neuraminidase inhibitors (influenza)	Zanamivir and oseltamivir
			DNA/RNA synthesis inhibitors (HIV, herpes, cytomegalovirus)	Acyclovir, ganciclovir and zidovudine
			Protease inhibitors (HIV)	Indinavir and saquinavir
			Interferon (hepatitis)	Interferon
Protozoa	Prokaryote versus eukaryote: eukaryotes Cellularity: unicellular Reproduction: asexual or sexual	No cell wall	Antimetabolites	Trimethoprim-sulfamethoxazole combination
			DNA synthesis inhibitors	
			• Nitroimidazoles (unknown mode of action)	Metronidazole
			• Quinolines	Chloroquine and quinacrine
Helminths	Prokaryote versus eukaryote: eukaryotes Cellularity: multicellular Reproduction: complex	No cell wall	Antimetabolites	
			• Benzimidazole	Mebendazole and praziquantel
Fungi	Prokaryote versus eukaryote: eukaryotes Cellularity: unicellular (yeasts) or multicellular (molds) Reproduction: asexual	Chitin cell wall Unique sterols (ergosterol) in the membrane	Ergosterol synthesis inhibitors	
			• Azoles	Ketoconazole (Nizoral) and miconazole (Monistat, Micatin)
			• Allylamines	Terbinafine (Lamisil)

	or sexual		Alters cell membrane permeability • Polyene Mitotic inhibitor (prevents cell replication)	 Amphotericin B Griseofulvin
Prions	Prokaryote versus eukaryote: neither Cellularity: acellular Reproduction: N/A	None (lack cells)	N/A	N/A

Abbreviations: DNA, deoxyribonucleic acid; HIV, human immunodeficiency virus; N/A, not applicable; RNA, ribonucleic acid

Description

The same physical properties and components that are used to determine the classification of microorganisms also affect how they invade the host, turn into an infection, and cause disease. Microorganisms possess properties that are unlike the properties possessed by human cells. These differences not only allow the immune system to recognize foreign invaders, but can also be exploited by researchers who seek to develop agents that can kill pathogens or otherwise inhibit their growth and spread. Well before Woese developed his classification system, Robert Koch and Louis Pasteur proved the germ theory of disease. Later, Paul Ehrlich pursued the idea that if an invading organism could be targeted and killed, the disease could be cured. Ehrlich wrote:

> If we picture an organism as infected by a certain species of bacterium, it will be easy to effect a cure if substances have been discovered which have a specific affinity for these bacteria and act on these bacteria alone. [If] they possess no affinity for the normal constituents of the body, such substances would then be magic bullets.

In 1909, Ehrlich discovered one such silver bullet—a chemical that killed *Treponema pallidum*, the microorganism responsible for the disease syphilis. Ehrlich realized that if he could manipulate a chemical so that it would fit into the "lock" of the offending organism but not into the "locks" on any human cells, he would be able to cure disease. In 1935, based on this idea, Bayer developed sulfanilamide, a drug that was found to be somewhat effective against staphylococcal and streptococcal infections. Sulfanilamide was derived from a coal tar compound.

This “magic bullet” archetype is still used in medicine today. All antibiotic, antiviral, and antifungal drugs are designed to target (1) specific proteins, macromolecules, cellular organelles, and enzymatic pathways or (2) reproductive strategies unique to the infectious agent that are not shared by their human host.

The Human Immune System

For people to contract a disease, they must be susceptible to that illness. Susceptibility is determined by numerous factors, such as nutritional status, immune status, genetic makeup, living conditions, and exposure. Diseases can be transmitted directly through inhalation, ingestion, or direct contact with infectious agents, or they can be spread indirectly via a vector (people, animals, and microorganisms), a **fomite** (an inanimate object such as clothing and furniture), or some other complex cycle of interactions.

Within the human body, there is a constant struggle between the host and would-be invaders, with both competing for nutrients, energy, and control of cellular synthetic mechanisms. The perpetual struggle between host and microbe pits the human immune defenses against microbes' ever-evolving ability to adapt to our defenses. These adaptations are often termed **virulence factors**, reflecting their contribution to the ability of the microbe to evade defenses and cause disease.

For the immune system to protect the body from invading microorganisms, it first must be able to recognize "self" components or cells and distinguish them from non-self components or cells. The immune system must be both highly specific (keeping watch for specific antigens) and general (able to keep up with numerous assaults without sending the body into a perpetual state of inflammation). The protection it provides must consist of several layers so that once one level of immunity has been breached, additional defenses against infection are launched and continue the assault. This multilayered system allows for a gradation of response, appropriate for the current threat. Additionally, the immune system must include cells that are designed to respond to many types of pathogens ("diversity") while recognizing the difference between the body's many cells and those that are non-self (**tolerance**). Finally, the immune system must be capable of "remembering" previous interactions so that it can mount a response to the same agent or a closely related agent sometimes years after the initial exposure—a feature called memory. All of these components must work in a coordinated effort, providing protection from infection and malignancy, without self-destruction.

Types of Immunity

Immunity can be either innate or adaptive. **Innate immunity** is immunity that an individual is born with. It provides protection from invading pathogens despite a lack of prior exposure to them. The skin and mucous membranes and their secretions provide mechanical and chemical barriers to invasion and are the primary components of innate immunity. Innate immunity is nonspecific, is activated immediately upon detection of invasion, and has no memory. The components of the innate immune system work to eliminate invading organisms through various methods, including activating the adaptive immune response and preventing the entry of the microorganisms into the body. In addition, nonspecific factors of the immune system help limit the growth of microorganisms within the body:

- Macrophages, a type of white blood cell, ingest and destroy microbes.
- Neutrophils, the most abundant innate immune cells, act as phagocytes.
- Natural killer cells, another type of white blood cell, have the job of recognizing and killing host cells that are infected with a virus.
- The complement system is a group of proteins that, when activated, begin a cascade of events that aid in the clearing of bacterial cells.
- Transferrin is a carrier protein that sequesters iron, keeping that vital element from being available to the invading microbes.

These parts of the innate system, in combination with the body's general responses to invasion such as fever or inflammation, react whenever the body perceives itself to be under assault by an invader.

Adaptive immunity (also referred to as acquired immunity) comes into play when the body's innate defenses are unable to stop the invading pathogen. Adaptive immunity develops as a result of interactions between components of the immune system and the invading microbe, thereby providing improved protection with repeated exposures to the same or a similar agent—a concept referred to as immunologic memory. The two main types of adaptive immunity are humoral and cell-mediated immunity. Humoral immunity is provided by B cells through the production of antibodies and by complement; cell-mediated immunity is provided by T cells. Cytokines and macrophages are modulators of both cell-mediated and humoral immunity, providing signals to the players—revving up or toning down the immune response as appropriate.

Adaptive immunity can be either active or passive.

- **Active immunity** refers to an ongoing process of developing antibodies and activating T cells in response to invading agents. It is activated either when an individual is exposed to microbes through the natural process of infection or when this process is artificially stimulated through a vaccine.
- **Passive immunity** is the process of giving an individual a preformed antibody (from a donor) in the event of an exposure to which the individual has not yet developed immunity. (There is some level of risk of contracting bloodborne infectious diseases from the use of preformed or pooled human immunoglobulin.) For example, if a provider were exposed to a patient known to have hepatitis B, the provider could be given hepatitis B immunoglobulin (HBIG) during the incubation period to prevent infection. Before the development of the hepatitis A vaccine, travelers to countries highly endemic for hepatitis A were administered preventive depot injections of standard immune globulin (formerly called gamma globulin), a concentrated solution of antibodies prepared from pooled human plasma. Passive immunity also occurs when antibodies from a mother are

passed to her fetus by crossing the placenta into the fetal circulation, or to an infant through breast milk.

Active immunity, once developed, provides long-lasting protection against invading microbes, but is initially slow to develop. Passive immunity is immediate but does not confer a lasting effect. Moreover, because it does not originate with the individual, it must be continually boosted. Vaccination schedules were created for precisely this purpose: Passive immunity in the infant lasts up to 1 year depending on the pathogen, so vaccines are given to ensure continued protection.

Antigens

An **antigen** is anything that can cause an immune response, but typically takes the form of a protein or sugar that is anchored into the cell membrane and displayed on the cell's surface. The word *antigen* is an abbreviation for *anti*body *gen*erator. An antigen is recognized by the immune system as either self or non-self. All cells display antigens, including humans' own cells. If an antigen is identified by the body as foreign or "non-self," the body initiates either a humoral or cell-mediated response to eliminate it.

Organs and Cells of the Immune System

The highly complex immune system is composed of many organs and cell types. The organs of the immune system are categorized by anatomic location, either central or peripheral.

The lymphatic system comprises the network of capillaries, vessels, ducts, nodes, and organs that produces and conveys lymph through the body **FIGURE 20-1**. The central lymphoid organs are the thymus and the bone marrow, which serve as the site of synthesis and differentiation of immune cells. The thymus is located in the mediastinal cavity anterior and superior to the heart. It weighs 15 to 35 g at birth and continues to increase in size until puberty, when it begins to shrink. The thymus is where the T lymphocytes differentiate from naïve, nonspecific T cells into T cells with specific purposes. In contrast, the bone marrow is the site of B-cell synthesis.

Like the veins, the lymphatic vessels contain valves that prohibit backflow. Lymph nodes are interspersed along the vessels and filter the lymph.

© Jones & Bartlett Learning.

Description

The peripheral lymphoid organs are where much of the immune cells' work is done; these organs include the spleen, lymph nodes, tonsils, intestinal Peyer patches, and mucosa. For example, the spleen is where encapsulated bacteria are encountered and destroyed. Removal of this organ leaves the patient more susceptible to infection, especially from *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Lymph nodes are made up of lymphoidal tissue located throughout the body; they are especially prominent in the neck, axilla, mediastinum, and groin. Lymphadenopathy, an increase in the size of a lymph node or lymph nodes, indicates a high level of immunologic activity. Thus, lymphadenopathy is a clinical sign commonly seen in patients fighting infection or cancer.

The T lymphocytes acquire their distinctive characteristics while maturing in the thymus. The mature cells express phenotypic markers or clusters of differentiation called CD markers. CD4+ cells are the helper T cells, and CD8+ cells are the cytotoxic suppressor T cells. The CD4+ helper T cells are regulators of the immune system. They help B cells develop into antibody-producing plasma cells. They also help activate CD8+ cells, and they participate in delayed hypersensitivity reactions, which is important in limiting *Mycobacterium tuberculosis* infections. CD8+ lymphocytes kill virus-infected and tumor cells.

The B lymphocytes mature in the bone marrow, where they acquire their characteristic markers (eg, CD20, CD21, CD37). B cells have two important roles in the immune system: They differentiate into plasma cells that produce specific antibodies on encountering an antigen, or they become memory cells.

Humoral Immunity

Humoral immunity is mediated by antibodies—that is, globulin proteins (immunoglobulins [Ig]) that react to antigens. Antibodies are produced by mature B cells, called plasma cells. There are five classes of antibodies: IgA, IgM, IgG, IgE, and IgD. Each immunoglobulin serves a different purpose. For example, IgA is found in secretions such as colostrum (early breast milk), saliva, and tears. This antibody is also present in the respiratory, intestinal, and genital tracts, where it prevents the attachment of bacteria and viruses to mucous membranes. IgG is the only immunoglobulin that crosses the placental barrier. IgG and IgM are the only two immunoglobulins that activate complement. IgE is important in protecting the body against certain parasitic infections, such as helminths or worms, and it mediates the immediate hypersensitivity reaction. IgE recognizes parasites; thus, an allergic reaction is actually the body believing it has been invaded by parasites. Antibodies and complement protect against infection by neutralizing toxins and viruses, and they make microorganisms more easily phagocytized (a process called **opsonization**).

The humoral (antibody-mediated) response is effective against agents that produce toxins, against bacteria that have polysaccharide capsules, and against some viral infections. The primary response occurs when the immune cells encounter a specific antigen for the first time. Antibodies do not appear until 7 to 10 days after the initial encounter with the antigen. Upon a second encounter with the same antigen, or a closely related antigen, the response occurs more rapidly. With this so-called secondary response, the lag time until the antibody is detected in the serum is only 3 to 5 days, and the antibody titers are much higher than those seen in the primary response. These differences arise because the first encounter leads to the production of memory B cells, which in turn promote a more rapid production of cells that can respond to neutralize the pathogen. With repeated encounters, the response is elicited more rapidly and becomes more specific.

Infection with a related virus may impart immunity against other viruses in the same family, because related viruses often contain similar structural proteins. If there are enough similarities, the immune system will recognize both the original and related viruses as non-self and destroy them before allowing infection to take hold. An example of how this effect can be exploited to protect against disease is the use of cowpox virus infection to prevent smallpox infection.

Some pathogens are never completely eliminated. For example, many health care–acquired infections (HAIs) and rickettsial diseases may never be completely eliminated from the body. It is important to differentiate between latent infection and chronic infection. A latent infection is present when the pathogen has infected the patient but is not reproducing or causing disease. A chronic infection is caused by a pathogen that the body has not successfully fought off and is accompanied by a reduced immune response.

Cell-Mediated Immunity

Cell-mediated immunity (CMI) plays an important role in defending against intracellular infections, such as tuberculosis or gonorrhea, as well as viral infections, fungal infections, parasites, and tumors. The strongest evidence of its importance is illustrated in acquired immunodeficiency syndrome (AIDS), a condition in which the destruction of cell-mediated immunity results in overwhelming infections and unusual tumors. Cells involved in CMI include the following:

- *CD4 helper T cells*: Help with antigen recognition and immune response by activating CD8 cytotoxic T cells, B cells, and macrophages.
- T_{reg} (*regulatory T cells*; formerly called suppressor T cells): Regulate the immune response to prevent over-response to a pathogen.
- *CD8 cytotoxic T cells*: Kill other infected or endogenous cells by producing perforins (proteins that cause holes to form in cell membranes, which lead to cell death through loss of the osmotic gradient) or by inducing **apoptosis** (programmed cell death).
- *Macrophages*: Ingest or destroy foreign cells, viruses, or debris (phagocytosis); present antigens (by activating T cells that can recognize foreign antigens); and produce cytokine (namely, interleukin 1 and tumor necrosis factor). The process of phagocytosis is carried out by macrophages, neutrophils, and

monocytes, which engulf and destroy bacteria, foreign antigens, and cellular debris. These cells process the bacteria, breaking them down by specialized cell processes.

- *Natural killer (NK) cells*: Large granular lymphocytes that do not express T-cell antigen receptors. NK cells destroy tumor cells or virus-infected cells by recognizing that those cells are not expressing “self” markers or do not appear abnormal; these cells kill any cells that appear different. Although NK cells are regulated by other proteins in the immune response, they do not require specific activation to produce perforin and granzymes that cause apoptosis or necrosis of target cells.
- *Cytokines*: Proteins produced by immune cells that modify the immune response. Chemokines are a type of cytokine that attract macrophages or neutrophils to the site of an infection.

Monoclonal Antibodies

Most naturally produced antibodies are polyclonal, meaning they are produced by many different types of B lymphocytes. Each of these antibodies has a slightly different specificity for the target antigen. For example, antibodies may bind different epitopes or may bind the same epitope with different affinities. However, large quantities of an antibody from a single B-cell clone can be produced to protect against a specific pathogen. These antibodies are called **monoclonal antibodies**.

Approximately 100 monoclonal antibodies have been developed and designated as drugs. These drugs, whose names all end with the suffix *mab*, are directed against various antigens and used to treat immunologic diseases and cancer and to reverse drug effects. They may target a plasma protein, an IgG receptor, an infectious organism, hematologic malignancies, solid tumors, autoimmune disorders, hypercholesterolemia, inflammatory bowel disorder, and even drug overdose (digitalis overdose). Use of monoclonal antibodies is particularly important in treating active disease or providing **prophylaxis** in people who have not been vaccinated but require protection against pathogens such as the SARS-CoV-2 virus (which causes COVID-19), the Ebola virus, or the Zika virus. For example, monoclonal antibody therapy may be given to pregnant women residing in Zika virus–endemic areas.

Hypersensitivity Reactions

The immune response can be harmful to the host when it is inappropriate or exaggerated. These types of harmful reactions, which are called **hypersensitivity** or allergic reactions, occur when people are exposed to a specific antigen. The first encounter sensitizes the person to the antigen and induces an antibody response. Subsequent encounters with the same or a closely related antigen then elicit the allergic response. This process explains why the first exposure to an allergen rarely induces an immune response, but subsequent exposures lead to progressively stronger reactions.

There are four major types of hypersensitivity reactions. Types I, II, and III are antibody-mediated responses, whereas type IV is a cell-mediated response.

Type I Reactions

Type I is an immediate hypersensitivity reaction involving IgE. The term *immediate hypersensitivity* reflects the fact that these reactions occur within minutes of exposure to the antigen. There are two categories of type I reactions: (1) atopy, which is a localized reaction, and (2) anaphylaxis, which is a systemic reaction.

In a type I reaction, excessive amounts of IgE are synthesized and bind to mast cells or basophils, which activates these cells and causes them to release their contents. The degranulation of mast cells releases histamine, leukotrienes, and tryptase, and stimulates the production of cytokines. In turn, the cytokines play roles in various reactions, including inducing rapid contraction of smooth muscle, increased vascular permeability, hypotension, and changes in the coagulation pathway. Localized histamine release causes urticaria, whereas systemic histamine release causes dose-dependent hemodynamic and cardiovascular changes, such as an increased heart rate, hypotension, and shock, which can be life threatening. Tryptase is an enzyme found in mast cells that, when released, activates complement proteins and the coagulation pathway; it has the potential to cause angioedema, clotting, and clot lysis, leading to disseminated intravascular coagulation in severe cases.

Anaphylaxis is defined as a serious systemic allergic reaction that has a rapid onset and a variable clinical presentation. If unrecognized, it can lead to respiratory arrest, circulatory collapse, and death. Common triggers for anaphylaxis include foods, medications, insect venom (particularly *Hymenoptera* venom), and some environmental agents such as latex. Anaphylaxis is frequently unrecognized and underreported. In fact, as many as 57% of anaphylaxis incidents related to food do not receive a diagnosis of anaphylaxis. For the CCTP, then, it is important to understand what anaphylaxis is and how to recognize it.

While anaphylaxis is a systemic event, the body systems involved vary from patient to patient and even from episode to episode in some patients. Most patients with anaphylaxis (as many as 90%) will have cutaneous involvement, including flushing, itching, urticaria, or angioedema. Upper airway involvement occurs in as many as 70% of patients, with signs and symptoms including changes in **phonation**, the sensation of throat closure or choking, cough, wheezing, and shortness of breath. As many as 45% of patients experience gastrointestinal conditions; cardiovascular involvement occurs in 45% of these patients.

Anaphylaxis may be difficult to diagnose if the patient does not develop the commonly discussed symptoms. While death from anaphylaxis is uncommon, a patient history of chronic obstructive pulmonary disease (COPD), asthma, or cardiovascular diseases should alert the caregiver that the patient is at greater risk of life-threatening anaphylaxis. The same is true for patients who have a history of severe eczema or severe allergic rhinitis. The use of beta blockers or angiotensin-converting enzyme (ACE) inhibitors may also increase the severity of anaphylaxis.

Anaphylactic symptom progression might take minutes to hours. Biphasic anaphylaxis occurs in as many as 20% of reactions. In a biphasic reaction, the initial resolution of symptoms is followed by a reappearance of symptoms; if this resurgence is not anticipated, it can be the cause of a life-threatening recurrence. In some rare cases, the reaction can last for many hours to days in patients with protracted anaphylaxis.

Some unique circumstances may place patients at increased risk for unrecognized anaphylaxis. For example, wheezing patients with a known history of asthma may be treated for an acute asthma exacerbation without taking into account any cutaneous symptoms, thereby placing them at greater risk for unrecognized anaphylaxis. Their wheezing may be mistakenly attributed to asthma, when it is actually occurring secondary to the respiratory symptoms associated with anaphylaxis. Having asthma puts patients at a high risk of death from anaphylaxis simply because the hypersensitivity reaction may not be recognized until much later in the presentation, delaying appropriate treatment. Patients with underlying neurologic impairment and psychiatric illnesses that interfere with cognition or impair judgment may not be able to express symptoms of **pruritus** or throat closure. Additionally, sedated patients are unable to recognize or communicate the presence of early symptoms; thus, it is incumbent upon the health care provider to recognize any subtle changes in the skin or vital signs that may signal the emergence of an allergic reaction.

Prompt assessment and treatment are critical for all patients with anaphylaxis. The first step in its management focuses on removal of the inciting antigen. Intramuscular epinephrine should be injected, and, if symptoms persist, an epinephrine drip should be established. As with all successful resuscitations, begin with airway management. If the patient shows any evidence of stridor, significant airway edema, or impending respiratory arrest, perform intubation immediately. Maintain breathing, and support circulation with supplemental oxygen and volume resuscitation. Place two large-bore intravenous (IV) lines for rapid fluid administration and place the patient on continuous cardiac/respiratory monitoring until the episode has resolved. All patients with anaphylaxis require fluid resuscitation, and those with hypotension or signs of shock should receive large-volume resuscitation. Adjunctive agents such as H_1 blockers (antihistamines) can be used for the treatment of itching or hives that fails to resolve after the administration of epinephrine. Patients who are wheezing can be treated with an inhaled beta-2 agonist if the wheezing does not resolve after treatment with epinephrine. The use of glucocorticoids does not appear to be helpful in acute anaphylaxis but may offer some protection against biphasic or protracted reactions.

A patient who is discharged from the hospital after an anaphylactic episode should be educated about their allergy. Such a patient should have an emergency action plan for any recurrence, including a prescription for and instruction in the proper use of an epinephrine auto-injector.

CONTROVERSIES

The term *anaphylactoid* is no longer in favor, although many providers continue to use this term. The difference between anaphylaxis, anaphylactoid, or pseudoanaphylaxis is not clinically significant.

Type II Reactions

Type II or cytotoxic hypersensitivity reactions are antigen-antibody reactions in which antibodies directed against an antigen on the surface of the host cell membrane cause activation of complement and subsequent lytic and osmotic damage to the host cells. They are seen in transfusion reactions, hemolytic disease of the newborn (erythroblastosis fetalis), and some autoimmune diseases. Either IgM or IgG antibodies are involved in this type of reaction.

Signs and Symptoms

Anaphylaxis (Type I Hypersensitivity Reaction)

Cutaneous involvement:

- Flushing
- Itching

- Urticaria
- Angioedema

Airway involvement:

- Changes in phonation
- Sensation of throat closure or choking
- Cough
- Wheezing or stridor
- Shortness of breath

Cardiovascular involvement:

- Tachycardia
- Hypotension

Transport Management

Anaphylaxis (Type I Hypersensitivity Reaction)

- Remove the antigen.
- Inject intramuscular epinephrine.
- If symptoms persist, establish an epinephrine drip.
- If there is any evidence of stridor, significant airway edema, or impending respiratory arrest, intubate the patient immediately.
- Provide oxygen supplementation and volume resuscitation.
- Place two large-bore IV lines for rapid fluid administration.
- Place the patient on continuous cardiac/respiratory monitoring including end-tidal carbon dioxide ($ETCO_2$) and pulse oximetry.
- In case of hypotension or signs of shock, provide large-volume resuscitation.
- Give H_1 blockers for ongoing itching or hives.
- Give an inhaled beta-2 agonist for ongoing wheezing.
- In case of a biphasic or protracted reaction, give glucocorticoids.

Type III Reactions

In type III hypersensitivity reactions, circulating antigen-antibody complexes are deposited in tissue or on the endothelium of blood vessels. There, they cause damage by activating complement proteins, releasing chemotactic and clotting factors, and attracting other immune cells to the area. Examples of this type of reaction include serum sickness, polyarteritis nodosa, glomerulonephritis, and systemic lupus erythematosus.

Type IV Reactions

In type IV (delayed-type) hypersensitivity reactions, tissue damage results from excessive activation of macrophages. Such reactions involve the interaction of macrophages and T cells, but the response is delayed from hours to days after the antigen is encountered. This hypersensitivity reaction is cell mediated and is not a humeral response, unlike types I, II, and III. Type IV reaction is exemplified by contact hypersensitivity, like that seen with exposure to poison ivy or poison oak.

Immunodeficiency

Immunodeficiency occurs when dysfunction in one or more of the components of the immune system leaves an individual vulnerable to disease. Immunodeficiency can be genetic or can occur secondary to environmental factors, medical interventions, or other diseases such as HIV/AIDS or malignancies. The specific component of the immune system that is not fully functional predisposes the patient to certain types of infection or disease. Patients with B-cell deficiencies, for example, are susceptible to recurrent infections with pyogenic bacteria such as *S pneumoniae* and *H influenzae*. A deficiency in T cells allows for recurrent infections with viruses, fungi, or protozoa.

Critically ill patients have few reserves to fight infections as a result of their diminished host defenses and loss of innate immunity. Features of chronic illness that decrease innate immunity include stress, malnutrition, invasive procedures, loss of physical barriers (eg, skin and mucosal surfaces), and pathogenic bacterial overgrowth or bacterial growth in normally sterile tissue. In addition, patients who are maintained on immunosuppressive therapy for the management of autoimmune diseases or to prevent rejection of a transplanted organ are at increased risk for a variety of infections and cancers.

Immunosuppression

Transplant Patients

Treatment of the transplant patient is an important aspect of critical care transports. Management of illnesses and injuries in such patients may be complicated by the side effects of medications or by their immunosuppressed condition. Immunosuppressive agents, such as cyclosporine, tacrolimus, azathioprine, and prednisone, are routinely prescribed to transplant patients in an effort to prevent rejection of the donor tissue. These medications can have serious side effects, including hypertension, hyperglycemia, hyperkalemia, nephrotoxicity, and neurotoxicity, so it is important to discuss the care plan with a transplant team representative prior to initiating transport.

In addition to surgical complications or manifestations of acute rejection, prevention and detection of infection are important when transporting transplant patients. For example, the presence of a life-threatening infectious illness may not become apparent until the diagnostic evaluations have been completed. In addition, mild symptoms that may be overlooked in routine transports could indicate serious conditions in transplant patients.

Rheumatology and Cancer Patients

More common than transplant recipients are patients with rheumatologic diseases or cancers whose treatment renders them significantly immunosuppressed. For conditions such as rheumatoid arthritis, vasculitis, or lupus, patients will often receive steroids (eg, prednisone) and additional immunosuppressive medications. A range of cancer therapeutics also cause various immune deficiencies. Often an infection in these immunosuppressed patients will manifest in more subtle ways because they lack the full immune reaction of healthy hosts.

Pathogenicity

Normal Bacteria

Not all bacteria are pathogenic; in fact, most bacteria have either beneficial or neutral effects. The presence of normal bacteria (commensal bacteria) in and on the body plays an important role in disease prevention through competition for space and nutrients. Nonpathogenic bacteria assist the immune system by preventing the overgrowth of pathogenic strains; they achieve this feat by using up available nutrients, maintaining a certain pH, and creating bacteriocins (antibacterial toxins).

A good example of this beneficial relationship is found in the normal microbiota of the adult vagina. Lactobacilli normally present in the vagina produce acid and keep the pH of the adult vagina between 3.5 and 4.5. This creates a hostile environment for *Candida albicans*, the causative agent of vaginal yeast infection. If the commensal bacteria of the vagina are reduced in numbers by extended use of antibiotics or excessive douching, the pH increases and *C albicans* can dominate, leading to fungal vaginitis.

Opportunistic Bacteria

Opportunistic infections are diseases caused by normally nonpathogenic agents in patients with an abnormally functioning immune system. The normally harmless organisms that cause these infections are termed *opportunistic bacteria*. In patients who are **immunocompromised**, the normal balance between host and microbe is upset by a weakness in the immune system—a deficiency caused by a genetic defect, specific medications, and/or chronic diseases. When the host defense system is compromised, microbes that are otherwise harmless may replicate unchecked.

In fact, AIDS is defined by the unusual infections found in patients who have compromised immune systems as a result of human immunodeficiency virus (HIV) infection. These rare and unusual opportunistic illnesses are called **indicator conditions** or AIDS-defining illness because they are rarely, if ever, seen in people without severe immune dysfunction. For example, the fungus *Pneumocystis jirovecii* (formerly *P carinii*) is a common environmental fungus that usually does not cause disease in healthy people, but is the most common opportunistic infection in HIV-infected people. *P jirovecii* is not responsive to antifungal treatments.

Many patients who require critical care transport are immunocompromised. CCTPs need to be keenly aware that these very sick patients can be inadvertently infected during the course of their care. To avoid this complication, CCTPs must adhere scrupulously to proper technique, keeping their equipment sanitized or sterile and using standard precautions such as masks and gloves when appropriate. Even a mild dermatitis on the hands of a healthy person or a few bacteria left on respiratory equipment can translate into a lethal infection in the immunocompromised patient.

Pathogenic Bacteria

A **pathogen** is simply defined as a microorganism capable of causing disease. Pathogenic organisms cause disease because they possess unique factors that help them gain entry into the body, colonize and overcome host defenses, produce toxins that cause cytopathic effects, or do mechanical damage to the body. Some pathogens may evade immune system destruction by producing capsules, slime layers, or specialized cell walls. Others may mount preemptive strikes by destroying phagosomes or by preventing phagocytosis.

Virulence Factors

The degree of pathogenicity is called the **virulence** of an organism. The following properties of microbes, known as virulence factors, may influence their virulence:

- Host and tissue specificity (the ability of the organism to gain entry into a host)
- Adherence to specific host cells
- Invasion of host tissues
- Evasion of host defenses
- Toxicity
- Development of a polysaccharide capsule (encapsulation)

Pathogenic organisms may possess one or more virulence factors. A common example of a virulence factor is the long, threadlike fimbriae of *Escherichia coli*, which allow adherence to host uroepithelial (bladder) cells. This adherence is a crucial step during the infection that allows uropathogenic *E coli* to colonize the urinary tract and prevents removal of the bacteria during urination.

Virulence can be experimentally quantified by two measures: the infective dose of an organism (ID_{50}) and the lethal dose of an organism (LD_{50}). The ID_{50} measures the number of organisms required to infect a susceptible test animal. The LD_{50} measures the number of organisms required to kill 50% of the infected test animals inoculated with the microbe. The lower the ID_{50} or the LD_{50}, the more virulent the organism is. For example, the infective dose of *Shigella* is about 10 to 100 organisms, whereas the infective dose of *Salmonella* is approximately 1 million organisms. Thus, it takes a larger quantity of *Salmonella* to produce an infection than it does *Shigella*; that is, *Shigella* is more virulent. By contrast, Ebola requires only a single **plaque-forming unit** to cause infection.

Host and Tissue Specificity

The portal of entry **FIGURE 20-2** is important because it can influence how the pathogen manifests disease, or if it is capable of causing disease at all. For example, various *Staphylococcus* species can cause localized skin infections such as an abscess. They can also cause toxic shock syndrome when present in large numbers in sites such as the vagina or sinuses and can release the exotoxin

TSST (toxic shock syndrome toxin) into the bloodstream. Other organisms are extremely site specific in terms of their portal of entry and infectivity. For example, *Salmonella typhi* causes no infection when inhaled, but does cause infection if it enters the digestive tract. Conversely, *S pneumoniae* does not cause disease if it is ingested but does cause pneumonia if it is inhaled.

Description

Adherence

Once inside the body, the pathogenic organism must be able to adhere to specific cells to begin reproduction. Most bacteria attach themselves to cell surfaces using specialized structures that project out of the cell wall, called pili or fimbriae **FIGURE 20-3**. Gram-negative bacteria possess a common type of pili that allow them to adhere to surfaces in the gastrointestinal tract. Other bacteria produce unique pili that bind to specific tissues.

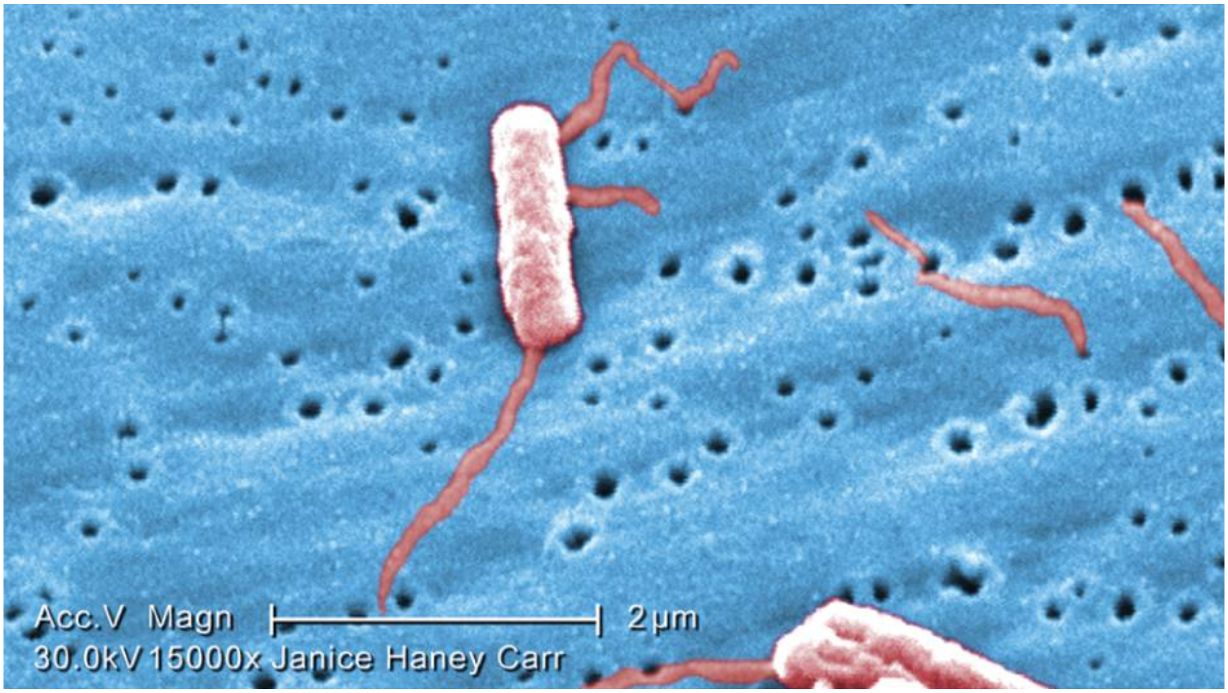

FIGURE 20-3 Pili (fimbriae) on a bacterium.

Courtesy of Janice Haney Carr/CDC.

Most organisms can begin to reproduce as soon as they have adhered to the host tissue. While these microbes reproduce, they remain bound to the surface of the host cells and spread along the tissue surface or are disseminated throughout the body.

Invasion

Once inside the host cell, the organisms multiply and easily invade neighboring cells through pores connecting the cells. This cell-to-cell infection also allows bacteria to evade destruction by the immune system. Other microbes invade tissues by producing enzymes that break down the molecules that hold cells together.

Toxicity

Bacteria are capable of producing two types of toxins: exotoxins or endotoxins. An **exotoxin** is produced inside the cell and secreted into surrounding tissues or fluids. An **endotoxin**, in contrast, is a structural component of the bacterial cell and is not released until the bacterium is destroyed. *Salmonella*, *Pseudomonas aeruginosa*, *E coli*, and other well-known bacteria produce medically important endotoxins.

Exotoxins are generally specified by genetic information carried on plasmids (small pieces of deoxyribonucleic acid [DNA] that are not part of the bacterial chromosome) or on bacteriophages (viruses capable of infecting bacterial cells). These toxins are highly specific and have differing modes of action. They are produced mostly by gram-positive bacteria but can be made by a few gram-negative organisms. Exotoxins can be grouped according to the tissue type affected:

- Neurotoxins damage nervous tissue. Botulinum toxin is a potent neurotoxin, produced by *Clostridium botulinum*, which inhibits the release of acetylcholine and results in paralysis.
- Enterotoxins affect the digestive tract and disrupt the epithelial lining of the gut, leading to severe diarrhea such as that caused by *Vibrio cholerae*, the causative agent of cholera.
- Erythrogenic toxins specifically target capillaries and produce a red skin rash. For example, such a rash is seen in scarlet fever, which is caused by *Streptococcus pyogenes*.
- Cytotoxins damage a variety of host tissues. *Corynebacterium diphtheriae* (the bacterium that causes diphtheria), *Shigella*, and

a number of other pathogens produce cytotoxins. For example, *Shigella* cytotoxins damage the cells of the digestive tract.

Encapsulation

Some organisms produce polysaccharide layers and surround themselves with capsules or slime layers. These polysaccharide layers inactivate proteins essential for the immune system's phagocytic mechanism to operate correctly. This activity not only makes ingestion of the pathogen by macrophages impossible, but also allows some bacteria to start reproduction within the macrophage or lymph nodes.

Still other microbes form biofilms, which are accumulations of bacteria and other organisms embedded in a matrix of polysaccharide along the surface of tissues. These microcolonies tend to be highly resistant both to antibiotics and to the host immune system.

Viral Pathogenicity

Viruses must gain entry into the body to cause disease. Some viruses simply enter through broken skin, such as a puncture wound, an insect bite, or the entry portal created by insertion of a hypodermic needle. Others enter the body through the respiratory or digestive tract and bind to the host's cell surface receptors using viral proteins found on the surface of the **virion**. The binding of these protein "spikes" induces receptor-mediated endocytosis that brings the virus directly into the cell. Once inside, the virus particle can be "uncoated," releasing the viral nucleic acid. The viral DNA or ribonucleic acid (RNA) then begins to direct synthesis of viral-encoded protein and nucleic acid molecules, and the process of new virion assembly begins.

The illness caused by a virus may result from the production of viral-specific molecules that deplete the host cell's resources and eventually lead to cell death. Other viruses cause illness by inducing apoptosis, even when they do little harm to the cell during their active growth cycle. Another pathogenic mechanism used by some viruses is the induction of large inflammatory responses, even with little or no actual damage to the host cell.

Epidemiology

Epidemiology is the study of how disease is distributed within populations and the factors that influence this distribution. It has several specific objectives:

- Identify the **etiology** (cause of disease)
- Determine the extent of disease within a given community
- Understand the natural history of disease
- Evaluate the effectiveness of therapeutic methods
- Identify sources of disease outbreaks
- Identify modes of disease transmission
- Develop methods of disease prevention

When discussing disease and the impact it has on the population, the incidence and prevalence of the disease must be quantified. The terms *incidence* and *prevalence* are often confused. The **incidence** of a disease is the number of new cases of that disease within a defined population over a defined period of time. The **prevalence** of a disease is the total number of cases of that disease within a population; it includes both old and new cases of the disease. For example, if in a population of 100 people there are 5 existing cases of a type of cancer, and 5 more cases are then diagnosed, the total number of people with cancer would be 10; therefore the prevalence is 10 in 100. Prevalence is preferred when you want to understand the total burden of a disease on a population, whereas incidence is preferred when you want to know how quickly a disease is spreading in a community. Both concepts are used for understanding the patterns of disease occurrence, for utilization planning of health services and facilities, and for determining the training of future providers.

The pattern of disease occurrence is another important element in understanding how populations are affected by disease. If a disease occurs only occasionally, it is called **sporadic**. If some cases of a disease are always present within a given population, and the numbers are expected and predictable, the disease is said to be **endemic**. Thus, an endemic disease is a disease that is always present and whose incidence is stable. If the number of cases of a disease clearly rises (above a threshold level) in a given time or geographic area, the disease is said to be **epidemic**. An epidemic is not specific to whether the disease is communicable, but rather refers to an outbreak of a disease that either is usually absent or has an incidence that has grown beyond the expected range. The term **pandemic** refers to a worldwide epidemic.

The detection of emerging or reemerging infectious diseases is possible through the systematic collection of data and constant surveillance of the incidence of disease. The Centers for Disease Control and Prevention (CDC) continually identifies certain "notifiable" diseases that require reporting to the health department as part of its effort to monitor and track the incidence of contagious diseases **TABLE 20-2**. New diseases can be recognized as such only when the normal background cases of infectious disease are well understood.

TABLE 20-2 Infectious Diseases Designated as Notifiable at the National Level

Anthrax
Arboviral diseases, neuroinvasive and non-neuroinvasive

- California serogroup virus diseases
- Chikungunya virus disease
- Eastern equine encephalitis virus disease
- Powassan virus disease
- St. Louis encephalitis virus disease
- West Nile virus disease
- Western equine encephalitis virus disease

Babesiosis
Botulism

- Botulism, foodborne

Coronavirus disease 2019 (COVID-19)
Cryptosporidiosis
Cyclosporiasis
Dengue virus infections

- Dengue
- Dengue-like illness
- Severe dengue

Diphtheria
Ehrlichiosis and anaplasmosis

- *Anaplasma phagocytophilum* infection
- *Ehrlichia chaffeensis* infection

- Botulism, infant
- Botulism, wound
- Botulism, other

Brucellosis
Campylobacteriosis
Candida auris, clinical
Carbapenemase-producing carbapenem-resistant *Enterobacteriaceae* (CP-CRE)
- CP-CRE, *Enterobacter* spp.
- CP-CRE, *E coli*
- CP-CRE, *Klebsiella* spp.

Chancroid
Chlamydia trachomatis infection
Cholera
Coccidioidomycosis
Congenital syphilis
- Syphilitic stillbirth

- *Ehrlichia ewingii* infection
- Undetermined human ehrlichiosis/anaplasmosis

Giardiasis
Gonorrhea
Haemophilus influenzae, invasive disease
Hansen disease
Hantavirus infection, non-hantavirus pulmonary syndrome
Hantavirus pulmonary syndrome
Hemolytic uremic syndrome, postdiarrheal
Hepatitis A, acute
Hepatitis B, acute
Hepatitis B, chronic
Hepatitis B, perinatal virus infection
Hepatitis C, acute
Hepatitis C, chronic
Hepatitis C, perinatal infection
HIV infection (AIDS has been reclassified as HIV Stage III)

Influenza-associated pediatric mortality
Invasive pneumococcal disease
Legionellosis
Leptospirosis
Listeriosis
Lyme disease
Malaria
Measles
Meningococcal disease
Mumps
Novel influenza A virus infections
Pertussis
Plague
Poliomyelitis, paralytic
Poliovirus infection, nonparalytic
Psittacosis
Q fever
- Q fever, acute
- Q fever, chronic

Rabies, animal
Rabies, human
Rubella

Spotted fever rickettsiosis
Streptococcal toxic shock syndrome
Syphilis
- Syphilis, primary
- Syphilis, secondary
- Syphilis, early nonprimary, nonsecondary
- Syphilis, unknown duration or late

Tetanus
Toxic shock syndrome (other than streptococcal)
Trichinellosis
Tuberculosis
Tularemia
Vancomycin-intermediate *Staphylococcus aureus* and Vancomycin-resistant *S aureus*
Varicella
Varicella deaths
Vibriosis
Viral hemorrhagic fever

Rubella, congenital syndrome
Salmonella Paratyphi infection (*Salmonella enterica* serotypes Paratyphi A, B [tartrate negative], and C [*S Paratyphi*])
Salmonella Typhi infection (*Salmonella enterica* serotype Typhi)
Salmonellosis
Severe acute respiratory syndrome–associated coronavirus disease
Shiga toxin–producing *E coli*
Shigellosis
Smallpox

- Crimean-Congo hemorrhagic fever virus
- Ebola virus
- Lassa virus
- Lujo virus
- Marburg virus
- New World arenavirus—Guanarito virus
- New World arenavirus—Junin virus
- New World arenavirus—Machupo virus
- New World arenavirus—Sabia virus

Yellow fever
Zika virus disease and Zika virus infection

- Zika virus disease, congenital
- Zika virus disease, noncongenital
- Zika virus infection, congenital
- Zika virus infection, noncongenital

Abbreviations: AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; spp, multiple species

Data from Centers for Disease Control and Prevention, National Notifiable Diseases Surveillance System (NNDSS). 2020 National notifiable infectious diseases (historical). https://wwwn.cdc.gov/nndss/conditions/notifiable/2020/infectious-diseases/. Accessed February 11, 2021.

Other important epidemiologic concepts to understand include the R_0 ("*R* naught") value, which represents the basic reproduction number of a disease. It indicates how many people typically become infected by each infected individual in the absence of public health interventions. For example, R_0 for measles is 12 to 17—a range determined by the number of contacts that infected people are likely to make during a specific period, the probability of transmission, and the amount of time an infected individual will be infectious. R_0 historically is central to disease forecasting models. Although it is influenced by biologic factors, such as mode of transmission, that remain fairly constant throughout a disease outbreak, it also depends on less-fixed dynamics, such as the frequency with which members of a population interact. In comparison to previous disease outbreaks, COVID-19 uniquely revealed the limitations of R_0, with estimates of R_0 during the pandemic ranging from 1.4 to 5.7 at different times and in different places.

The R_0 value also influences the level of "herd immunity" necessary to halt spread. For measles, 83% to 94% of the population needs to be immune to extinguish the disease. For the COVID-19 pandemic, the different R_0 led epidemiologists to predict that 70% to 80% of the population would need immunization to achieve herd immunity.

Another variant of R, called R_t, describes disease transmission as an outbreak progresses. It is useful in understanding why some people become immune to a disease, whether by surviving infection or by becoming vaccinated. For epidemiologic purposes, when a new virus, such as SARS-CoV-2, begins to spread, everyone may be considered susceptible to infection. At that stage, epidemiologists may use R_0 to build models of how the disease might spread. Over time, the focus shifts to R_t (ie, how more people may survive). As with R_0, epidemiologists must take social dynamics into account when calculating R_t. R_t represents only an average across a region, so it can miss regional clusters of infection, or "superspreader" events.

The effective rate of spread, designated as R or R_e, is similar to the basic reproductive number, but determines the number of people who will become infected in the presence of public health interventions such as vaccination programs. A reproductive rate (R_0) of less than 1 suggests that disease progression is controllable, whereas a rate greater than 1 suggests it will continue to spread.

An infectious disease can be either communicable or noncommunicable. A communicable disease can be transmitted from person to person, whereas a noncommunicable disease, such as tetanus, cannot be transmitted from person to person. A contagious disease is one that is highly communicable.

CONTROVERSIES

Prior to the creation of the childhood vaccination schedule, childhood infectious diseases were responsible for a significant number of deaths. Despite the widespread availability of effective vaccines, many vaccine-preventable diseases are now reemerging.

While the reemergence of these diseases is not always completely understood, we do know that over the past few decades some parents have made a decision not to vaccinate their children out of fear that the vaccines will cause autism. This fear is often based on a fraudulent study conducted by Andrew Wakefield, whose medical license was revoked following the discovery of his fraud. Wakefield's research, which was published in *The Lancet* in 1998, was subsequently retracted in 2010, but it remains perhaps the most damaging medical fraud in modern history.

Another concern held by parents, albeit to a lesser extent, is that some of the preservatives in vaccines, especially aluminum, may be toxic to the recipient. However, the body burden of aluminum remains below the minimal risk levels even when an infant is formula fed and receives all first-year vaccines. Aluminum has been used in vaccines for more than six decades, with no scientific evidence indicating it raises safety concerns.

Yet another argument against vaccinations is that the diseases really are not so bad—that is, that a child who becomes sick with a mild illness actually boosts their immune system. Quite the opposite happens with measles. Measles infections appear to weaken the immune system. In children not vaccinated for measles who develop measles, their mortality from infections other than measles can be higher.

In 2015, Spain experienced its first case of diphtheria since 1986; the affected child died. The parents had not vaccinated their child because of the antivaccine movement. Diphtheria historically carries a 10% mortality rate among children and is so severe in its impact that one outbreak in the 1600s was termed the "year of strangulations." As evidence of the positive impact of vaccination, worldwide incidence of measles decreased by 73% from 2000 to 2018; in that time, vaccine rates among children younger than 1 year rose from 72% to 86%. The World Health Organization (WHO) estimates that measles vaccination campaigns saved 23.2 million lives in this time. These mortality rates directly contradict the argument that "childhood illnesses" are benign.

Some parents use herd immunity as an excuse to exclude their own children from vaccination: If everyone else is vaccinated, why should my child be? This logic has contributed to many recent outbreaks. In 2019, 1,282 cases of measles were confirmed in the United States, most of them in people who were not vaccinated. Since 2015, several mumps outbreaks have been reported, the largest of which occurred in a community in Arkansas in 2016–2017, resulting in nearly 3,000 cases. As these cases suggest, when a significant portion of the "herd" remains unvaccinated, their status puts the vaccinated individuals at risk as well. For example, mumps immunity diminishes over time, a factor that often contributes to outbreaks.

The prevalence or incidence of disease within a population accounts for only clinical illness or disease that produces symptoms. Disease without symptoms is *not* equivalent to no disease or no risk of spreading disease. For example, some people have subclinical manifestations and can still transmit the disease, while others can be carriers without ever expressing symptoms. Factors such as the incubation period of the disease and the presence of different carrier states may allow the disease to go undetected and unaccounted in an individual, yet place others at risk for contracting the disease because prevention and disease control efforts are not employed. This concept is a critical one in the safe transport of patients. CCTPs are at risk for contracting disease from each patient transported; therefore, the use of disease control and prevention practices must be evaluated and employed as appropriate every time that care is provided to patients, regardless of whether the patient is or is not currently exhibiting symptoms.

Reservoirs of Infection

For a microorganism to infect and reinfect other organisms, it must have the ability to survive, duplicate or reproduce, and spread to new hosts. A **reservoir of infection** provides a supply of nutrients and an environmental niche that supports long-term microbial survival. Bacteria have developed some unique systems that enable them to withstand hostile environments. For example, the spore-forming bacterial species anthrax is resistant to drying and environments with low nutrients, and can exist in soil as a spore for decades. Encapsulated bacteria are resistant to changes in pH levels and can live outside the host for long periods.

Both wild and domestic animals can act as reservoirs of infection. A disease that occurs in animals and can also be transmitted to humans is called a **zoonosis**. Once it has spread to humans, such a disease might stay with the infected person (as is the case with bubonic plague) or be transmitted from person to person (as is the case with pneumonic plague).

Influenza is the prototypic zoonosis. This virus jumps from an animal host to a human, who can then infect other humans. In this case, the virus’s transmissibility between the animal reservoir and the human host provides selective pressure to the virus that supports its long-term survival. The influenza virus will alter its surface proteins so that it can then reinfect and cause illness in people who have developed immunity to the old strain. The new strain is just different enough to escape activation of immune memory.

In the same way that animals can serve as reservoirs of infection, humans can act as reservoirs of infection. A person who is colonized by pathogenic species but does not have symptoms of the infection is called asymptomatic or a latent **carrier**. These individuals have important roles in perpetuating diseases such as diphtheria, AIDS, hepatitis, gonorrhea, and amoebic dysentery.

It is important to differentiate between a reservoir and a carrier. A reservoir refers to something that leads to the long-term survival of the organism. A broader concept is “disease ecology,” which refers to the totality of all components of the disease–environment–host system. When an Ebola epidemic struck in West Africa in 2014, scientists struggled to understand the ecology of the disease and determine its natural reservoir. They tested plants, insects, bats, and animals indigenous to the areas of the outbreak. While the reservoir was not discovered during the outbreak, the researchers determined a certain type of fruit bat was an intermediate host and was, at minimum, very important to the ecology of Ebola.

Finally, the health care environment itself may serve as a reservoir of infection. Some organisms are remarkably resistant to the effects of drying and, therefore, can survive on inanimate objects (fomites) for an extended period of time. Durable medical equipment, even when treated with antimicrobial solutions, can harbor bacteria several days to several weeks after inoculation.

Modes of Transmission

Understanding the different modes of transmission of microorganisms is the first step in developing effective infection prevention measures. The unique properties and characteristics of the infectious agents determine how the disease is spread and how the infection is contracted. Infectious diseases can be transmitted directly, indirectly, or mechanically.

Direct transmission can occur vertically or horizontally. Types of direct horizontal transmission include sexual transmission, exchange of respiratory droplets or secretions, and transmission by contact. Vertical transmission is the exchange of an infectious agent between mother and fetus in utero. Perinatal transmission, another form of direct transmission, occurs when the pathogen is transmitted from mother to newborn during the birthing process. The risk of vertical transmission of HIV can be greatly reduced by initiating therapy in a pregnant woman with zidovudine (AZT), a nucleoside reverse transcriptase inhibitor, between 14 and 34 weeks' gestation.

Indirect transmission occurs when there is an intervening step in the transmission from reservoir to susceptible host. This intermediate step involves an inanimate object or fomite such as towels, bedding, thermometers, contaminated syringes, or even doorknobs. Prevention of infection via indirect transmission can be as simple as properly disposing of contaminated materials and cleaning equipment between patients, or it may require thorough decontamination of the entire patient area and caregiver materials.

Many infectious diseases are transmitted through the use of a medium, such as water, food, air, or contaminated body fluids. Water can be either the reservoir of disease or a vehicle for the disease's transmission. Water that contains raw or poorly treated sewage is the perfect vehicle for the **fecal-oral route** of cholera transmission. *Vehicle* transmission can usually be prevented by good hygiene, proper food preparation and storage, and a reliable water supply or the prolonged boiling of questionable water.

Vector transmission is the movement of a pathogen from an infected organism to a susceptible host via an animal or insect. The method of vector transmission can be either mechanical or biological.

- *Mechanical* transmission is the passive transport of pathogens on the body of the animal to the susceptible host. Typhoid, while most commonly associated with the fecal-oral route of spread, is an example of an infectious agent that can be transmitted on the feet of houseflies.

- *Biologic* transmission involves the vector, usually an arthropod, ingesting a blood meal from an infected organism and transmitting it after the pathogen has multiplied in the digestive tract of the vector, increasing the likelihood of transmission to a new host. Biologic transmission is seen in malaria, bubonic plague, and African sleeping sickness.

Selected Diseases

As noted earlier, CCTPs are exposed to deadly agents on a daily basis. When providing care for sick patients, contracting their diseases is an inherent risk of the job, as is the risk of passing the diseases on to other patients, fellow providers, or even family members. Knowledge of common infectious diseases and the appropriate responses can prevent the spread of disease. Many such diseases initially present as influenza like illness (ILI), which makes their diagnosis more challenging. Moreover, whenever a person has a fever and a rash, there is a strong likelihood that the individual is contagious.

Meningitis

Meningitis is an umbrella term that refers to five types of inflammation of the leptomeninges, the membranes that cover and enclose the spinal cord and brain. The meninges are organized into three distinct layers: the dura mater (external layer), the arachnoid mater (middle layer), and the pia mater (internal layer). Meningitis is a serious medical condition that may be caused by bacterial, viral, parasitic, or fungal pathogens. The fifth type, which is noninfectious, results from medications, cancer, or other injury.

Bacterial Meningitis

Bacterial meningitis occurs when a bacterial infection migrates to the meninges. It may occur after cranial trauma in which the normal barriers to infection are damaged. Bacterial meningitis may also result from septicemia if it spreads bacteria to the meninges. This life-threatening illness has an acute onset and is considered a medical emergency requiring prompt diagnosis and treatment to preserve life and neurologic function. Bacterial meningitis is fatal in as many as 30% of patients and causes permanent neurologic impairment in 10% of surviving patients.

Signs and Symptoms

The classic triad of symptoms observed in patients with bacterial meningitis consists of fever, nuchal rigidity, and altered mental status, although these symptoms are seen together in fewer than 50% of patients. Most patients (as many as 95% at presentation) have fever, usually greater than 100.4°F (38°C), and almost all patients with meningitis have at least one of the other classic triad of symptoms. Other symptoms of meningitis include headache, significant photophobia, and cutaneous manifestations such as petechiae or palpable purpura.

Additionally, neurologic complications may be present early in the disease course or occur as a late complication. Seizures and neurologic deficits, such as an altered mentation or oculomotor nerve palsies, have been described in as many as 30% of patients. Hearing loss is a late neurologic complication seen especially among children with meningitis. Treatment with dexamethasone, given at the same time as or before the first dose of antibiotics, may reduce the risk of mortality and adverse neurologic deficits in meningitis caused by *S pneumoniae*.

Patients may not specifically complain of a stiff neck, but nuchal rigidity can be demonstrated clinically by a few simple maneuvers. If the patient is unable to touch the chin to the chest by either active or passive flexion, the CCTP should suspect nuchal rigidity. While not very sensitive, the Brudzinski and Kernig signs are often used to determine whether neck signs are present.

- The *Brudzinski sign* is positive when spontaneous involuntary flexion of the hips occurs during attempted passive flexion of the neck. This sign may be elicited by having the patient look down at the feet while laying supine; if the legs draw up, it is considered positive.
- The *Kernig sign* is elicited by straightening a patient’s flexed legs. The inability to allow full extension of the knees when the hips are flexed is interpreted as a positive result.

Management

When meningitis is suspected, the patient should undergo a lumbar puncture to obtain cerebrospinal fluid (CSF), unless this procedure is contraindicated. If the collection of CSF is delayed, blood culture results are often reliable and can be useful for diagnosis in the event that CSF cannot be obtained prior to the administration of antibiotics. Some physicians will delay the lumbar puncture until a computed tomography (CT) scan has been obtained to exclude the possibility of increased intracranial pressure that may lead to cerebral herniation during the removal of CSF. It is not normally necessary to obtain a CT scan prior to a lumbar puncture except in the following circumstances:

- History of immunosuppression (eg, a patient with HIV infection or a patient who has received a transplant)
- Seizure (new onset, within 7 days of presentation)
- History of central nervous system disease (tumor, stroke, or focal infection)
- Abnormal level of consciousness
- Focal neurologic deficit
- Papilledema

If for any reason the collection of CSF is delayed, the administration of antibiotics should not be withheld. Empirical antibiotic treatment is warranted when bacterial meningitis is suspected clinically.

Infecting Organisms

Clinicians use epidemiologic knowledge to predict the infecting organism by understanding which bacterium (or virus) is the most likely pathogen, given the patient's age, medical history, immune status, and presenting symptoms. The organisms that cause community-acquired bacterial meningitis are quite different from those that cause meningitis in hospitalized patients or in immunosuppressed patients. The major causes of community-acquired bacterial meningitis in adults are *S pneumoniae* and *Neisseria meningitides*.

Listeria monocytogenes is a major cause in patients older than 55 years.

The epidemiology of bacterial meningitis underwent a major change after the introduction of the *Haemophilus influenzae* type b (Hib) conjugate vaccine in 1987. Before the 1990s, most cases of meningitis were seen in infants and children, and were caused by *H influenzae*, a gram-negative bacterium. Today, most cases of bacterial meningitis are observed in adults and can be caused by a variety of bacterial species, including *N meningitidis*, *S pneumoniae*, and *H influenzae*.

Haemophilus influenzae type b is a small bacterium that can colonize the respiratory tract of humans. Individuals colonized with *H influenzae* may be asymptomatic, and most isolates of this bacterium are not pathogenic. Hib is the most virulent form, and it is encapsulated, which enables it to evade destruction by phagocytic cells. This pathogen spreads from one individual to another via airborne droplets or direct contact with contaminated secretions. *H influenzae* is most commonly found in the nasopharynx of healthy asymptomatic children ages 2 to 5 years. When *H influenzae* meningitis is encountered in the adult population, the patient often has a predisposing medical condition such as paranasal sinusitis, otitis media, alcoholism, head trauma, asplenia, or immunocompromised states. For this reason, the *H influenzae* vaccine is recommended for both children and susceptible adults.

Neisseria meningitidis can cause meningitis, though this disease is rare in the United States. This bacterium is pathogenic only in humans and is spread during prolonged close contact with infected people through direct contact with respiratory secretions. Thus, outbreaks of this type of meningitis typically occur in prisons, military barracks, and college dormitories. The bacterium can be isolated from 10% to 30% of healthy adults, but the disease is not common. When a case of *N meningitidis* infection is reported, all close contacts of the infected individual are treated prophylactically with a short course of antibiotics.

The *N meningitidis* pathogen enters the body through the epithelial surfaces of the nasopharynx. If the bacteria reach the bloodstream, they can cause gram-negative sepsis, extensive tissue damage, and death. The onset of symptoms is abrupt (ie, fever, headache, and other systemic symptoms). Patients with *N meningitidis* meningitis often develop a characteristic rash that starts as **petechial lesions** (1- to 2-mm purple hemorrhagic spots that do not blanch with pressure) and advances to **palpable purpura** (larger areas of bleeding under the skin) within a short time. Caregivers should maintain a high index of suspicion, because this rash is considered a classic presentation. The mortality rate for untreated *N meningitidis* meningitis is nearly 100%.

Streptococcus pneumoniae is the most common cause of community-acquired bacterial meningitis. This bacterium possesses several pathogenic properties that make infection with *S pneumoniae* a serious medical event. Its polysaccharide capsule prevents this organism from being opsonized and phagocytized. It is able to adhere to the surface of epithelial cells, which allows *S pneumoniae* to colonize these cells, and it produces toxins that directly inhibit the body's cell-mediated phagocytic activity.

In healthy people, *S pneumoniae* is commonly isolated from the nasopharynx. The rate of colonization is estimated to be as high as 70% in the winter and spring. Patients with chronic bronchitis are frequently colonized by this bacterium.

The development of *S pneumoniae* meningitis is often preceded by a mild upper respiratory tract infection. People at highest risk for contracting *S pneumoniae* infection include those with sickle cell anemia, chronic alcoholism, multiple myeloma, functional or anatomic asplenia, and general disability. The mortality rate of *S pneumoniae* meningitis in older adults and people who are immunocompromised is quite high, even when treatment is initiated promptly. Therefore, vaccination against *S pneumoniae* is strongly encouraged for at-risk populations and is now included in the routine childhood vaccination schedule.

Signs and Symptoms

Bacterial Meningitis

Classic triad of symptoms:

- Fever
- Nuchal rigidity
- Altered mental status

Possible other symptoms:

- Headache
- Photophobia
- Focal neural deficits
- Seizures

N meningitidis meningitis:

- Fever
- Headache
- Meningismus
- Petechial lesions (1- to 2-mm purple hemorrhagic spots that do not blanch with pressure), progressing to palpable purpura (larger areas of bleeding under the skin)

Differential Diagnosis

Bacterial Meningitis

- Viral meningitis
- Brain tumor
- Subarachnoid hemorrhage
- Herpes simplex encephalitis
- Febrile seizure
- Delirium tremens
- Hepatic encephalopathy
- Brain abscess

Transport Management

Bacterial Meningitis

- Administer IV fluids.
- Administer corticosteroids (such as dexamethasone) if indicated per protocols.

- Continue IV administration of antibiotics or other medications that have been started by the sending facility.
- Wear proper PPE.

Viral Meningitis

Cases of viral meningitis are reported each year in the United States, although the specific number cannot be verified. Although all age groups are affected, this type of meningitis is more commonly seen in young adults. Viral meningitis can be acute, subacute, or relapsing. The peak incidence occurs in summer.

A variety of species can cause viral meningitis, including Coxsackie A and B viruses, echovirus, adenovirus, lymphocytic choriomeningitis virus, cytomegalovirus, poliovirus, and Epstein-Barr virus. Enteroviruses are the most common cause of aseptic meningitis; all enterovirus species are transmitted through the fecal-oral route. The meningitis will often originate from structures close to the brain, such as the middle ear, sinuses, or respiratory tract, which can be colonized by pathogenic species.

Viral meningitis presents with the same symptoms as bacterial meningitis and is also considered a serious medical condition; however, it typically resolves without intervention within 7 to 10 days. Because it is difficult to distinguish between bacterial and viral meningitis at the onset of symptoms, all cases should be treated as bacterial in origin until this possibility has been ruled out.

Signs and Symptoms

Viral Meningitis

- Fever
- Severe headache
- Nuchal rigidity
- Nausea
- Vomiting
- Photophobia
- Malaise

Generally, when providing care for a patient suspected of having viral meningitis, careful handwashing should be employed to prevent the spread of the disease.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) causes seasonal outbreaks of acute respiratory infections. Its clinical manifestations depend on the age and health of the affected individual. RSV season in the United States occurs in the winter months, with the peak incidence of this disease occurring in January and February.

Each year in the United States, RSV infections account for 58,000 hospitalizations in children younger than 5 years. In infants 1 year or younger, the virus usually causes a lower respiratory tract infection, either bronchiolitis or pneumonia. Apnea is a risk for 20% of all infants hospitalized with the infection and may put the child at risk for sudden death.

People older than 1 year may also be infected with RSV. In fact, most children test positive for RSV by the time they reach the age of 2 years. Older children and adults may present with a mild ILI. Persons at risk for severe infections or complications from infections include those with a history of prematurity and those who are immunocompromised. RSV detected in adults usually does not cause long-term pulmonary dysfunction, but infection does result in 177,000 hospitalizations each year in older adults.

Currently, no vaccine exists to prevent respiratory tract infections caused by RSV. A monoclonal antibody called palivizumab does confer passive immunity to recipients; it can be used prophylactically in premature infants at risk for severe infections.

Transmission is known to occur via respiratory droplets and via direct contact with hands that have been contaminated with mucus from the nose or mouth of an infected individual. To avoid contracting this disease, CCTPs should employ droplet and contact precautions when transporting patients with a suspected or a confirmed case of

RSV. Diagnosis is made by testing the respiratory secretions of the infected individual using polymerase chain reaction technology.

Signs and Symptoms

Respiratory Syncytial Virus

- Runny nose
- Congestion
- Cough
- Sore throat
- Headache
- Malaise
- In infants and young children: listlessness, decreased appetite, fever, wheezing, tachypnea, and cyanosis

Differential Diagnosis

Respiratory Syncytial Virus

- Asthma
- Bronchiolitis/bronchitis
- Pneumonia
- Foreign body aspiration
- Pertussis

Transport Management

Respiratory Syncytial Virus

- Provide supportive care.
- Administer fluids.
- Administer oxygen.
- Administer a nebulized bronchodilator for wheezing, if indicated by protocols.
- Monitor mechanical ventilator, if applicable.

Skin and Soft-Tissue Infections

Cellulitis and abscess are common skin and soft-tissue infections. Cellulitis presents as an area of skin with indistinct borders and is characterized by erythema, edema, and warmth (**FIGURE 20-4**). It is most commonly seen in middle-aged and older adults. Erysipelas, a specific type of cellulitis, is more common in young children and older adults (**FIGURE 20-5**). A skin abscess is a collection of pus within the dermis or subcutaneous space. These conditions are commonly misdiagnosed, and providers should carefully consider possible alternative diagnoses.

Risk factors for cellulitis and skin abscess include the following:

- Traumatic disruption of the skin barrier (eg, penetrating wound, pressure ulcer, insect bite, injection drug use)
- Skin inflammation (eg, eczema, radiation therapy, psoriasis)
- Edema caused by impaired lymphatic drainage

- Edema caused by venous insufficiency
- Obesity
- Immunosuppression
- Skin breaks between the toes (toe web intertrigo)
- Preexisting skin infection (eg, tinea pedis, impetigo, varicella)
- Close contact with someone infected with or carrying methicillin-resistant *S aureus* (MRSA)

The most common cause of cellulitis is infection with beta-hemolytic streptococci. These bacteria are classified as group A, B, C, G, or F. The most common source of infection is group A *Streptococcus* or *S pyogenes*. *S aureus* (including methicillin-resistant strains), a less common cause, should also be considered. Most cases of erysipelas are caused by beta-hemolytic streptococci.

Necrotizing Fasciitis

First noted by Hippocrates, **necrotizing fasciitis** is a limb-threatening and life-threatening infection of the soft tissue that affects the subcutaneous tissues, fat, and fascia, but initially spares the skin and the muscle. Prompt diagnosis and treatment with antibiotics and complete surgical debridement are important to reduce the high mortality rate associated with this disease.

Two main types of necrotizing fasciitis are distinguished. Type I is polymicrobial, meaning that the infection results from a mixture of aerobic and anaerobic microorganisms. This type is commonly seen in postoperative patients with comorbid conditions such as diabetes and peripheral vascular disease. The microorganisms seen in type I necrotizing fasciitis may be a mixture of *S aureus*, *Streptococcus* species, *Enterococcus* species, *E coli*, *Peptostreptococcus* species, *Bacteroides* species, *Vibrio vulnificus*, and *Clostridium* species.

Type II is a monomicrobial infection caused by the group A streptococci (GAS) known as *Streptococcus pyogenes*. This infection was previously known as “streptococcal gangrene.” Breaching of the skin barrier during surgery is thought to create the portal of entry for GAS infection.

Fournier gangrene is a specific type of necrotizing fasciitis that occurs in the skin and fat of the perineum, usually associated with genital, urinary, anal, or abdominal infections. It typically occurs in men older than 50 years and people with diabetes. In men, it creates an infected perineal site that initially spares the testes.

Initial symptoms of necrotizing fasciitis include warmth, erythema, or edema at the site, with no distinct borders. The initial site is often an extremity. Occasionally fever or hypotension will begin early. As symptoms progress, the patient may develop bullae, crepitus, and restricted limb movement (secondary to pain). As with compartment syndrome, the pain is disproportionate to the visible injury. Fever, tachycardia, and hypotension may evolve as the infection worsens. Gas, as evidenced by crepitus on exam, may develop under the skin. Often this gas can be detected on radiographic imaging as air along the fascial planes. Vomiting, fatigue, and nerve involvement are later signs. Visible skin necrosis is a very late sign; fat and fascia are much more involved than the skin, such that exploratory surgery is often required to make the diagnosis.

When necrotizing fasciitis is recognized in the field, the area should be covered with sterile gauze. Aggressive fluid replacement should also be initiated. Treatment using antibiotics alone, without surgical intervention, is associated with a nearly 100% mortality rate. Time is of the essence when dealing with a patient with necrotizing fasciitis. Any delay in surgical diagnosis and treatment may increase mortality and cause extension of the disease. Sometimes hyperbaric oxygen therapy, nutritional support, skin grafting, or amputation is used in the treatment of patients with necrotizing fasciitis.

Signs and Symptoms

Necrotizing Fasciitis

- Unexplained pain that increases over time and is out of proportion to the exam
- Mild erythema that develops into a dark red to purple color within 24 to 48 hours

- Blisters or bullae
- Fever or tachycardia
- Hypotension
- Gas, as evidenced by crepitus on exam

Differential Diagnosis

Necrotizing Fasciitis

- Cellulitis
- Gas gangrene
- Toxic shock syndrome

Transport Management

Necrotizing Fasciitis

- Provide supportive care.
- Apply sterile gauze over the site.
- Provide aggressive fluid replacement.
- Continue IV administration of antibiotics that have been started by the sending facility.
- Perform cardiac monitoring.
- Monitor urine output to the indwelling catheter, if one has been placed at the sending facility.
- Provide rapid transport (to be followed by surgical intervention).

CCTPs may be called on to transport patients to facilities that have the resources needed to care for these patients. In any case of suspected or known necrotizing fasciitis, contact precautions must be maintained at all times, and all equipment must be thoroughly disinfected after the transport is complete.

Epiglottitis

Epiglottitis is caused by an infected and inflamed epiglottis, aryepiglottic folds, and/or surrounding tissues. In the past, most cases were caused by infection with Hib. Since the introduction of the Hib vaccine in 1991 in the United States, however, the epidemiology of this disease and others caused by Hib has been changing. The incidence of epiglottitis has been drastically reduced in vaccinated children, but because of its severity and rapid progression to airway obstruction and continued infection patterns in adults, it remains important for health care providers to be familiar with this disease's clinical presentation.

Epiglottitis can occur at any age, although most cases in the past occurred in children ages 1 to 5 years. The causative agent and median age at presentation have now shifted to adult forms of the disease as the population continues to be immunized against Hib. Today, causes of epiglottitis may include *Haemophilus parainfluenzae*, *S pneumoniae*, *S aureus*, and beta-hemolytic *S pyogenes*. Hib epiglottitis still may occur, but is most likely to affect children who are incompletely immunized or those who are noncompliant with vaccinations. There is no predominant bacterial species found in adults with epiglottitis.

An abrupt onset of symptoms is the common theme in the presentation of epiglottitis. Symptoms include high fever, severe sore throat, dysphasia, and dysphonia. Often, a child will start drooling as a result of painful or difficult swallowing. The child's speech or voice may be altered so that it is muffled, and has been described classically as the "hot potato voice." As the symptoms progress, the child may assume a distinctive posture: While sitting, the arms are outstretched to support the forward-leaning trunk, and the chin is thrust forward to maximize the diameter of the hypopharynx. Unlike in croup, stridor is not a predominant sign and increased respiratory effort with use of accessory muscles may not be present; thus, the severity of the disease may be underestimated. The symptoms of epiglottitis can rapidly progress to airway obstruction, hypoxia, and cardiopulmonary arrest.

The diagnosis of epiglottitis can be made by visualization of a fiery-red and edematous epiglottis. The optimal method of visualization is under controlled conditions via direct laryngoscopy by an otolaryngologist. Radiographs are not usually necessary to make the diagnosis of epiglottitis; however, if direct visualization cannot be achieved and doubt remains, a lateral soft-tissue neck radiograph may aid in diagnosis. If a radiograph is obtained, the patient should not go to the radiology department unaccompanied. An advanced airway cart should always be readily available, and a person trained in advanced airway management should accompany the patient if the patient leaves the emergency department prior to placement of a secure airway.

Epiglottitis is a potentially life-threatening infection; as such, patients with epiglottitis must be promptly treated with empirical antibiotics. The antibiotic regimen should be selected to provide coverage for streptococci, pneumococci, staphylococci, and Hib.

CCTPs must maintain a high level of suspicion for epiglottitis in any patient who presents with the abrupt onset of fever, sore throat, muffled voice, and drooling. Agitation of the patient should be minimized, as it may lead to worsening of the patient’s condition and hasten the progression to complete airway obstruction. Interactions with children should be conducted in a manner that minimizes their anxiety, because agitation only makes the situation worse.

If airway intervention is necessary in the prehospital environment, it should be performed by the most experienced team member, as orotracheal intubation can be difficult secondary to edema and anatomic distortion. Patients with epiglottitis often require advanced airway management. Providing rapid transport to the nearest, most appropriate level of care/facility is a must.

Signs and Symptoms

Epiglottitis

- High fever
- Severe sore throat
- Dysphasia
- Dysphonia

- Drooling as a result of painful or difficult swallowing
- Alteration of speech or voice so that it is muffled—“hot potato voice”
- Sitting with the arms outstretched to support the forward-leaning trunk, with the chin thrust forward to maximize the diameter of the hypopharynx

Differential Diagnosis

Epiglottitis

- Anaphylaxis
- Foreign body aspiration
- Laryngotracheobronchitis
- Mononucleosis
- Pertussis
- Pharyngitis
- Pneumonia
- Caustic ingestion

Transport Management

Epiglottitis

- Support the airway.
- Continue IV administration of antibiotics if they have been started by the sending facility.
- Note: When epiglottitis is strongly suspected, transfer of a patient without an artificial airway (endotracheal tube or tracheostomy) is unsafe.

Tuberculosis

Tuberculosis (TB) is caused by the acid-fast bacterium called *Mycobacterium tuberculosis*. The genus *Mycobacterium* includes other ominous organisms such as the pathogen that causes leprosy (*Mycobacterium leprae*) and *Mycobacterium avium-intracellulare* complex (MAC), which causes a tuberculosis-like pneumonia usually seen only in immunocompromised patients such as those with advanced HIV/AIDS. MAC is particularly insidious because these organisms are very resistant to antibiotics and are becoming even more resistant at an alarming rate.

Tuberculosis causes more deaths globally than any other single microbial agent, killing 1.4 million people in 2019. The risk of contracting this highly infectious disease is increased in people who live in poor housing conditions, those who are usually malnourished, and those who are coinfected with HIV. Owing to better recognition of TB and appropriate treatments for this disease, the United States saw only 8,916 cases in 2019, roughly one-tenth the yearly total seen in the early 1950s. The case rate of TB continues to steadily decrease in the United States as a result of education and quick actions taken to control the spread of the disease.

Pathophysiology

The *M tuberculosis* bacterium is transmitted via respiratory droplets from the cough of an infected person, which then contact the respiratory epithelium of a susceptible person. The first site of infection is the lungs. The bacterium, being an obligate aerobe, has a propensity to set up infection in the upper lobes of the lungs because that tissue is highly oxygenated. TB can also spread to the kidneys or spine.

After a person recovers from a primary infection, the immune system resists secondary infection and reactivation through cell-mediated immunity. (Reactivation of a previously contained infection may occur in an immunocompromised or debilitated patient.) Antibodies to tuberculin are formed, and their existence is exploited in tuberculin skin testing (TST) with the purified protein derivative (PPD). In TST, the tuberculin antigen is injected into the skin; if positive, it indicates a previous infection, but does not necessarily indicate active disease. If the reaction is large enough (more than 15 mm in diameter in healthy patients not from a country highly endemic for TB), then the person is considered to be actively infected and should receive treatment. As with some other infectious diseases, there is a delay between the primary infection and a positive PPD test result: It takes approximately 6 weeks for the TB skin test to be reactive. The induration seen following injection of PPD is a type IV delayed hypersensitivity reaction, used for diagnostic advantage in TST. Interferon-gamma release assays (IGRAs) can help detect *M tuberculosis* infection but do not differentiate latent tuberculosis infection from tuberculosis disease.

A vaccine is available for the prevention of TB. The bacillus Calmette-Guérin (BCG) vaccine is made from a related bacterium, *Mycobacterium bovis*, which usually infects bovines (cows). The BCG vaccine is not used in the United States because it is effective only 70% of the time, but is used in countries highly endemic for TB. Inoculation with the BCG vaccine causes a person to have a weakly positive PPD test result.

Diagnosis and Management

Most people infected with *M tuberculosis* are asymptomatic. The immune status of the patient, in large part, determines the clinical symptoms of an infection with this bacterium. Persons with active pulmonary TB typically have five symptoms: cough, fever, weight loss, night sweats, and fatigue.

Infection with *M tuberculosis* can be difficult to diagnose because it is a slow-growing bacterium, taking weeks to culture. Because treatment must begin as soon as possible, diagnosis is based on clinical signs and confirmed via positive acid-fast staining of three sputum samples from patients suspected of being infected **FIGURE 20-6**.

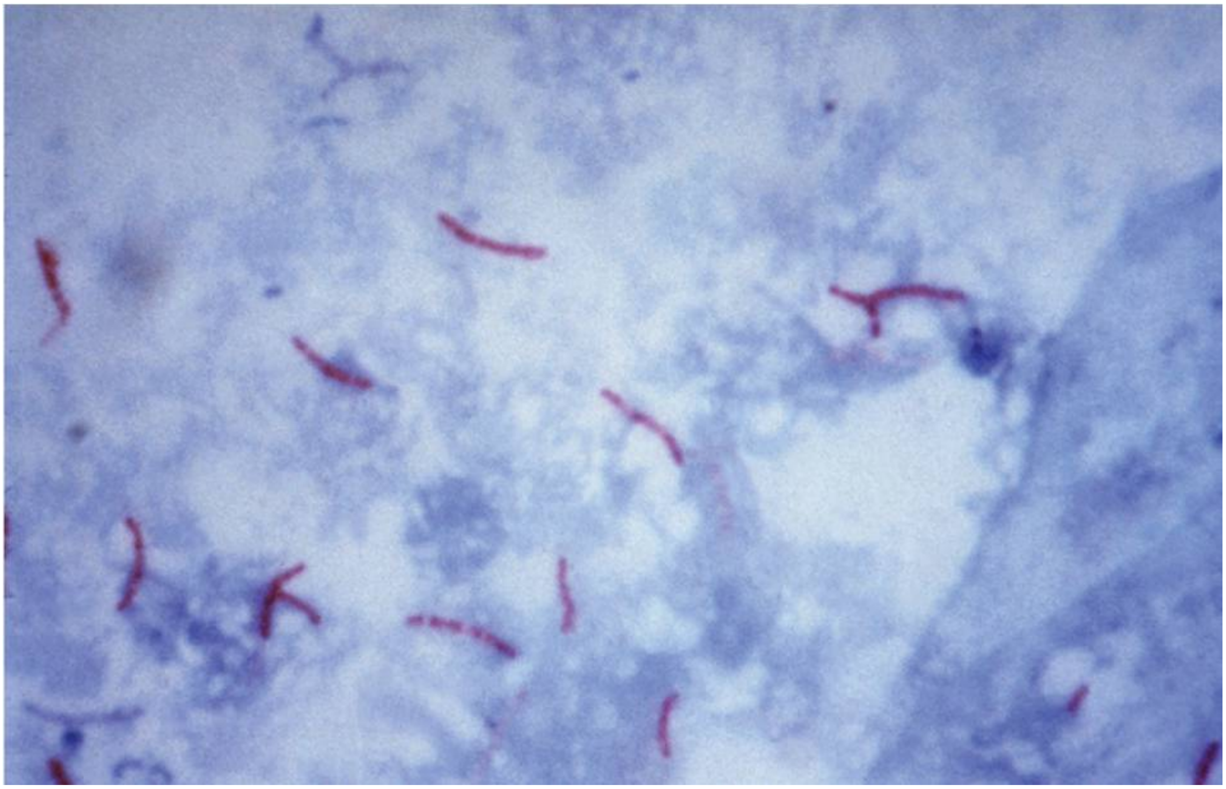

FIGURE 20-6 Acid-fast staining technique to diagnose tuberculosis.

Courtesy of Dr. George P. Kubica/CDC.

The emergence of drug-resistant strains of TB has precipitated the use of a multidrug regimen for curing patients with this disease. The individual drugs used may vary slightly according to known sensitivities, but the mainstay of therapy is isoniazid. The drugs are typically given for many months.

Multidrug-resistant tuberculosis (MDR-TB) is TB that is resistant to at least two of the standard anti-TB medications, isoniazid and rifampin. Extensively drug-resistant TB (XDR-TB) is TB that is resistant to isoniazid, rifampin, any fluoroquinolone, and at least one second-line IV drug. Because XDR-TB is resistant to many first- and second-line drugs, treatment options are limited for patients with this form of the disease. Both MDR-TB and XDR-TB are contracted via the same mechanism as TB—that is, through the inhalation of infected droplets from a person who is already infected when that person coughs, sneezes, or spits into the environment. These infected droplets can exist in the air for several hours, and anyone who breathes in these particles is at risk for contracting the disease.

When transporting a patient with a history of fever, weight loss, and night sweats, and anyone with a cough, take proper precautions for airborne pathogens by placing a mask on the patient (if tolerated); the CCTP should also wear an N95 mask. CCTPs should comply with yearly TST or IGRA testing to determine their personal exposure history. If care was provided for a patient known to have TB and exposure was a possibility, providers should undergo PPD or IGRA testing 6 weeks after exposure to assess their own status. If the test result is negative, the CCTP can resume routine TB screening tests. If the TB screening test result is positive, a chest radiograph will be required to determine whether signs of active or previous TB infection exist.

Signs and Symptoms

Tuberculosis

- Cough
- Fever
- Weight loss
- Night sweats
- Fatigue

Differential Diagnosis

Tuberculosis

- Chronic cough
- COPD
- Histoplasmosis
- Lung abscess
- Lung cancer
- Mesothelioma
- *Pneumocystis jirovecii* pneumonia

- Q fever
- Toxoplasmosis
- Typhoid fever

Transport Management

Tuberculosis

- Provide supportive care.
- Continue administration of IV antibiotics if they have been started by the sending facility.
- Ensure meticulous airborne respiratory isolation precautions.

Pneumonia

Pneumonia is a leading cause of death in the United States, with approximately 50,000 people dying from this cause in 2017. Most patients affected with pneumonia are adults.

Pneumonia is an infection of the lung parenchyma that is caused by bacterial, viral, or fungal agents. Physicians normally classify pneumonia as either community acquired or **nosocomial** (contracted in a medical facility) because the differential acquisition of pneumonia influences the most likely infecting agent, treatment, and prognosis. The mortality rate for community-acquired pneumonia ranges from 5% to 14%, whereas the mortality rate for nosocomial pneumonia is as high as 40%.

Pneumonia is generally diagnosed in a patient presenting with symptoms of sudden-onset fever, chest pain, or dyspnea, and leukocytosis. Patients may also have a cough, either dry or productive, depending on the causative agent. Plain chest radiographs, posteroanterior and lateral, are the gold standard for diagnosing a consolidated or infiltrative lesion.

Community-Acquired Pneumonia

The most common pathogen in all age groups of patients with community-acquired pneumonia is *S pneumoniae*. This bacterium gains entry to the respiratory tract following aspiration into the lungs from previously colonized nasopharyngeal mucosa. Older adult patients and those with other comorbidities are at a higher risk for succumbing to pneumonia infections. A history of tobacco use, COPD, immunosuppression, and obesity are independent risk factors for developing community-acquired pneumonia.

Many different bacterial species cause pneumonia, with the most common being *S pneumoniae*, *H influenzae*, *S aureus*, *Chlamydia pneumoniae*, and *Legionella pneumoniae*. Symptoms of bacterial pneumonias include high fever, productive cough, and pleuritic chest pain.

Mycoplasma pneumoniae and viruses cause atypical pneumonias. These infections are considered atypical because patients usually present with a slower onset of symptoms, low-grade fever, and a dry cough. *Mycoplasma* pneumonia is often misdiagnosed as viral because of its less severe presentation. The clinical lung exam result may be normal, but the chest radiograph will demonstrate infiltrates. *Mycoplasma* pneumonias are often preceded by a flulike **prodrome** consisting of headache, malaise, and fever.

Viral pneumonia is more common in infants and young children. RSV and parainfluenza virus are the most common causes of viral pneumonia in pediatric patients. The incidence of these viral infections peaks in the fall and winter. Viral pneumonia is often preceded by an upper respiratory tract infection. As with atypical pneumonias, its onset can be slower than the onset of bacterial pneumonia.

Nosocomial Pneumonia

Hospitalized patients, particularly older adults, are susceptible to nosocomial pneumonias. The definition of nosocomial or **hospital-acquired pneumonia (HAP)** is a pneumonia that occurs in a hospitalized patient at least 48 hours after admission. (In other words, this type of pneumonia was not apparent at the time of admission.) Among all nosocomial infections, HAP is the leading cause of death, with a mortality rate as high as 50%. **Ventilator-**

associated pneumonia (VAP) is a type of HAP that occurs in ventilated patients and that appears more than 48 hours after endotracheal intubation. **Health care–associated pneumonia (HCAP)** is a pneumonia that occurs in nonhospitalized patients who have contact with health care facilities or personnel, such as residents of long-term health care facilities, those undergoing hemodialysis, and those who have had a recent admission to an acute care facility.

HAP, VAP, and HCAP can be caused by a number of pathogenic bacteria and can be polymicrobial in origin. Commonly implicated pathogens include *E coli*, *Klebsiella pneumoniae*, *Enterobacter*, *Pseudomonas*, *S aureus*, and *Streptococcus*. Nosocomial bacterial pneumonias secondary to viral or fungal infection are much less common except in patients with severe immunosuppression.

Pneumocystis jirovecii (previously *P carinii*) pneumonia (PCP) is a fungal infection that is seen in patients with immunosuppression, such as those taking immunosuppressive therapy for solid-organ transplantation and those infected with HIV. It is included in the list of AIDS-defining illnesses. In fact, a patient whose CD4 cell count is less than 200 cells/μL is placed on trimethoprim-sulfamethoxazole prophylactically to prevent the development of PCP. The classic radiographic findings for PCP are bilateral interstitial infiltrates.

Management

As with all patients who have respiratory illnesses, CCTPs should use standard precautions when caring for patients suspected of having pneumonia and those diagnosed as having pneumonia. If a patient is actively coughing, place a mask on the patient (if tolerated) and on yourself, wear gloves, and use good handwashing technique between transports. Thoroughly clean and decontaminate your equipment, including the transport vehicle, before undertaking further transports.

Signs and Symptoms

Pneumonia

- Sudden-onset fever
- Chest pain
- Dyspnea
- Leukocytosis
- Cough, either dry or productive

Differential Diagnosis

Pneumonia

- Asthma
- Bronchiectasis
- COPD
- Lung cancer
- Pulmonary edema
- Pulmonary emboli

Transport Management

Pneumonia

- Provide supportive care.
- Continue administration of IV antibiotics or other medications if they have been started by the sending facility.

Fungal Diseases

Over the past 20 years, the incidence of serious fungal infections has been increasing. These infections are not particularly contagious to healthy people, but their presence in patients is an indication of serious immunosuppression. It is especially important to decontaminate equipment, such as laryngoscopes and suction equipment, after transporting patients with oral candidiasis (thrush) or patients infected with *P jirovecii*.

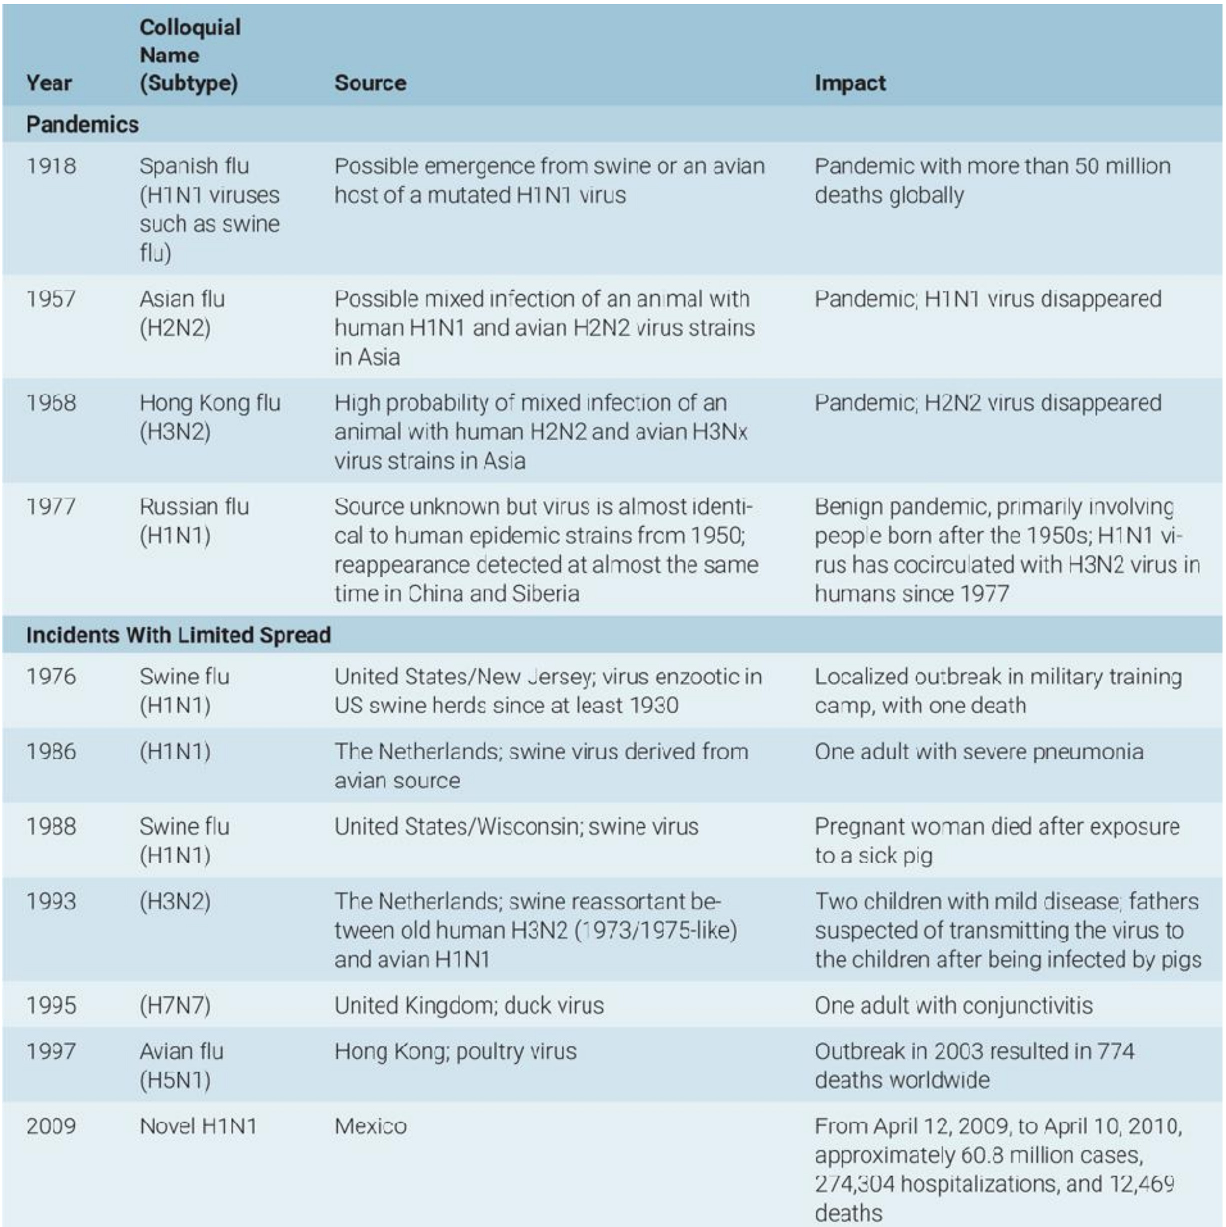
Influenza

Influenza virus causes an acute upper respiratory illness lasting between 7 and 14 days depending on the severity of symptoms. The causative agent is an orthomyxovirus that has three variants (A, B, and C).

Influenza has an incubation period of about 1 to 3 days and is spread by droplet or fomite transmission. Complications in older adults and the very young can include the development of primary or secondary pneumonia.

An influenza epidemic may potentially cause illness in 10% to 20% of the population. Influenza viruses are responsible for as many as 36,000 deaths and more than 100,000 hospitalizations per year **TABLE 20-3**.

TABLE 20-3 **Influenza Landmarks in Humans**



Year	Colloquial Name (Subtype)	Source	Impact
Pandemics			
1918	Spanish flu (H1N1 viruses such as swine flu)	Possible emergence from swine or an avian host of a mutated H1N1 virus	Pandemic with more than 50 million deaths globally
1957	Asian flu (H2N2)	Possible mixed infection of an animal with human H1N1 and avian H2N2 virus strains in Asia	Pandemic; H1N1 virus disappeared
1968	Hong Kong flu (H3N2)	High probability of mixed infection of an animal with human H2N2 and avian H3Nx virus strains in Asia	Pandemic; H2N2 virus disappeared
1977	Russian flu (H1N1)	Source unknown but virus is almost identical to human epidemic strains from 1950; reappearance detected at almost the same time in China and Siberia	Benign pandemic, primarily involving people born after the 1950s; H1N1 virus has cocirculated with H3N2 virus in humans since 1977
Incidents With Limited Spread			
1976	Swine flu (H1N1)	United States/New Jersey; virus enzootic in US swine herds since at least 1930	Localized outbreak in military training camp, with one death
1986	(H1N1)	The Netherlands; swine virus derived from avian source	One adult with severe pneumonia
1988	Swine flu (H1N1)	United States/Wisconsin; swine virus	Pregnant woman died after exposure to a sick pig
1993	(H3N2)	The Netherlands; swine reassortant between old human H3N2 (1973/1975-like) and avian H1N1	Two children with mild disease, fathers suspected of transmitting the virus to the children after being infected by pigs
1995	(H7N7)	United Kingdom; duck virus	One adult with conjunctivitis
1997	Avian flu (H5N1)	Hong Kong; poultry virus	Outbreak in 2003 resulted in 774 deaths worldwide
2009	Novel H1N1	Mexico	From April 12, 2009, to April 10, 2010, approximately 60.8 million cases, 274,304 hospitalizations, and 12,469 deaths

Modified from H1N1 flu. Centers for Disease Control and Prevention website. https://www.cdc.gov/h1n1flu/estimates_2009_h1n1.htm. Updated June 24, 2014. Description

Evolution of New Influenza Strains

Influenza type A is divided into subgroups based on the presence of two surface proteins (also called envelope spikes): hemagglutinin and neuraminidase. Unlike influenza B and C, this form of influenza is subject to **antigenic drift**, which is caused by small genetic changes in the virus. This process alters the virus just enough that antibodies generated during previous infections no longer recognize the viral **epitope** or surface protein and, therefore, do not protect the body from the symptoms of a new infection. Influenza A is also subject to more drastic changes called **antigenic shift**, in which the protein structure of one or both of the spike proteins changes. Antigenic shift typically occurs only once in several years, whereas antigenic drift occurs more frequently. The phenomenon of antigenic drift is what precipitates the need for yearly preparation of influenza vaccine and, therefore, annual immunization.

The influenza virus can infect species of animals other than humans. In fact, waterfowl are the natural reservoir for the influenza A virus. Influenza A is an avian virus that has “jumped species” to infect humans and other mammals. Humans, pigs, ducks, chickens, and other animals are susceptible to influenza A. This variability of hosts causes mutations to occur in the virus that facilitate antigenic drift. When animals are infected with swine, human, and avian influenza simultaneously, mixing of the genes that encode the neuraminidase and hemagglutinin proteins can occur. Many different variations of these proteins are possible because there are 9 known variations of neuraminidase and 16 known variations of hemagglutinin.

Variations in influenza A are closely monitored by WHO, the CDC in the United States, and other global health associations. The subtypes of influenza A are categorized and tracked each year. The predominant subtypes of influenza A circulating throughout the world in 2014–2015 were H3N2 (a designation indicating that the hemagglutinin is type 3 and the neuraminidase is type 2) and H1N1. The highly pathogenic forms of avian influenza are H5 and H7. When influenza undergoes a major antigenic drift or a novel combination of hemagglutinin and neuraminidase emerges (antigenic shift), people have little or no antigenic protection based on their prior infections. Pandemics of influenza may then break out and spread quickly, causing major illness around the world.

Historically, new strains of influenza A virus have arisen in Asia, likely because of socioeconomic and geographic factors there. It is common for farmers in southeast China to live in close proximity with pigs and ducks. This sets up a perfect environment for the avian and human strains to recombine in pigs, and then jump species back into humans with an antigenic shift. Each year, WHO and the CDC collect samples from Asia to use as sentinel viruses when preparing the influenza vaccine subsequently offered in the United States and other countries.

Management

Treatment for influenza is mostly supportive. When an individual is diagnosed within the first day of symptoms, however, treatment with an antiviral medication may reduce the severity and duration of symptoms.

CCTPs should be aware of the signs and symptoms of influenza infection and should use standard and respiratory precautions to avoid infection and spread of infection.

Signs and Symptoms

Influenza

- High fever
- Runny nose or congestion
- Cough
- Sore throat
- Muscle aches
- Fatigue
- Headache
- Nausea, vomiting, or diarrhea

Differential Diagnosis

Influenza

- Bacterial infection
- Fungal infection
- Parasitic infection
- Viral infection
- Typhoid

Transport Management

Influenza

- Provide supportive care.

Herpesviruses

The herpesvirus family is a group of double-stranded DNA viruses, all of which share the characteristic of being surrounded by a lipoprotein envelope. Herpesviruses are noted for their ability to cause latent infections when the acute viral syndrome is followed by a symptom-free period during which the virus is **quiescent** (inactive). Depending on the species, reactivation of the virus can occur when the patient is immunosuppressed or through inciting agents.

Six pathogenic herpesviruses cause significant disease in humans:

- Herpes simplex types 1 and 2
- Varicella zoster virus
- Cytomegalovirus
- Epstein-Barr virus
- Human herpesvirus 8

Both Epstein-Barr virus and human herpesvirus 8 are associated with the development of cancer, Burkitt lymphoma, and Kaposi sarcoma.

Herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2) cause lesions, but the lesions differ in their location. HSV-1 is transmitted in saliva, whereas HSV-2 is transmitted via sexual contact. Therefore, it follows that HSV-1 causes lesions above the waist, whereas HSV-2 causes lesions below the waist. However, either virus can be isolated from either location after oral-genital contact.

HSV-1 causes an acute gingivostomatitis in children and recurrent *herpes labialis* in adolescents or adults, commonly known as cold sores. It can also cause keratoconjunctivitis and encephalitis in immunocompromised hosts. HSV-2 commonly causes genital herpes.

HSV-1 and HSV-2 can cause infection of the fingers with recurring painful blisters, a condition called herpetic whitlow (**FIGURE 20-7**). This condition is seen commonly in health care professionals such as respiratory therapists and dentists following a break in barrier protections (eg, gloves). It can also develop with exposure to genital secretions.

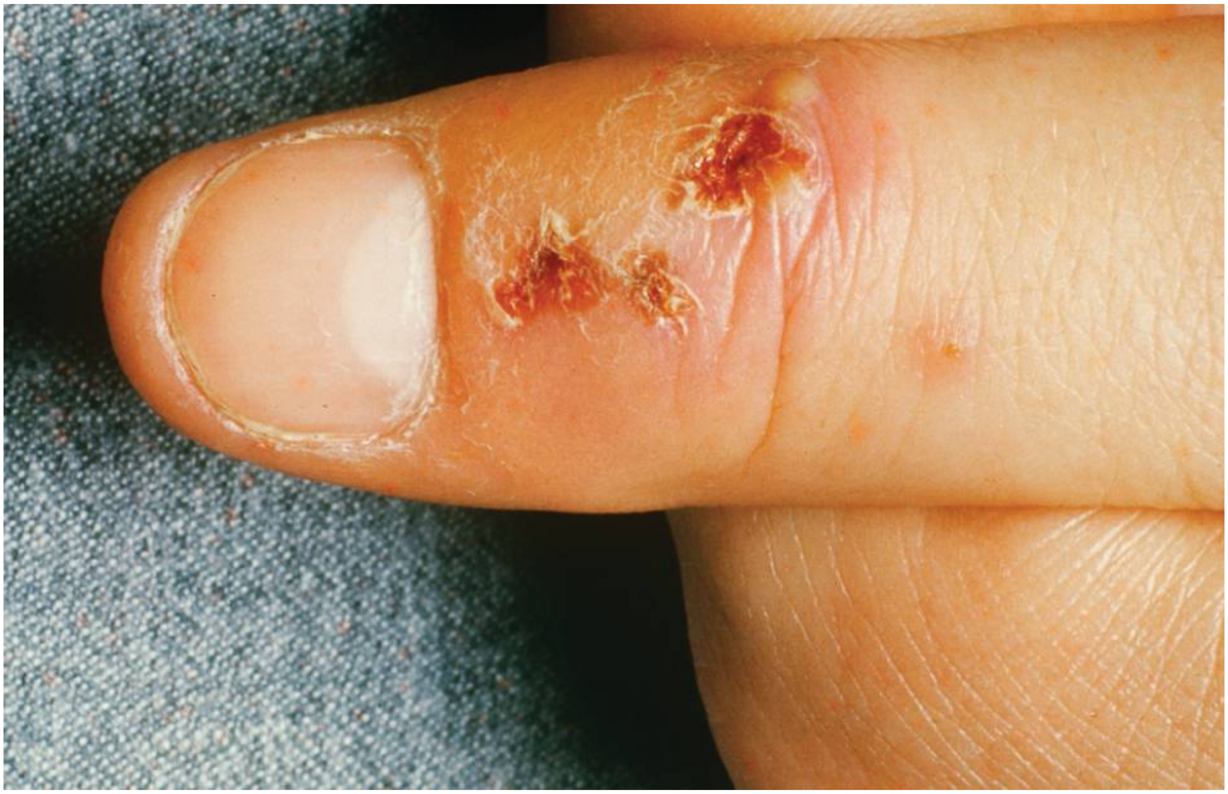

FIGURE 20-7 Herpetic whitlow can produce painful blisters on the finger.

Viral Hepatitis

Hepatitis is the inflammation of the liver. This disease can be caused by exposure to infectious agents (usually viral), toxins (eg, alcohol), or drugs (eg, acetaminophen). The course and severity of the illness range from acute to chronic and from mild to life threatening, respectively. Signs and symptoms of liver disease can range from subclinical symptoms and nonspecific malaise to jaundice, hepatomegaly, bleeding **dyscrasias**, altered mental status, and multiple organ failure. Damage to the liver can be caused by direct injury to the hepatocytes caused by the agent, or it may result indirectly from an inflammatory response or an autoimmune attack.

There are six known hepatotropic viruses (hepatitis A, B, C, D, E, and G), each of which has its own characteristic causative agent, mode of transmission, incubation period, associated risk factors, and sequelae. Viral hepatitis is first classified by the duration of the illness as either acute or chronic. Acute viral hepatitis is defined as the presence of signs or symptoms of liver inflammation for less than 6 months duration, whereas chronic viral hepatitis is defined as the presence of persistent liver inflammation for 6 months or longer. Liver inflammation can also be described by histologic and pathologic findings, which allows for the grading and staging of liver disease. The grade of liver disease describes the severity of the inflammatory process and cell necrosis, and the stage of liver disease describes the severity of the scarring of the liver tissue.

Elevation of liver enzyme levels in the serum is considered evidence of damage to the liver, and the pattern of their elevation provides insight into the nature and probable cause of the insult. An acute viral hepatitis will have an acute onset and be accompanied by marked elevations in aspartate aminotransferase (AST) and alanine aminotransferase (ALT); by comparison, a chronic viral hepatitis produces more moderate and persistent elevations in these same enzymes. The ratio of serum AST to ALT is commonly greater than 2 in patients with liver disease caused by alcohol abuse, whereas the ratio is characteristically less than 1 in patients with liver disease caused by viral agents.

Alkaline phosphatase (AP) is an enzyme that is present in many different tissues within the body, such as the bones, intestine, kidney, liver, and placenta. When a rise in AP levels is accompanied by a rise in gamma-glutamyl transferase (GGT) levels, this condition is assumed to have a hepatic origin. Elevations in levels of AP and GGT are seen with damage to the bile canaliculi—the cells that line the intrahepatic bile ducts. Such damage can occur acutely when bile ducts are blocked by an obstructive process, such as an impacted gallstone, or it can develop more slowly from a chronic process.

Chronic viral hepatitis may produce swelling within the liver that results in compression of the pericanalicular cells, leading to a marked rise in the so-called cholestatic enzyme levels, with the rise in the levels of hepatocellular enzymes being more moderate. The elevation of GGT and AP levels that results from a viral process then occurs later in the course of the disease, and the elevation is more moderate.

Signs and Symptoms

Hepatitis

- Nonspecific malaise
- Jaundice
- Abdominal pain
- Loss of appetite
- Intermittent nausea and diarrhea
- Scleral icterus
- Hepatomegaly
- Bleeding dyscrasias
- Altered mental status
- Multiple organ failure

Differential Diagnosis

Hepatitis

- Alpha-1 antitrypsin deficiency
- Biliary obstruction
- Drug-induced liver disease
- Sclerosing cholangitis
- Wilson disease

Transport Management

Hepatitis

- Provide supportive care.

Hepatitis A

Hepatitis A virus (HAV), previously known as infectious hepatitis, is a positive single-stranded RNA virus of the Picornaviridae family. Sexual and parenteral transmission of HAV is possible; however, because the period of **viremia** is brief, fecal-oral transmission is more common. Large-scale outbreaks can occur, usually as the result of contaminated food or drinking water.

Incidence of HAV cases decreased by more than 95% from 1995 to 2011, but since 2016 there has been a dramatic increase in incidence due to person-to-person outbreaks. In 2018, 12,474 cases were reported in the United States, though the actual number of cases was probably twice as high; many HAV infections are asymptomatic and likely go unreported. Vaccination of all children 12 to 23 months of age remains crucial to preventing the spread of infection.

The clinical features of HAV include jaundice, fatigue, abdominal pain, loss of appetite, and intermittent nausea and diarrhea.

People at highest risk of HAV infection are household/sexual contacts of already-infected people, international travelers, and people living in American Indian reservations, Alaskan Native villages, and other regions with endemic HAV. During localized outbreaks, people at greatest risk include children who attend day-care centers and such centers' employees, men who have sex with men, and IV drug abusers.

The incubation period for HAV infection ranges from 2 to 6 weeks. The period of greatest infectivity is the last 2 weeks of incubation, just before the onset of clinical symptoms. Nevertheless, the infected individual remains infectious by shedding virus in the feces for 2 to 3 weeks after the onset of clinical symptoms.

The diagnosis of HAV is made by detection of anti-HAV IgM antibody. Anti-HAV IgG antibody is detected in the blood after exposure and recovery or immunization, which provides lifelong immunity.

HAV infection can be prevented by active immunization with the HAV vaccine or by passive immunization with immune globulin administered before or after a known exposure. The vaccine is highly effective and is recommended for children starting at age 1 year and for people at high risk of HAV infection, such as those planning to travel abroad, people living in HAV-endemic areas, and children and caregivers at day-care centers. The prevention of infection can also be accomplished by improving sanitation and by employing good personal hygiene and handwashing.

Hepatitis B

Hepatitis B virus (HBV) is a double-stranded DNA virus of the Hepadnaviridae family. It is transmitted through parenteral routes (non-oral transmission) and has an incubation period of 1 to 6 months. Transmission can occur by sharing needles, having sex with an infected person, or accidental medical exposures, such as needlesticks, blood spray, or touching bloody items with unprotected hands. Although blood is the most effective fluid of transmission, the virus lives in all human body fluids and is present in semen, saliva, urine, and breast milk.

In the United States, 3,322 acute HBV infections were reported in 2018. The actual case number, accounting for underreporting, was likely closer to 21,600. Persons at highest risk for contracting HBV include people who participate in high-risk behaviors; live in or travel to disease-endemic areas such as parts of Greenland, northern

Canada, southeast Asia, China, and all of Africa; and those exposed to infected body fluids through their lifestyles or occupations. They include IV drug users, sexually active heterosexuals, men who have sex with men, people of low socioeconomic status, children of immigrants from disease-endemic areas, infants born to infected mothers, and patients receiving hemodialysis. In addition, because health care providers routinely come into contact with patients who are infected with HBV, they are considered an at-risk group for viral infection and should receive the HBV vaccine series, with immunity subsequently confirmed by titer.

The clinical features of HBV are similar to those of HAV, including jaundice, scleral icterus, fatigue, abdominal pain, loss of appetite, and intermittent nausea or vomiting **FIGURE 20-8**. However, unlike HAV, HBV can induce other disease states in addition to causing acute infections. Specifically, it can cause acute hepatitis, fulminant hepatitis, and chronic hepatitis. Fulminant hepatitis is a severe inflammation of the liver that is accompanied by rapid destruction of the liver, leading to liver failure. The liver damage is accompanied by encephalopathy within 8 weeks of the onset of the symptoms. Coagulopathy, electrolyte disturbances, and cerebral edema are common in the setting of fulminant hepatitis, and death is likely if the patient does not receive an urgent liver transplant.

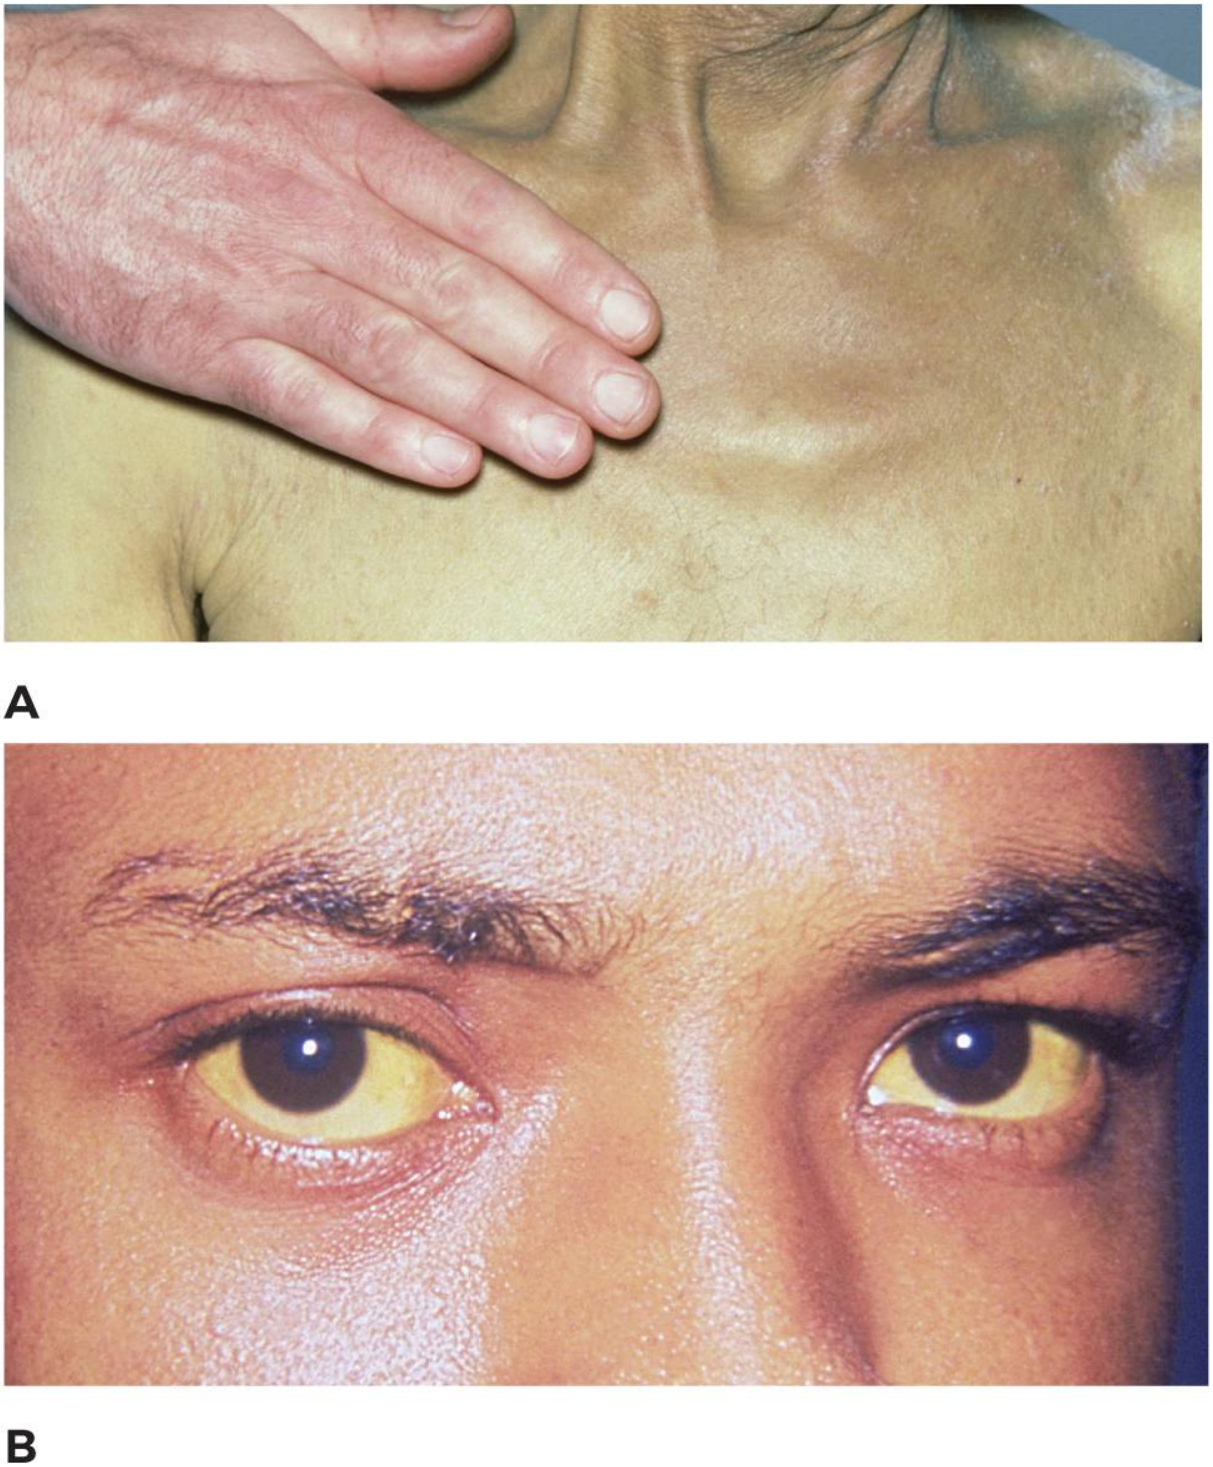

FIGURE 20-8 A. Jaundice. **B.** Scleral icterus.

Chronic HBV can take several forms. A patient can be chronically infected, yet remain symptomless—that is, a chronic asymptomatic carrier. Such an individual never develops immunity to the virus, but harbors the virus and is infectious to others without actually sustaining liver damage. There were an estimated 257 million carriers of HBV worldwide in 2015. In contrast, chronic-persistent hepatitis is infection with HBV that “smolders”: it is a persistent low-grade infection from which the patient eventually recovers. In chronic-active hepatitis, the patient has an active hepatitis state for more than 6 months, but neither recovers nor experiences a severe decline in liver function during this period. The identification and treatment of people with chronic infections and asymptomatic carriers is important for preventing the spread of the disease.

The key to understanding HBV serology, infectivity, and immunity begins with knowledge of the structure of this enveloped DNA virus. Immunity to HBV is acquired after exposure to the surface antigen through exposure either to the natural virus or to viral surface components in the vaccine. In either case, immunity is acquired through the development of antibodies to the surface antigen (anti-HBs). Antibodies to the core proteins (anti-HBc) do not confer immunity because, for an individual to ward off the virus, antibodies must attack the intact virion before the virus has a chance to replicate and before the individual is exposed to the core antigen. If the person has only anti-HBc, an immune response will not be mounted until the core protein is unmasked, which is too late to prevent infection. Therefore, antibodies to the core antigen (anti-HBc) are not protective and do not confer immunity; rather, their presence in the serum is considered a marker of previous exposure. Only anti-HBs will develop in response to the hepatitis B vaccine.

This information helps a provider determine how immunity to HBV was acquired. For example, if an individual has both anti-HBs and anti-HBc, then they have been exposed to the wild-type virus (because of the presence of anti-HBc) and are now immune (because of the presence of anti-HBs). The subtype of immunoglobulin yields information about the duration of infection. If the anti-HBc consists of IgM-type immunoglobulin, then the infection is acute or from a recent exposure. The presence of anti-HBc IgG indicates that the exposure occurred more than 3 months prior and the infection is resolving or is chronic.

Measures to prevent HBV infection include screening the blood supply and removing HBV-contaminated units and donors from the blood donation pool. The HBV vaccine is recommended for all infants at birth and for children up to age 18 years. It is also recommended that adults with a high risk of exposure be vaccinated. All pregnant women should be screened for the disease, and infants born to infected mothers should receive treatment with HBIG at birth, in addition to completing the vaccination series during the first 6 months of life. The vaccine is given in three separate doses at 0, 1, and 6 months. Passive immunity can be conferred by giving HBV immunoglobulin to people who experience known exposures within 24 hours of the exposure.

Primary hepatocellular carcinoma is a known complication of chronic HBV infection. The risk of its development is 200 times greater for those people with chronic HBV infection relative to those people who are not infected. In the United States, 20% of people with hepatocellular carcinoma are hepatitis B surface antigen–positive. Other potential complications of HBV infection include cirrhosis and fulminant liver failure (in fewer than 1% of cases).

Hepatitis C

Hepatitis C virus (HCV) is an enveloped RNA virus of the Flaviviridae family, which was originally known as non-A, non-B hepatitis. HCV causes both acute and nonacute or chronic hepatitis. The virus is transmitted parenterally through transfusion or IV drug use, through sexual contact with infected people, and from mother to infant; however, the vertical transmission rate of HCV is significantly lower than that of HBV. The incubation period of HCV varies from 2 weeks to 6 months.

In 2018, 3,621 cases of acute HCV infection were reported in the United States, although the actual case number, accounting for underreporting, was likely more than 50,000. In cases of acute hepatitis, the symptoms usually consist of nausea, vomiting, and jaundice. In most cases (more than 85% of infections), acute infection leads to chronic infection; spontaneous clearance of the virus is rare once chronic infection is established. Chronic infection typically begins with a long period in which the patient has no symptoms. The natural history of HCV has been difficult to determine because the disease is so often silent and goes undetected during the early stages, and the interval from infection to the development of cirrhosis can exceed 30 years. Most chronic infections lead to hepatitis and fibrotic liver disease. Cirrhosis develops in 5% to 25% of infected people. HCV cirrhosis is the major cause of liver transplantation.

The risk factors most strongly associated with HCV infection include IV drug use and a history of blood transfusion before 1990. Others at risk for HCV infection include patients receiving hemodialysis, health care workers, sexual contacts of infected people, hemophiliacs, and infants born to infected mothers.

Anti-HCV antibodies develop after exposure to the virus but do not confer immunity. Their presence in the blood is exploited by serologic assays that screen for contaminated blood products and seek to identify the carriers of infection. The antibody is detected through an enzyme-linked immunosorbent assay, a technique that has a sensitivity of 97%, but only a 25% positive predictive value in low-risk populations. Other screening techniques, such as a recombinant immunoblot assay, have been developed and are more useful for testing low-risk populations.

While cures for HCV disease caused by genotypes 1 and 4 have been recently developed, no vaccine is available to prevent infection. Patients with chronic active HCV infections are candidates for treatment. The goal of treatment is to prevent the development of cirrhosis and liver failure, but its success is limited and the side effects of treatment with interferons and antivirals can be difficult to tolerate. Most clinicians agree that treatment should be offered to those patients who have detectable levels of HCV RNA with persistently elevated liver transaminases and who demonstrate evidence of liver damage on biopsy.

Hepatitis D

Hepatitis delta virus (HDV) is another RNA virus that is transmitted parenterally, but it can replicate only with the aid of HBV. HDV is endemic in the Mediterranean region, the Middle East, and parts of South America. Outside of these areas, most HDV infections are a result of transfusion with tainted blood products or IV drug use.

Hepatitis E

Hepatitis E virus (HEV) is rare in the United States and is limited to travelers to endemic areas of India, Southeast Asia, Africa, and Mexico. The virus is transmitted via the fecal-oral route through the ingestion of contaminated food or water sources. Its transmission and course are similar to those of HAV, but HEV is associated with a high fatality rate in pregnant women.

Hepatitis G

Hepatitis G virus (HGV) is another RNA virus of the Flaviviridae family and is transmitted through parenteral routes. It has frequently been detected in patients with chronic liver disease, but a causative link has not yet been established.

Human Immunodeficiency Virus

Human immunodeficiency virus causes HIV disease, which in turn can lead to AIDS.

Epidemiology

The first reported case of AIDS occurred in 1981 in Los Angeles. Although the disease was first encountered in homosexual men, it was also seen in IV drug users, transfusion recipients from Haiti, female sexual contacts of infected men, prisoners, and Africans. In the beginning, many theories were proposed regarding the causative agent of the disease, but the observation that the epidemiology of AIDS was similar to that of hepatitis B infection persuaded researchers to search for a viral component. The cause of AIDS, a novel retrovirus that belongs to the human T-lymphotropic virus group, was isolated in 1983; it was positively identified as the primary cause of AIDS in 1984. At the end of 2018, the estimated prevalence of HIV in the United States—that is, the total number of people living with HIV infection—was estimated at 1.2 million, with 14% of these individuals believed to be unaware of their infections. AIDS is now pandemic: According to recent estimates, nearly 38 million people around the globe are infected with HIV, with 770,000 people dying from AIDS-related illnesses in 2018.

Transmission of HIV infection occurs by the transfer of infected cells or free virus from one individual to another. Transmission occurs horizontally via sexual contact or by exposure to infected blood, and vertically from mother to neonate across the placenta or during delivery. An infant can also contract HIV from an infected mother through breast milk. The transmission rate of HIV during pregnancy or delivery is 5% to 10%, versus 10% to 20% while breastfeeding. The transmission rate can be reduced to less than 1% if the mother is treated adequately with AZT during her pregnancy, the infant is delivered by cesarean section, and the mother does not breastfeed. The HIV transmission rate increases in people who also have other sexually transmitted infections (STIs), especially STIs that disrupt the mucous membrane barrier.

The risk of contracting HIV from a blood transfusion has been reduced through aggressive screening of donated blood; this risk is now extremely low but cannot be completely eliminated, because there is a small window of time when the virus is not detected in people with new infections. The CDC, in partnership with 14 countries in Africa and the Caribbean and under the President’s Emergency Plan for AIDS Relief, has worked to reduce the risk of transmitting HIV through blood transfusions. The goal is to deliver an adequate supply of safe blood to these participating countries by collecting blood from low-risk, voluntary, nonremunerated donors and strengthening laboratory and screening capacity.

Prevention of exposure (ie, needlesticks) is the most important method of protecting health care workers against HIV transmission. The incidence of needlesticks has been reduced by advances in needleless devices, safety education, and emphasis on proper sharps disposal. Even so, needlestick injuries continue to occur. Fortunately, the risk of becoming infected with HIV after a significant exposure to body fluids from a patient infected with HIV is low. The estimated risk of transmission is 0.33% for hollow-bore needlesticks and 0.09% for mucosal contact; there are no known cases of HIV transmission with intact-skin exposures.

Pathophysiology

HIV is a retrovirus that infects T lymphocytes and other cells that display the CD4 surface protein **FIGURE 20-9**. It belongs to a subgroup of retroviruses called the lentiviruses, which cause "slow" infections with long incubation periods.

Description

Three essential enzymes are enclosed in the retroviral capsid of the virus:

- *Reverse transcriptase* is an RNA-dependent DNA polymerase that gives the retrovirus its name. This enzyme is responsible for converting the RNA viral genome into a DNA provirus.
- *Integrase* is the enzyme that catalyzes the integration of the newly transcribed proviral DNA into the host cell genome.
- *Protease* is the enzyme that is responsible for producing functional viral proteins.

Understanding these specific retroviral enzymes is important for understanding how antiretroviral therapy was designed for the treatment of HIV/AIDS.

HIV infects CD4+ helper T cells and kills them, resulting in the suppression of cell-mediated immunity. There are three stages in HIV infection: acute, latent, and late (or the period of immunodeficiency). The stage of the illness is largely determined by the CD4 cell count and symptoms of the disease **TABLE 20-4**. The disease classification is based on the lowest CD4 cell count, not the current count. Once a patient has a CD4 count of less than 200 cells/μL, the patient is diagnosed with AIDS regardless of whether the T cells rebound with therapy.

TABLE 20-4 **HIV/AIDS: Classification of Disease Stage**

Stage	Classification	CD4 Cell Count (cells/μL)
1	Asymptomatic	≥500
2	AIDS-related complex	200–499
3	AIDS	<200

Abbreviations: AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus

© Jones & Bartlett Learning.

The initial exposure to the virus triggers a sequence of events that generally goes unnoticed by the individual but allows the virus to become permanently established in the immune system. Thereafter, HIV infection can be divided into two phases: acute infection and chronic **TABLE 20-5**.

TABLE 20-5 **Stages of HIV Infection**

Stage	Description
Acute	Also called primary HIV infection or acute seroconversion syndrome, among other terms
Chronic	Further subdivided into the following stages: • Chronic infection, without AIDS • AIDS, characterized by a CD4 cell count <200 cells/μL or the presence of any AIDS-defining condition • Advanced HIV infection/AIDS, characterized by a CD4 cell count <50 cells/μL

Adapted from Sax PE, Wood BR. The natural history and clinical features of HIV infection in adults and adolescents. *UpToDate*. https://www.uptodate.com/contents/the-natural-history-and-clinical-features-of-hiv-infection-in-adults-and-adolescents?search=aids%20definition&source=search_result&selectedTitle=1~150&usage_type=default&display_rank=1. Updated November 21, 2019. Accessed February 12, 2021.

The initial infection begins in the immune cells of the genital tract, and the virus quickly spreads to localized CD4+ helper T cells. However, the virus is not detected in the blood until 4 to 11 days after the initial infection.

The acute phase of the disease occurs 2 to 6 weeks after the initial exposure. The patient may present with mononucleosis-like symptoms of fever, lethargy, generalized lymphadenopathy, pharyngitis, and arthralgias. A maculopapular rash on the trunk, arms, and legs, sparing the palms and soles, may also be seen during this time. The acute phase of the disease usually resolves within 2 weeks.

Antibodies to HIV are not detected in the blood until 2 to 4 weeks after the initial infection. Once antibodies are detected in the serum, the patient is said to have seroconverted. The inability to detect antibodies in the blood prior to **seroconversion** results in false-negative serologic test results. This has important implications for transmission of the virus and for screening of the blood supply. The HIV-infected person is capable of spreading the disease through sexual or blood contacts during this window of time, even though the HIV antibody test result might be negative.

After the initial viremia, a viral set point is reached. The viral set point represents the amount of virus present in the blood (the viral load) and tends to remain fairly constant for many years. The lower the viral set point at the end of the initial infection, the more likely the patient is to remain in the latent stage of the disease. The latent stage usually lasts for years (the median duration is 10 years), and the patient is generally asymptomatic during this period. While the patient may be asymptomatic and the symptoms are latent, the virus is *not* truly “latent,” but rather is actively replicating within the patient’s lymph nodes. The most important effect of HIV infection is viral entry into the CD4+ lymphocytes, which leads to slow depletion of the patient’s CD4+ lymphocytes or cells. The depletion of these CD4+ cells leads to loss of cellular immunity.

AIDS is defined as the late stage of HIV infection. The criteria for AIDS diagnosis include HIV infection with a CD4+ helper T cell count of less than 200 cells/µL and/or the presence of an AIDS-defining condition. The presence of an AIDS-defining condition supersedes any CD4 cell count **TABLE 20-6**.

TABLE 20-6	**AIDS-Defining Conditions**
Bacterial infections, multiple or recurrent[a]	
Candidiasis of the bronchi, trachea, or lungs	
Candidiasis of the esophagus	

Cervical cancer, invasive[b]

Coccidioidomycosis, disseminated or extrapulmonary

Cryptococcosis, extrapulmonary

Cryptosporidiosis, chronic intestinal (>1 month duration)

Cytomegalovirus disease (other than in the liver, spleen, or nodes), onset at age >1 month

Cytomegalovirus retinitis (with loss of vision)

Encephalopathy attributed to HIV

Herpes simplex: chronic ulcers (>1 month duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)

Histoplasmosis, disseminated or extrapulmonary

Isosporiasis, chronic intestinal (>1 month duration)

Kaposi sarcoma

Lymphoma, Burkitt (or equivalent term)

Lymphoma, immunoblastic (or equivalent term)

Lymphoma, primary, of the brain

Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary

Mycobacterium tuberculosis of any site, pulmonary,[b] disseminated, or extrapulmonary

Mycobacterium, other species or unidentified species, disseminated or extrapulmonary

Pneumocystis jirovecii pneumonia

Pneumonia, recurrent[b]

Progressive multifocal leukoencephalopathy

Salmonella septicemia, recurrent

Toxoplasmosis of brain, onset at age >1 month

Wasting syndrome attributed to HIV

Abbreviations: AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus

Selik RM, Mokotoff ED, Branson B, et al. Revised surveillance case definition for HIV infection —United States, 2014. *MMWR Recomm Rep*. 2014;63:1.

Patients with HIV often present many years after the initial infection or the acute stage of the disease because in the initial stages, the disease is often mild and the symptoms are nonspecific. In many patients with HIV, the illness is noticed only when the patient begins to experience symptoms such as generalized lymphadenopathy, weight loss, fatigue, fevers, or night sweats. As the disease progresses, the patient may experience frequent severe herpes infections of the mouth or anus and/or recurrent or persistent yeast infections. The loss of cell-mediated immunity predisposes the host to many opportunistic infections. Symptoms of opportunistic infections commonly seen in patients with AIDS include cough, dyspnea, headache, altered mental status, memory loss, seizures, ataxia, dysphagia, nausea, vomiting, severe persistent diarrhea, and marked weight loss.

The viral load is estimated by determining how much viral RNA is present in the blood. The viral load indicates the magnitude of HIV replication and its associated rate of CD4 cell destruction. This measure is the most accurate indicator of the risk for disease progression and is used in planning and monitoring antiretroviral therapy. The CD4 cell count is used to evaluate the extent of HIV-induced immune damage, to estimate the patient’s immunologic status, and to predict the patient’s likelihood of developing opportunistic infections. In the past, antiretroviral therapy was formally initiated based on the viral load, the CD4+ T cell count, and the patient’s clinical condition. Today, however, most clinicians initiate therapy as soon as HIV infection can be confirmed.

Management

Six general classes of antiretroviral drugs are currently available for the treatment of HIV infection:

- Nucleoside (and nucleotide) reverse transcriptase inhibitors (NRTIs)
- Nonnucleoside reverse transcriptase inhibitors (NNRTIs)
- Protease inhibitors (PIs)
- Integrase strand transfer inhibitors (INSTIs)
- Entry inhibitors: CCR5 antagonists
- Entry inhibitors: fusion inhibitors

Each class of drugs attacks HIV in a different way.

NRTIs target the enzyme known as reverse transcriptase (RT). They act to block the transcription of the viral RNA to the proviral DNA by competing with physiologic nucleosides for the enzyme-binding sites. Once they are added to the growing DNA sequence, they block the addition of the next nucleoside, thereby interrupting the synthesis process and causing chain termination. The prototype of the NRTIs is AZT.

NNRTIs are similar to the NRTIs in that they target the same viral enzyme, reverse transcriptase. In contrast to the NRTIs, NNRTIs are not competitive inhibitors of the enzyme, but rather noncompetitive inhibitors of reverse transcriptase. They bind to the enzyme near the binding site for the nucleoside substrate and alter the configuration of the enzyme, thereby preventing it from carrying out its catalytic function. The two classes of RT inhibitors are considered the backbone of anti-HIV treatment.

PIs target the viral enzyme protease that cuts the viral polyprotein into functional individual proteins. Inhibiting this protease prevents the processing of viral proteins, which then prevents the construction of the mature virion. Indinavir is an example of a typical PI. Because the step that the PIs inhibit occurs late in the viral replication process, these therapies are most often used in combination with other agents.

Integrase inhibitors target a protein in HIV called integrase, which is essential for viral replication. Integrase is responsible for inserting viral genomic DNA into the host chromosome. The integrase enzyme binds to the host cell's DNA, prepares an area on the viral DNA for integration, and then transfers this processed strand into the host cell's genome.

Entry inhibitors stop HIV from entering human cells. There are two types: CCR5 inhibitors and fusion inhibitors.

To enter a host cell, HIV must bind to two separate receptors on the cell's surface: the CD4 receptor and a co-receptor (CCR5 or CXCR4). Once HIV has attached to both, its envelope can fuse with the host cell membrane and release viral components into the cell. CCR5 inhibitors prevent HIV from using the CCR5 co-receptor by binding to it, blocking viral entry. CCR5 inhibitors do not work in all patients, however, and are very rarely used as first-line treatments. A test is required to determine if this type of treatment would be effective before it is initiated.

A fusion inhibitor (enfuvirtide) is available by injection only and is used in patients who have no other treatment options. It works by stopping the fusion of the HIV envelope protein with the CD4 cell.

The goal of current therapies for HIV infection is to prolong life, while maintaining the best possible quality of life. Achieving this goal requires weighing the benefits from preventing opportunistic infections and malignancies, and slowing the rate of virus production, against the side effects of therapy. In addition, therapy must be delivered to the patient in a manner that promotes compliance. Although the PIs are highly effective at reducing HIV viral load, their serious side effects (ie, fat redistribution with facial wasting, insulin resistance with hyperglycemia, high cholesterol, and liver problems) and the improved effects of other classes of antiretrovirals have limited their usefulness for initial therapy. Initial antiretroviral regimens should typically be based on tenofovir and have a high barrier to resistance. This treatment is very effective in prolonging life and reducing the viral load, but ensuring patient compliance can be challenging because the regimens are often complicated and the side effects can be debilitating. Viral resistance to the antiretroviral drugs increases when patients use the drugs intermittently or incorrectly. Patient adherence to uninterrupted HIV treatment has been greatly assisted by fixed-dose pills that combine two or three antiretroviral drugs from more than one class into a single pill that is taken once per day.

The risks of occupational exposures and postexposure prevention protocols are discussed later in this chapter.

Signs and Symptoms

HIV Infection/AIDS

Early symptoms:

- Generalized lymphadenopathy
- Weight loss
- Fatigue
- Fevers
- Night sweats

Symptoms associated with disease progression:

- Frequent, severe herpes infections of the mouth or anus
- Recurrent or persistent yeast infections

Symptoms associated with opportunistic infections:

- Cough
- Dyspnea
- Headache
- Altered mental status
- Memory loss
- Seizures
- Ataxia
- Dysphagia
- Nausea
- Vomiting
- Severe persistent diarrhea
- Marked weight loss

Transport Management

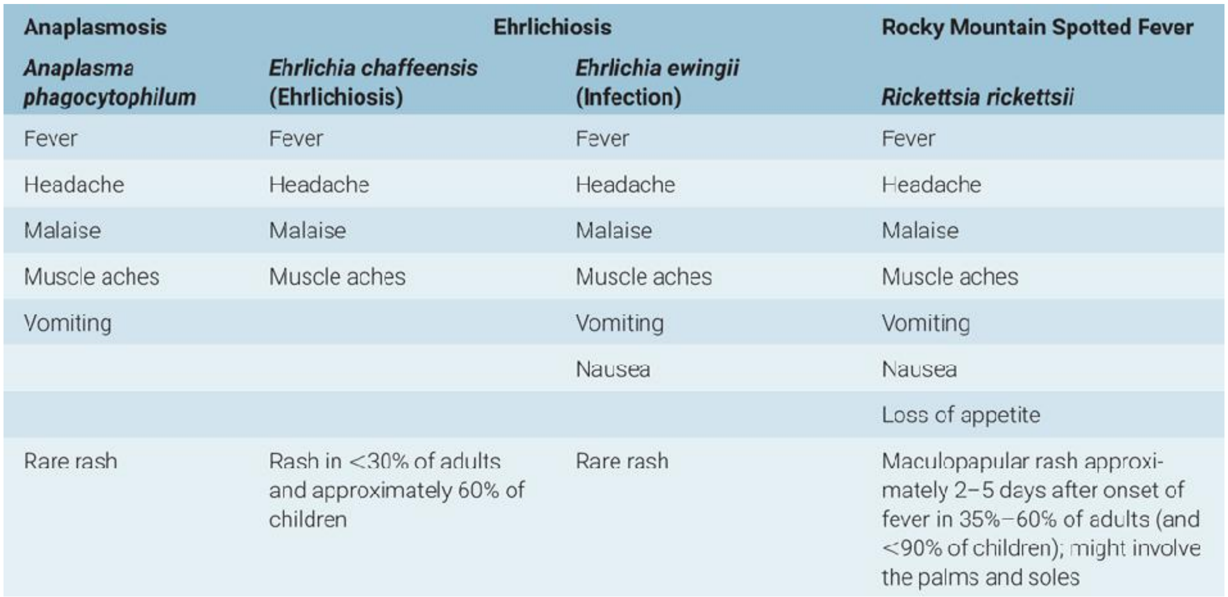
HIV Infection/AIDS

- Provide supportive care.

Rickettsial Diseases

Rickettsial diseases are transmitted via tick bite. In consequence, patients with these diseases are not considered infectious by human-to-human contact, although transmission is known to have occurred via blood transfusion from an infected but asymptomatic donor. Three major diseases are classified as tick-borne rickettsial diseases: Rocky Mountain spotted fever, ehrlichiosis, and anaplasmosis. Of these diseases, the highest mortality rate is seen with Rocky Mountain spotted fever. Early signs and symptoms of these tick-borne diseases are generally mild and nonspecific, making diagnosis problematic; however, Rocky Mountain spotted fever should be considered a possible diagnosis in all patients presenting with fever and having suspected or known tick exposure (through outdoor activities during April through September in North America). In particular, children and young adults are at risk because of their increased outdoor activity. Despite its name, Rocky Mountain spotted fever is seen mostly in the southeastern United States (especially North Carolina), followed by two midwestern states (Missouri and Tennessee). **TABLE 20-7** compares initial signs and symptoms of anaplasmosis, ehrlichiosis, and Rocky Mountain spotted fever.

TABLE 20-7 | **Initial Signs and Symptoms of Tick-Borne Rickettsial Diseases**



Anaplasmosis	**Ehrlichiosis**		**Rocky Mountain Spotted Fever**
Anaplasma phagocytophilum	***Ehrlichia chaffeensis* (Ehrlichiosis)**	***Ehrlichia ewingii* (Infection)**	***Rickettsia rickettsii***
Fever	Fever	Fever	Fever
Headache	Headache	Headache	Headache
Malaise	Malaise	Malaise	Malaise
Muscle aches	Muscle aches	Muscle aches	Muscle aches
Vomiting		Vomiting	Vomiting
		Nausea	Nausea
			Loss of appetite
Rare rash	Rash in <30% of adults and approximately 60% of children	Rare rash	Maculopapular rash approximately 2–5 days after onset of fever in 35%–60% of adults (and <90% of children); might involve the palms and soles

Centers for Disease Control and Prevention. Symptoms of tickborne illness. http://www.cdc.gov/ticks/symptoms.html. Reviewed January 10, 2019. Accessed February 12, 2021.

Description

Rocky Mountain spotted fever begins acutely with fever accompanied by one or more of the following: headache (usually severe), rash, muscle aches, nausea and vomiting, and malaise. Patients may also exhibit neurologic symptoms resembling those associated with meningitis. Children may present with abdominal pain, altered mental status, and conjunctival injection (bloodshot eyes). Within a few days after the initial fever, a petechial rash develops on the hands and feet, which then spreads to the rest of the body in approximately half of all adults and most children. The skin on the hands and feet of some patients will slough off about a month after a severe petechial rash occurs. Of patients with tick-borne rickettsial diseases, 50% or more require hospitalization, and some patients will experience long-term complications such as renal failure, myocarditis, meningoencephalitis, hypotension, adult respiratory distress syndrome, thrombocytopenia, and multiple-organ failure.

Diagnosis is determined by using a serum antibody test or polymerase chain reaction test, or by obtaining a biopsy specimen of the rash. If rickettsial disease is suspected, treatment with doxycycline (or a similar antibiotic) should be initiated immediately and not delayed by waiting for results from diagnostic tests.

Prevention of tick-borne diseases includes using insect repellents that contain *N*,*N*-diethyl-meta-toluamide (DEET) and wearing light-colored clothing (to make ticks more visible). If possible, individuals should wear long sleeves and long pants, and tuck their pants into their socks when outside, particularly when walking through grassy areas. They should also inspect their body for ticks after being outdoors.

Embedded ticks should be removed with tweezers or gloved hands; avoid removal with bare hands. Grasp the tick as close to the skin as possible and lift the tick with enough force to “tent” the skin surface. Hold the tick in this position for a minute or until the tick lets go. Then, either save the tick for analysis (in a plastic bag placed in the freezer) or dispose of the tick by flushing it down a drain. To avoid contamination from body fluids, do not crush or squeeze the tick. After removal, thoroughly wash the area of the tick bite with soap and warm water and apply rubbing alcohol. Wash hands with soap and water.

Emerging Infectious Diseases

The influenza pandemic of 1918–1919, which caused more than 20 million deaths, was thought to be a phenomenon of historic interest. With the advent of effective vaccinations and antibiotics, the death rate from infectious disease declined dramatically during the 20th century, but these successes should not lead to complacency. Hantavirus, West Nile virus, SARS, and avian influenza have emerged as new threats on the medical landscape. The emergence and reemergence of drug-resistant infectious agents, such as methicillin-resistant *S aureus*, vancomycin-resistant enterococci, and MDR-TB, have increased dramatically in the past two decades.

The term *emerging infectious disease* refers to both new and reemerging diseases caused by infectious agents that have recently increased in incidence or those that threaten to increase in the near future. The CDC has identified several major factors that contribute to the development or reemergence of infectious disease—namely, changes in human behaviors or ecology, changes in economic and technologic advances, and adaptive changes of the infectious agents. The high mobility of modern society has greatly facilitated the movement of people, animals, and other commodities across countries and continents; unfortunately, this population on the move also includes carriers of disease. The triangle of transmission between microbe, vector, and host is exacerbated when microbes and vectors have access to naïve populations who lack immunity (herd immunity). Selective pressures from overuse of antibiotics have precipitated the development of resistant microbes, and abuse of antimicrobials has allowed the reemergence of more deadly infections.

Additionally, infectious agents are now thought to be important in the etiology of many diseases previously classified as noninfectious. *Helicobacter pylori* has long been found in association with peptic ulcer disease, but it is now known to have a causative association.

Human papillomavirus (HPV) is the major cause of cervical cancer (an HPV vaccine is now available). Hepatitis C virus is a leading cause of chronic liver disease and cirrhosis in the United States and is a major risk factor for the development of hepatocellular carcinoma.

Emerging infectious diseases can be particularly damaging to immunocompromised people, such as those with HIV disease, those receiving immunosuppressive therapy (eg, recipients of organ transplants), and those who are immunosuppressed as a result of their treatment for cancer. Public water supplies that are contaminated by emerging infectious agents put entire communities at risk. In 1993, *Cryptosporidium* contaminated a municipal water supply in Wisconsin; 4,400 people were ultimately hospitalized with infections. Large segments of populations may also be exposed to emerging infections through contaminated food sources. For example, *E coli* O157:H7 in contaminated beef cooked in fast-food restaurants caused a multistate outbreak of hemorrhagic colitis and serious kidney disease and resulted in the deaths of at least four children. Emerging diseases include HIV infections, SARS CoV-1, SARS-CoV-2, Lyme disease, *E coli* O157:H7, *Cryptosporidium*, hantavirus, dengue fever, West Nile virus, and Zika virus. In addition, multidrug-resistant bacterial infections can be considered emerging diseases.

To effectively detect and ward off the threat of emerging infections, the public health sector, health care providers, and emergency medical services must cooperate to control any potential outbreaks and prevent the spread of potentially deadly diseases. Such cooperation can have a significant impact when emergency medical services (EMS) is involved in surveillance and education of the community. As part of this effort, all health care workers should follow the recommendations for using standard precautions **TABLE 20-8** and PPE **TABLE 20-9**.

TABLE 20-8 | Recommendations for the Application of Standard Precautions for the Care of All Patients in All Health Care Settings

Component	Recommendations
Hand hygiene	After touching blood, body fluids, secretions, excretions, and contaminated items; immediately after removing gloves; and between patient contacts
Personal protective equipment	Gloves, mask, and gown
Gloves	For touching blood, body fluids, secretions, excretions, and contaminated items; for touching mucous membranes and nonintact skin
Mask, eye protection, and face shield	During procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, and secretions; N95 mask to prevent respiratory transmission
Gown	During procedures and patient care activities when contact of clothing/exposed skin with blood/body fluids, secretions, and excretions is anticipated
Soiled patient care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; and perform hand hygiene
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas
Textiles (linen and laundry)	Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharps	Do not recap, bend, break, or hand-manipulate used needles; use safety features when available; and place used sharps in a puncture-resistant container
Patient resuscitation	Use a mouthpiece, resuscitation bag, or other ventilation device to prevent mouth contact
Patient placement	Prioritize admission to a single-patient room if the patient is at increased risk of transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk of acquiring infection or developing an adverse outcome following infection

Component	Recommendations
Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients, beginning at the initial point of the encounter)	Instruct symptomatic people to cover their mouths/noses when sneezing/coughing; use tissues and dispose in a no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; and place a surgical mask on the patient if tolerated, wear an N95 mask, or maintain spatial separation, greater than 3 feet (1 m) if possible

Data from Centers for Disease Control and Prevention (CDC), Department of Health and Human Services, 2004. Severe acute respiratory syndrome: public health guidance for community-level preparedness and response to severe acute respiratory syndrome (SARS)—Version 2, January 8, 2004. http://www.cdc.gov/sars/guidance/core/downloads/core-full.pdf. TABLE 20-9 Personal Protective Equipment Recommended (by Infectious Disease)

Disease	**Airborne**		**Droplet**	**Standard Precautions**	
	Negative-Pressure Transport	N95 Mask	Surgical Mask	Contact Gloves Face and Gown	Eye Protection Goggles or Mask/Shield
Respiratory Infections					
Respiratory syncytial virus			Required	Required	Recommended
Influenza			Required	Required	Recommended
Novel respiratory infection (such as SARS or avian flu)	Required	Required	Required if N95 is not available	Required	Required
SARS-CoV-2		N95 or higher[a] (respirator) required	Face mask required of the patient	Gown, gloves	Face shield or goggles[a]
Pulmonary TB	Recommended	Recommended	Required if N95 is not available	Required	
Meningitis			Surgical mask	Required	
Hepatitis				Required	Recommended
MDR diseases					
MRSA or VRSA			Recommended	Required	Recommended
VRE			Recommended	Required	Recommended
MDR TB	Recommended	Recommended	Required if N95 is not available	Required	Recommended
Clostridioides difficile				Required	
Human immunodeficiency virus		Required	Required if N95 is not available	Required	Required
Necrotizing fasciitis			Required	Required	
Hemorrhagic fevers of unknown etiology	Recommended	Recommended	Required if N95 is not available	Required	Required
Any contact with blood, body fluids, or feces, especially if aerosolized			Required	Required	Required

Abbreviations: MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; SARS, severe acute respiratory syndrome; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; TB, tuberculosis; VRE, vancomycin-resistant enterococci; VRSA, vancomycin-resistant *Staphylococcus aureus*

[a] Each EMS agency should follow the CDC recommendations closely, paying attention to guidance for aerosol-generating procedures and changes relative to the level of community spread.

Description

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is an emerging lower respiratory tract illness caused by a coronavirus. A coronavirus causes infection in the nose, sinuses, or upper throat. Most coronaviruses are not dangerous. However, SARS first appeared as a highly contagious, deadly virus early in 2003 in the Guangdong Province of China. The virus quickly disseminated via person-to-person droplet transmission to people in Hong Kong and Vietnam, and subsequently to people in Singapore and Canada. Those at highest risk during the early stages of the epidemic were health care workers. Ultimately, the epidemic spread to 29 countries, resulting in more than 8,000 infected people and 780 deaths. The cooperative efforts of scientists and physicians in WHO and the CDC as well as in China, Canada, Hong Kong, and other countries led to quick identification of the etiologic agent and isolation and prevention of the spread of the disease. Because of the high morbidity and mortality associated with SARS, the CDC has included it on its list of notifiable diseases to ensure careful monitoring of the US population for further outbreaks.

Special Populations

Zika virus (ZIKV) was first recognized in humans in 1954, but caused only sporadic infections and outbreaks. Thus, this disease attracted little attention until an outbreak occurred in Yap in 2007. The disease was originally thought by some to cause nothing more than a rash and a fever. As ZIKV infection spread throughout Latin America and the Caribbean, however, scientists began to observe far more troubling effects: microcephaly and brain damage in infants born to mothers who became infected during pregnancy, as well as an increased incidence of Guillain-Barré syndrome. Although strong evidence suggests a connection between the virus and these conditions, researchers are still working to clearly describe the pathophysiologic mechanisms and establish a definitive link.

The Zika virus is a mosquito-borne pathogen; specifically, it is carried by the *Aedes* species. The mosquito obtains the virus from the blood of an infected human and spreads it to others who are not infected. In some cases, the disease has been spread sexually from a recently infected man to others. This mode of transmission is possible because, like Ebola, ZIKV can persist in immunologically protected areas, including where semen is produced and stored. While individuals infected with Zika fever usually present with little more than an ILI, there is growing concern over the newly recognized connection to microcephaly and other previously unrecognized neurologic effects.

COVID-19

In early 2020, after a December 2019 outbreak in China, WHO identified SARS-CoV-2 as a new type of coronavirus. Coronaviruses cause most of the colds that affect populations during the year. Most strains are not a serious threat to otherwise healthy people, but SARS-CoV-2, along with the strains of coronavirus that cause Middle East respiratory syndrome (MERS) and SARS, poses a greater threat to humans.

The disease caused by SARS-CoV-2 was named COVID-19, an abbreviation for “CoronaVirus Infectious Disease discovered in 2019.” COVID-19 can affect the upper respiratory tract, lower respiratory tract, gastrointestinal tract, and heart. The virus spreads the same way as other coronaviruses do, mainly through person-to-person contact. Transmission is principally by airborne droplets within 6 feet, but airborne transmission has been demonstrated at greater than 6 feet when there is inadequate ventilation or when people are exposed to respiratory particles generated with expiratory exertion, such as singing, shouting, or exercising.

Effects of infection range from mild symptoms to death. Associated symptoms reported to the CDC in the United States include the following:

- Cough in 50% of patients
- Fever (subjective determination or temperature great than 100.4°F [38°C]) in 43%
- Myalgia in 36%
- Headache in 34%
- Dyspnea in 29%
- Sore throat in 20%

- Diarrhea in 19%
- Nausea/vomiting in 12%
- Loss of smell or taste, abdominal pain, and rhinorrhea in fewer than 10% each

Within 1 year after the first report of SARS-CoV-2, the COVID-19 pandemic had spread around the world, with more than 70 million people infected globally and more than 16 million people infected in the United States. The global mortality was more than 1.6 million, including more than 300,000 deaths in the United States.

Two key characteristics increase the likelihood that severe illness will develop in a person infected with SARS-CoV-2: older age and comorbidities. In an analysis from the United Kingdom, the risk of death among people 80 years and older was 20 times higher than among people 50 to 59 years old. The following comorbidities place a patient at higher risk of severe illness:

- Cardiovascular disease
- Diabetes mellitus
- Hypertension
- Chronic lung disease
- Cancer
- Chronic kidney disease
- Obesity
- Smoking

Several complications of COVID-19 have been described, including the following:

- Respiratory failure
- Cardiac and cardiovascular complications
- Thromboembolic complications
- Neurologic complications

- Inflammatory complications
- Secondary infections

During the COVID-19 pandemic, health care workers have been encouraged to adhere strictly to PPE guidelines and infection control policies when interacting with patients, even those who do not seem to be sick with COVID-19. By September 1, 2020, at least 7,000 health workers had died worldwide after contracting COVID-19. For the health care community and the general population alike, measures to reduce transmission, such as social distancing and wearing face masks, have been crucial in controlling the spread of this disease. Development of improved treatments and COVID-19 vaccinations, the first of which were approved for use in the United States in December 2020, have provided hope that the pandemic may be controlled in the same manner as past global diseases.

Transport Management

COVID-19

- All crew members don proper PPE.
- Place a mask on the patient.
- Keep the patient in respiratory isolation.
- Monitor the mechanical ventilator, if applicable.
- Use noninvasive means of oxygenating patients with hypoxemic respiratory failure.
- Avoid all aerosol-generating procedures.
- Minimize suctioning of the patient's airway.
- Continue IV administration of any medications if they have been started by the sending facility.
- Perform high-level disinfection of all equipment after transport.

Escherichia coli O157:H7

E coli is a family of microorganisms found in the intestinal tract of humans and other mammals. Hundreds of different strains of *E coli* exist, most of which are harmless. A few strains are pathogenic, however. These strains often have specialized fimbriae (finger-like borders), allowing them to adhere to certain intestinal epithelial cells and produce toxins that cause gastrointestinal conditions. Several specific pathogenic groups of *E coli* are distinguished, including enterotoxigenic, enteroinvasive, enteroaggregative, enteropathogenic, and enterohemorrhagic variants. *E coli* O157:H7, which causes hemorrhagic colitis, is emerging as a particularly virulent strain.

E coli O157:H7 is found in the intestinal tracts of ruminant animals, especially cattle. People have become infected with these bacteria after eating undercooked, contaminated ground beef; drinking unpasteurized milk and fruit drinks; eating unwashed lettuce or sprouts; eating salami; and swimming in or drinking sewage-contaminated water. Transmission can also occur via person-to-person contact, usually from infected people who have poor hygiene or handwashing technique. It takes fewer than 10 *E coli* bacteria to cause the onset of symptoms.

The Shiga-like toxins produced by these microorganisms are responsible for causing hemorrhagic colitis, an inflammation of the colon with bleeding and abdominal cramps. Most episodes are self-limiting and last only 5 to 10 days. A small number of infected people, usually those younger than 5 years or older than 65 years, experience hemolytic uremic syndrome. This syndrome is manifested when the toxin affects the kidneys, leading to kidney failure and end-stage renal disease that necessitates dialysis or transplant to sustain life.

Diagnosis of *E coli* infection relies on stool cultures performed using a specialized growing medium such as sorbitol-MacConkey agar plates. Treatment is difficult because of emerging antibiotic resistance. Thoroughly cooking beef, avoiding unpasteurized drinks, and washing hands after handling raw meat can prevent infection with *E coli* O157:H7.

West Nile Virus

West Nile virus (WNV) is an arthropod-borne virus that was first isolated in Uganda’s West Nile district in 1937. A single-stranded RNA

Flavivirus of the Flaviviridae family, WNV is a member of the Japanese encephalitis virus serocomplex that contains other medically important viruses, such as the St. Louis encephalitis virus. The close antigenic profiles of the flaviviruses, especially those of the Japanese encephalitis group, cause serologic cross-reactions in the diagnostic laboratory.

Epidemiology

In 1999, the first US cases of WNV–associated encephalitis were reported in New York City. Evidence suggests that international travel and commerce have played a significant role in this pathogen's introduction into the Western hemisphere. In Africa and Asia, disease outbreaks caused by WNV were infrequent and were not associated with serious morbidity or mortality. Since the virus's introduction in the United States, however, the frequency and apparent severity of WNV cases have increased, spiking in 2012 with more than 5,674 cases before settling down to an annual average of approximately 2,000 cases per year. The WNV epidemic of 2002, the largest meningoencephalitis epidemic recorded to date, resulted in more than 4,000 cases and 200 deaths.

In 2015, an outbreak in the United States led to more than 1,900 people becoming infected and 111 deaths. The majority of these cases occurred in California (including 100 cases in Orange County), where there is an ongoing drought. Without rain to flush them away, mosquitoes were able to lay and hatch their eggs in stagnant pools of water in drainage systems, resulting in an explosion in the mosquito population. WNV is a mosquito-borne pathogen. Adult mosquitoes emerge in the spring. Viral amplification occurs through mosquito–bird–mosquito cycling until early fall, when female mosquitoes begin diapause and infrequently bite humans or other animals (typically horses) to gain protein for egg development from a blood meal **FIGURE 20-10**. The virus is found in the salivary glands of the mosquito and is transferred during the bite. Mosquitoes are the bridge vectors that maintain the cycle of infection by feeding off both humans and birds.

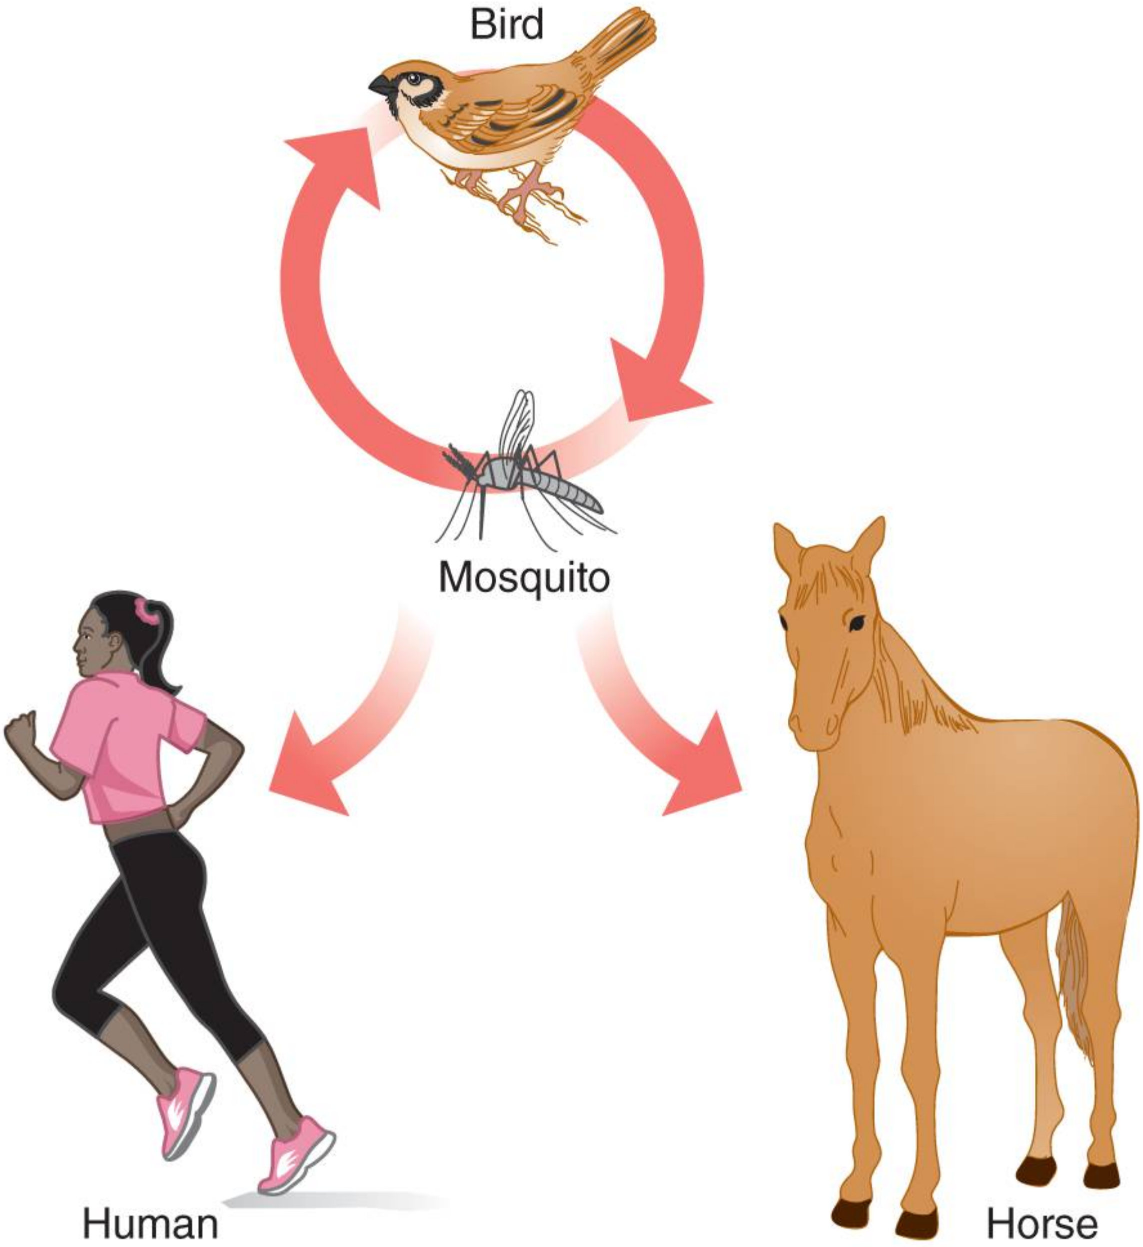

FIGURE 20-10 Transmission cycle of the West Nile virus.

© Jones & Bartlett Learning.

Description

In temperate climates, human disease outbreaks peak in late summer and continue into fall; however, year-round transmission is possible in the more southern states. WNV is endemic in all of the continental United States and in the District of Columbia (as well as in Canada and Mexico). The mosquito responsible for transmission to humans is primarily the *Culex* species; however, other types of mosquito can carry the disease as well.

Diagnosis and Management

The incubation period of WNV ranges from 3 to 14 days. Most infections are subclinical, and patients remain asymptomatic. A febrile viral syndrome develops in approximately 20% of infected people; only 50% of those infected will seek medical attention. The signs and symptoms of WNV infection vary, but frequently include sudden onset of fever with malaise, anorexia, nausea, vomiting, eye pain, headache, and myalgia, which last 3 to 6 days. Symptoms may also include rash, lymphadenopathy, fatigue, and arthralgias. Approximately 1 in 100 infections results in meningitis or encephalitis. Advanced age is the most significant risk factor associated with severe neurologic sequelae following infection.

A high index of clinical suspicion is required for prompt diagnosis. Arboviral disease should be included in the differential diagnosis in any older adult who presents with a sudden onset of unexplained encephalitis or meningismus in the late summer or early fall. The presence of local WNV enzootic activity or other human cases should amplify the level of suspicion. Because WNV infections have occurred in people of all ages and because year-round transmission is possible in southern states, any person presenting with unexplained encephalitis or meningismus should trigger suspicion of WNV infection.

WNV is most efficiently diagnosed by detection of IgM antibody to WNV in the CSF via antibody-capture enzyme-linked immunosorbent assay. The presence of WNV-positive IgM antibody in the CSF strongly suggests WNV infection of the central nervous system, because IgM antibody does not cross the blood–brain barrier. The CSF may reveal normal to elevated leukocyte levels, with lymphocytes predominating; an elevated protein level; and normal glucose levels. Serum samples also have a high rate of positive results for WNV IgM antibody.

There is no cure for WNV encephalitis. Infections are treated symptomatically, and supportive therapy is important for patients with more severe illnesses.

Prevention of Infection

WNV encephalitis has been added to the list of nationally notifiable arboviral encephalitides. The timely identification of acute WNV has substantial public health implications, and case reports will likely prompt a vigorous public health response to reduce the risk of additional human infections.

Integrated vector management programs are the best way to control mosquito populations and prevent human infection. Mosquito control measures should emphasize the elimination of standing water. Mosquito development consists of three aquatic stages: egg, larva, and pupa. Therefore, elimination of this environmental niche is an effective way to reduce mosquito populations without resorting to insecticides.

CCTPs working outdoors should apply an insect repellent while engaging in prolonged extraction or search-and-rescue activities. The CDC recommends repellents containing the active ingredient DEET for this purpose. Increasing the concentration of DEET in the repellent does not increase its strength, but does increase the duration of effect. DEET concentrations of 50% or more do not increase the duration of protection significantly, so little benefit is gained by using them. DEET does not kill mosquitoes, but rather prevents them from detecting human skin odors and, therefore, finding a blood meal.

Peak mosquito biting times are dawn, dusk, and early evening. Long pants and long-sleeve clothing provide an added measure of protection.

Signs and Symptoms

West Nile Virus Infection

- Sudden-onset fever
- Malaise

- Anorexia
- Nausea
- Vomiting
- Eye pain
- Headache
- Myalgia
- Rash
- Lymphadenopathy
- Fatigue
- Arthralgias

Differential Diagnosis

West Nile Virus Infection

- *Borrelia burgdorferi* infection
- Brain abscess
- Brain tumor
- Dengue fever
- Guillain-Barré syndrome
- Leptospirosis
- Meningitis
- Paraspinal epidural abscess
- Stroke
- Tick paralysis
- Eastern equine encephalitis
- Other infectious encephalitis

Transport Management

West Nile Virus Infection

- Provide supportive care.

Strategies for the Treatment of Infectious Disease

As discussed earlier in this chapter, microorganisms possess unique properties that allow them to invade their human hosts, evade immune detection, and establish infection. These same properties are exploited when developing agents to inhibit their growth or eliminate them from the body. The goal of any such therapy is to eradicate the pathogen without causing undue harm to the host. This section explores how antibiotics, antivirals, and antifungal agents are designed to target the unique organelles of each class of organism.

Antibiotics

Antibiotics are compounds that are produced by bacteria or fungi and that inhibit the growth of or kill other bacterial organisms. Compounds that inhibit bacterial growth are called **bacteriostatic**, whereas compounds that kill bacteria are termed **bactericidal**. Synthetic antimicrobials are designed using the "magic bullet" concept, exploiting the differences between human and microbial cells. The beta-lactam antibiotics include penicillin, ampicillin, amoxicillin, and carbenicillin, among others. These bactericidal drugs act on gram-positive bacteria by competitively inhibiting transpeptidase, the enzyme that catalyzes peptidoglycan cell wall synthesis.

Different families of bacterial cells have unique components that are targeted by different classes of antibacterial drugs. All antibacterial agents follow the same basic principle of targeting bacterial proteins, processes, or cellular components that are not found in human cells. Even though human cellular components are not the targets of antimicrobial therapies, these agents may have some adverse effects that must be considered when choosing the appropriate therapy. For example, quinolones such as ciprofloxacin can cause tendon rupture, particularly in people older than 60 years;

alternative antibiotics may be selected for members of this age group.

Antivirals

Viruses account for millions of severe illnesses every year worldwide. The common seasonal influenza viruses alone account for 3 to 5 million severe illnesses annually and 290,000 to 650,000 deaths from respiratory illness. Despite these staggering numbers, relatively few treatment modalities have been developed to care for patients with viral illnesses. The difficulty lies in isolating the steps of the viruses' replication, which are intimately involved with the normal synthetic processes of the human host cell. The medications that are effective against viral diseases focus on interrupting the viral replication cycle at a specific step. Virus replication takes place during an incubation period, when the patient is asymptomatic and, therefore, not likely to be taking any antiviral medication. A virus can also become latent within the body, rendering it almost impossible to eradicate.

Three classes of antiviral medications have been developed: nucleoside analogs, enzyme inhibitors, and interferon. Nucleoside analogs such as acyclovir and AZT are used to treat herpesviruses and HIV infection, respectively. Enzyme inhibitors are used to treat influenza; they include drugs such as indinavir and zanamivir. Alpha-interferon is used to treat viral hepatitis.

Because of the limited number of medications available to treat active viral infections, prevention of viral infections in health care workers is best achieved through vaccination, when available. Meanwhile, biochemists continue working to create novel medications to treat both viral and bacterial infections.

Antifungals

Human and fungal cells are similar in that both are eukaryotic. Because of their similar makeup, finding agents that affect the fungal cell without harming the human cell can be challenging. Indeed, many antifungal agents can produce toxic results when used systemically. A primary difference between human and fungal cells is their membrane components. The fungal cell membrane contains ergosterols, whereas the human cell membrane contains cholesterol. This structure is different enough for the fungal cell membrane to be a target of antifungal therapy. Polyene compounds bind with the sterols in this membrane, making the membrane less fluid and more susceptible to rupture. As a result of the change in fluidity, the cell membrane leaks and loses its integrity, which leads to cell death. Other antifungal therapies are available, but all represent a variation on this theme; that is, they all target pathways or enzymes that are specific to fungal cells.

The Post-Antibiotic Era

Before the advent of antibiotic agents, bacterial infections were the cause of significant morbidity and mortality. In 1900, the three leading causes of death in the United States were infectious diseases. In 2019, the leading causes of death were noninfectious diseases: heart disease, cancer, and unintentional injuries. Even so, many scientists worry that we are entering a “Post-Antibiotic Age” because of the emergence of antibiotic-resistant bacteria. Almost all important pathogenic bacteria have demonstrated resistance to current Food and Drug Administration (FDA)–approved antibiotics. Antibiotic resistance has become one of the world’s most pressing public health problems in the 21st century.

Antibiotic resistance can cause significant morbidity and mortality in people infected with previously easily treatable infections. Staphylococci, for example, are one of the most common causes of community- and hospital-acquired infections. *Staphylococcus* commonly colonizes the skin and nares of healthy people. If this bacterium causes a simple infection, most people can be successfully treated with beta-lactam antibiotics. However, staphylococci also cause serious infections, such as postoperative infections or pneumonia; treatment of these infections becomes increasingly difficult as resistance develops.

Three important factors contribute to the emergence of resistant bacteria within a given population or community:

- Misuse or overprescription of antibiotics
- Poor infection control
- Importation or intrusion of already resistant strains

The continual use of antibiotics paradoxically leads to declining effectiveness through selective pressures and the development of resistance, because increasing resistance causes a concomitant decrease in the therapeutic options for eliminating infections. In the critical care environment, there are many opportunities for contamination and subsequent cross-transmission of resistant bacteria. Infection control measures—for example, handwashing, patient isolation, and proper disposal of contaminates—are important in breaking this cycle of transmission. It is important for CCTPs to be keenly aware of how their actions can either hinder or hasten the spread of disease.

Antibiotic Resistance

Causes of Resistance

Antibiotic resistance occurs when the bacteria acquire new properties through mutation, protein alteration, or conjugative transfer of plasmid-encoded resistance factors. Resistant organisms coexist with healthy skin or gastrointestinal flora. When antibiotics are used to treat infection or used inappropriately for viral infections, the normal, protective flora is eliminated, allowing the resistant strains to dominate. This relative decrease in the sensitive strains and increase in the resistant strains leads to selective pressure on the weaker protective bacteria. The bacteria that are not eliminated are stronger (ie, more resistant to antibiotics), making it more difficult to cure the patient, and these resistant strains move on to cause infection in the next host. When this theme is applied on a grander scale to the critical care setting, where the use of antibiotics is routine and infectious sources are plentiful, the true magnitude of the problem becomes apparent.

Another emerging concern related to transferrable antimicrobial resistance is extended-spectrum beta-lactamase (ESBL). ESBL is an enzyme produced by some bacteria and is an urgently important mechanism of resistance to beta-lactams such as penicillin and third-generation cephalosporins, including ceftriaxone and cefotaxime. A particularly troubling aspect of ESBLs is that they can be transferred between strains of a single microbial species, and even between species. Complicating the problem is the difficulty in detecting which bacterial species possess the enzyme. A large percentage of *E coli* and *K pneumoniae* species are now known to express these enzymes. Infection with ESBL-expressing bacteria has resulted in treatment failures, and the prevalence of such disease is clearly increasing worldwide.

Prevention of Resistance

Infection control is critically important in thwarting the development of new resistant strains and preventing the spread of currently resistant strains. Unfortunately, health care workers are a major source of cross-infection between critically ill patients. Handwashing is the single most important act that a health care provider can perform to reduce the spread of infection. However, even under the best circumstances, compliance with handwashing is low. It is even more difficult to accomplish in the critical care transport environment, but is incumbent upon CCTPs as part of their role: If CCTPs do not practice proper hand sanitation methods when providing care, their hands may become vectors for transmission of infectious disease.

Another important method for reducing the spread of resistant bacteria is the isolation of infected patients. Methods of isolation include geographic isolation, negative-pressure isolation, contact precautions, and barrier isolation.

Antibiotics should be prescribed only when they are likely to be beneficial. The choice of antibiotic should be appropriate—using a drug that will eliminate the pathogen most likely to be causing the infection or, better yet, using definitive culture and sensitivity testing to identify the infecting bacterial strain and then combating it with the correct drug. The prescription should be written for the appropriate dose and duration of treatment. Using a drug for longer than is required to eliminate the offending bacteria does not offer any additional benefit to the patient.

Each year in the United States, an estimated one-third of all antibiotics prescribed are unnecessary, a trend that has contributed to increasing antibiotic resistance. Members of the public must be made aware of the role they play in promoting the emergence of resistant strains and, in turn, educated to reduce their demands for inappropriate prescriptions. Even though these agents are completely ineffective against viral infections, tens of millions of antibiotic prescriptions are written each year for viral illnesses. Time pressure on physicians and patients alike, diagnostic uncertainty, and demand from uninformed patients all contribute to the continued inappropriate use of antibiotics. To ensure that patients return to their practice, physicians are often under pressure to prescribe, but prescribing just for the sake of convenience and to satisfy a patient's demand is never appropriate.

Patients, for their part, must take appropriately prescribed antibiotics as directed and for the full duration of the intended treatment. All too often, once symptoms of the illness are relieved, patients stop taking the drug, even though the infection may not be completely eradicated. When infections are treated incompletely, the weaker strains of bacteria are killed, but the stronger or antibiotic-resistant strains may be left unharmed; their survival then contributes to the emergence of resistance by selection.

Patients should also be warned against the dangers of using “leftover” antibiotics prescribed from prior infections to treat their current ailments. First, their symptoms may not be caused by a bacterial infection. Second, if they do truly have a bacterial infection, the drug may be completely ineffective against the particular causative bacterial strain and may cause the patient to become sicker. Also, partially treating bacterial infections with antibiotics may make it more difficult to isolate, identify, and perform sensitivity testing on the culprit microbe, making treatment decisions all the more difficult for the health care provider.

Methicillin-Resistant Staphylococcus aureus

Methicillin-resistant *S aureus* (MRSA) is a gram-positive, coagulase-positive, nonmotile coccus that produces an altered penicillin-binding protein that confers resistance to beta-lactam antibiotics, including methicillin. Most strains of MRSA are also resistant to multiple classes of antibiotics, making these infections difficult to control. MRSA can colonize a variety of tissues, causing infections such as cellulitis, cutaneous abscesses, wound infections, osteomyelitis, septic arthritis, endocarditis, pneumonia, and septicemia.

MRSA was first detected in Europe and Australia in the 1960s, and it was identified in the United States 10 years later. It has gradually become a major player in resistant nosocomial infections. Humans are the major reservoir of MRSA. Most carriers are colonized in the nares, pharynx, and skin. High rates of MRSA are found among residents of long-term care facilities, but serious infections with MRSA are more prevalent in acute care settings. Risk factors for colonization include dialysis, diabetes, use of injectable drugs, chronic skin conditions such as decubitus ulcers, and a history of prior antibiotic use. MRSA is also emerging as a community-acquired pathogen; that is, MRSA may be acquired by people who have not been hospitalized recently and have not undergone a recent medical procedure.

Transient contamination of the hands of health care providers often results in the transmission of resistant organisms to other patients. MRSA may be spread by direct contact with patients who are infected, or by contact with contaminated objects. Given this risk, patients with known MRSA infections should be placed on contact precautions until they have been successfully treated and the results of their nasal and rectal swabs are negative. As always, CCTPs should avoid direct contact with wounds by wearing gloves during all dressing changes and avoiding direct contact with any patient with a known MRSA infection.

Vancomycin is the drug of choice for treating MRSA infection. An alternative to vancomycin for the treatment of MRSA skin infections and nosocomial pneumonia is linezolid. Linezolid’s key advantage is that it is available in an oral form, whereas vancomycin is not absorbed in the gastrointestinal tract. Until recently, all strains of MRSA had been sensitive to vancomycin; however, vancomycin-resistant *S aureus* has also emerged and resulted in deaths in the United States.

The emergence of vancomycin-resistant MRSA poses a serious threat to patients and health care workers; if it is encountered, the patient should be isolated and the infection should be reported to public health authorities. Implement contact precautions, minimize the number of people with access to the colonized/infected patient, and provide dedicated one-on-one care to minimize exposure. Avoid transferring infected patients between or within facilities. If a transfer is necessary, fully inform the receiving institution of the patient's status.

Vancomycin-Resistant Enterococci

Enterococcus is a gram-positive bacterium normally found in the intestinal tract (ie, it is part of the normal flora); however, antibiotic-resistant species of *Enterococcus* have become a major cause of nosocomial infection in the United States. These bacteria rarely cause illness in healthy people, but can cause serious infections in immunocompromised, postoperative, and other seriously ill people. Because enterococcal bacteria colonize the intestinal tract, transmission is largely the result of direct person-to-person contact or indirect contact (eg, doorknobs and toilet seats) from inadequate handwashing after evacuation of feces.

Two types of antibiotic resistance are found in enterococci: intrinsic and acquired. Intrinsic resistance, a natural resistance found in the bacteria, is caused by the vanC gene. Acquired resistance is genetically transferred from another resistant organism. The two responsible genes are transmissible to other bacteria by plasmids and transposons, and they confer resistance to much higher levels of vancomycin. Another critical consideration is that the vancomycin-resistant genes present in vancomycin-resistant enterococci (VRE) have the potential to be transmitted to other gram-positive organisms, such as *S aureus.*

For these reasons, health care facilities should test all people at high risk for VRE; if found to be positive, patients should be isolated and standard precautions should be used during their care. Because patients can carry VRE organisms for long periods of time, particularly in their stool, the CDC and the Hospital Infectious Control Practices Advisory Committee recommend that isolation should continue until the patient has three sets of negative cultures from all appropriate sites taken at least 1 week apart.

In the critical care environment, there are many opportunities for contamination and subsequent cross-transmission of resistant bacteria. When transporting VRE-positive patients, infection control measures such as handwashing, patient isolation, use of protective barriers such as gloves and gowns, and proper disposal of contaminated materials are important in breaking the cycle of transmission.

Carbapenemase-Producing Gram-Negative Bacilli

Carbapenem antibiotics are unique in their ability to act against the gram-negative pathogens that are resistant to beta-lactam antibiotics such as cephalosporins. In recent decades, however, the clinical efficacy of these antibiotics has been threatened by the emergence of carbapenem-hydrolyzing beta-lactamases, increasing the threat of extreme drug resistance in gram-negative bacilli.

The *K pneumoniae* carbapenemase (KPC) is the most common carbapenemase in the United States. It was first described in a clinical isolate of *K pneumoniae* in the late 1990s in North Carolina and has since been identified in isolates from most other states. These organisms can easily spread by person-to-person transmission.

Carbapenemase-producing organisms can cause bloodstream infections, ventilator-associated pneumonia, urinary tract infection, and central venous catheter infections, as well as asymptomatic colonization. These organisms have been isolated from respiratory tract specimens, abdominal swabs, catheters, abscesses, urine, and surgical wounds. They have caused sporadic hospital-acquired infections, and outbreaks have been reported in both tertiary and community hospitals.

Bioterrorism

Bioterrorism (biologic weapons) is an emerging threat to the health and safety of the community. Many countries currently have or are developing offensive biologic weapons programs. Since the terrorist events of September 11, 2001, and with the continued threat of terrorism in the United States, there is increasing concern over the possibility of terrorists using biologic agents against civilian populations. To prepare for potential intentional biologic disasters, local, state, and federal officials have implemented education and training of first responders related to these threats **FIGURE 20-11**. The biologic agents that might potentially be used for bioterrorism are considered "the poor man's nuke," because just a small amount of agent can cause a large number of infections. For example, if 110 pounds (50 kg) of anthrax spores was released from a low-flying aircraft along a 1.25-mile (2-km) line above a population base of 500,000, it is estimated that there would be 125,000 people infected and 95,000 deaths. Anthrax spores can travel more than 12 miles (20 km).

Description

The goals of a bioterrorism emergency response should be to contain the agent, protect critical personnel, and manage the health consequences of the event. Containment of a contagious disease resulting from deliberate release of an infectious agent requires that the incident be recognized as a non-natural event based on a disease presentation that differs from the usual background of endemic infectious diseases that affect the community. The first cases are likely to go unrecognized, because most agents likely to be used for bioterrorism purposes present with initial nonspecific flulike symptoms such as fever, malaise, and headache; these types of findings make the biologic attack difficult to recognize during the initial stages of infection.

The covert release of a biologic agent could take place over a period of days to weeks, and it might be even longer before the initial cases of infection are identified, depending on the mode of transmission and the agent’s incubation period. As the span of time between exposure and symptoms increases, so does the likelihood that the agent will become distributed over a wide geographic area and result in an epidemic.

It is also possible that the deliberate release of a biologic agent would be publicly announced by the attacker(s)—a possibility that poses a different set of problems for the emergency response system. Such an announcement would likely trigger large-scale panic, with many people calling for emergency services without actual need, overwhelming health care systems and preventing the efficient use of medical resources. The challenge would then be to differentiate those people who were actually exposed to the agent from those whose fear of the agent has caused them to seek care. A number of bioterrorism events have been publicly announced in the United States since 1998, though they were later determined to be hoaxes.

The CCTP must be prepared to deal with either scenario. Knowledge of epidemiologic principles is crucial in differentiating between the presentation of a naturally occurring disease and an unusual, non-natural event that should raise concern that a bioterrorist event has been initiated and that local emergency response systems should be activated.

The CCTP must maintain an index of suspicion regarding a potential threat because early symptoms may be nonspecific, but early treatment will be required to prevent severe injury or death. Before approaching a patient, CCTPs must always take steps to protect themselves first, using the standard precautions and additional precautions outlined in Table 20-9. In addition, immunologic protection is the responsibility of the CCTP. All CCTPs must stay current on required and recommended vaccines, keeping in mind what is appropriate for a particular patient population, and consider the appropriateness of being vaccinated against agents that may be exploited in bioterrorism attacks. For the most updated information, visit the CDC's website (www.cdc.gov) and search for the Infection Control Guidelines.

Exposure and Protection

CCTPs have unique occupational exposures to a variety of biologic, chemical, and physical hazards. These professionals are routinely in contact with critically injured and very sick patients, often in uncontrolled settings under emergent conditions. Resuscitating critically ill patients is associated with being in contact with potentially infected body fluids 31% of the time. CCTPs also care for trauma patients with open wounds that may be actively bleeding. Managing trauma patients is associated with exposure to body fluids 80% of the time. In the chaos of providing care for life-threatening diseases or injuries in unpredictable or dangerous conditions, adhering to well-established exposure prevention procedures is essential to protect the health of the CCTP.

The health risks associated with being a CCTP are not simply limited to blood or body fluid exposures; infectious agents also pose a significant risk. The greatest risks come from patients who are actively infectious but undiagnosed. Activities and tasks during which exposure may take place include the following:

- Patient assessment
- Airway management
- Establishing IV access
- Cleanup of the vehicle and equipment
- Assisting in childbirth
- Contact with blood or body fluids

CCTPs must take prophylactic measures to prevent infection prior to their exposure. Several effective strategies may be used to reduce the risk of contracting an infectious agent or transmitting infections to patients, but disease prevention is best achieved when the CCTP is fully prepared and properly equipped.

The use of PPE reduces exposure risks. Employers are required to provide their employees with PPE at no cost to the employee. Proper handling of contaminated medical devices, such as sharps, soiled bandages, linens, and reusable medical equipment, is also essential in reducing the risk of indirect transmission of infectious diseases **FIGURE 20-12**. In addition, the consistent implementation of isolation precautions is required to control the spread of infections to others.

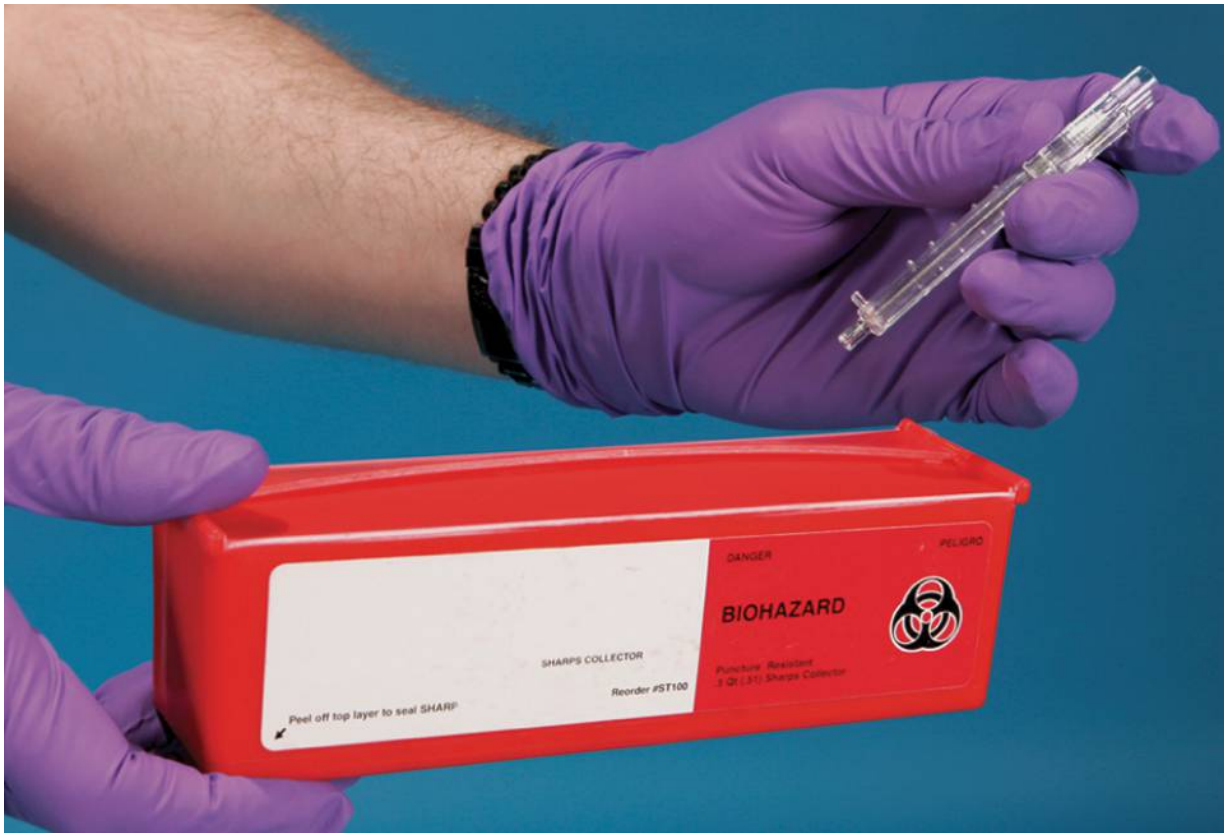

FIGURE 20-12 All sharps must be placed into containers that are puncture-resistant, closable, and leakproof, and that are labeled with the biohazard symbol.

© Jones & Bartlett Learning.

Immunizations

The CDC recommends that all emergency medical care providers be vaccinated against preventable infectious diseases. The specific immunization recommendations are based on the risk of exposure.

Any new employees should not begin taking an active role in caring for patients until their immunization status is reviewed and up-to-date.

The current recommendations for emergency medical care providers call for them to obtain (and maintain) the following vaccinations:

- Measles
- Mumps
- Rubella
- Varicella (immunization or proof of prior infection)
- Hepatitis B
- Annual influenza
- SARS-CoV-2
- Pertussis
- Tetanus
- Polio
- Diphtheria
- Pneumococcal vaccine
- Meningococcal vaccine

If health care providers may be exposed to blood or other infectious materials during the course of performing their work-related duties, their employers are required to provide the hepatitis B vaccine to those employees at no cost. Ideally, the vaccination should start during the training period, before patient contact is initiated. The HBV vaccine is administered at 0, 1, and 6 months, with 95% of healthy adults developing protective titers on completion of the three scheduled immunizations. If an employee has already received the full series of vaccinations, an antibody titer should be drawn to verify immunity. The duration of the HBV vaccine's protection is unknown, but it has been shown to last at least 7 years in healthy young adults. If the CCTP has a medical contraindication to the vaccine, this issue should be documented and readdressed if the medical condition changes. Any employee who declines the HBV vaccine must sign a waiver releasing the employer from responsibility for work-related exposures.

The influenza vaccine is recommended for CCTPs because the influenza virus easily spreads through close contact with infected people via small aerosolized particles. Although most healthy adults are able to recover from influenza without significant morbidity, sick and older patients do not have the same immunologic reserves. On that basis, the influenza vaccine is recommended for CCTPs to prevent spread of the virus to their patients, thereby preventing significant morbidity and mortality.

Measles, mumps, and rubella—although now rare—can cause significant disease in susceptible people. The risk of contracting such infections is increased 13 times for the CCTP compared to the general public. Most adults in the United States have been immunized for these diseases, but immunity should be confirmed via a serologic titer. This is especially important for women of childbearing age to prevent the development of rubella syndrome in pregnancy.

The varicella vaccine is important for CCTPs for two main reasons. First, varicella is highly contagious, and varicella infection can cause serious complications in normally healthy adults. Second, vaccination of CCTPs is important to prevent the transmission of the disease to their patients. People with a positive history of chickenpox as children are considered immune, but if CCTPs' medical history of varicella is in doubt, they should undergo immunologic confirmation of serologic status. If an individual is seronegative and has no contraindications to the vaccine, the vaccine should be administered.

The FDA approved two SARS-CoV-2 vaccines under its emergency use authorization in December 2020. Since then, more vaccines have been developed and made available for public use. All of these vaccines are highly effective, are safe, and possess a favorable side-effect profile. Based on current understanding of the infectivity of SARS-CoV-2, it is believed that approximately 70% to 80% of the population must develop immunity to achieve the herd immunity required to end the COVID-19 pandemic.

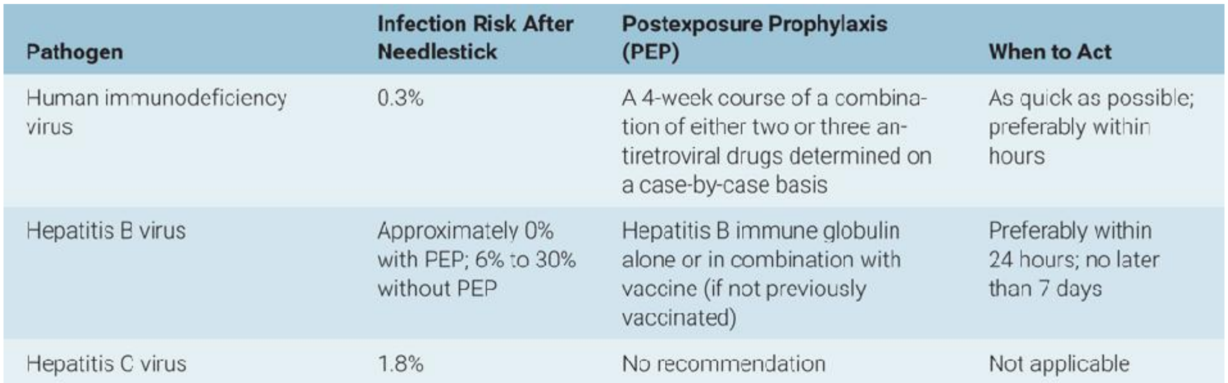
Vaccines are considered a safe and effective way to prevent contagious diseases. All CCTPs are encouraged to discuss immunizations with their employer's health personnel or their own private physicians before vaccinations are given to ensure that there are no contraindications to receiving specific vaccines.

Needlestick Injuries

Needlestick injuries continue to occur, despite efforts to curtail these events. By law, all needlesticks and other injuries involving sharps contaminated by blood must be reported to the employer. Reporting sharps injuries is necessary when the injury occurs in the course of performing work-related duties and when the object causing the injury is contaminated with blood or other potentially infectious materials. It is not necessary to report sharps injuries that occur with clean objects. When reporting the injury, it is important to characterize it by type of injury (ie, splash, spill, stick, or cut) and by the type and amount of contaminating fluid (eg, saliva, semen, ascites, or blood). It is also important to determine the infectious status of the source patient. The Ryan White Act of 1990 mandated that all EMS personnel could request testing of a source patient to determine if they have been exposed to a life-threatening disease, with the results then being given to the affected employee. When the act was renewed in 2006, the clauses protecting emergency personnel were removed by Congress, making it much more difficult for the CCTP to gain access to this critical information.

The risk of a CCTP acquiring an infectious disease from a contaminated sharps exposure depends on the infectivity of the source and the type or severity of the exposure (**TABLE 20-10**). The larger the number of viral particles encountered during the exposure, the greater the risk is. The estimated risk of HIV transmission is 0.33% for hollow-bore needlesticks and 0.09% for mucosal contact; there are no known cases of HIV transmission for intact-skin exposures.

TABLE 20-10 Risk of Infection and Required Postexposure Prophylaxis for the Three Most Commonly Transmitted Pathogens



Pathogen	Infection Risk After Needlestick	Postexposure Prophylaxis (PEP)	When to Act
Human immunodeficiency virus	0.3%	A 4-week course of a combination of either two or three antiretroviral drugs determined on a case-by-case basis	As quick as possible; preferably within hours
Hepatitis B virus	Approximately 0% with PEP; 6% to 30% without PEP	Hepatitis B immune globulin alone or in combination with vaccine (if not previously vaccinated)	Preferably within 24 hours; no later than 7 days
Hepatitis C virus	1.8%	No recommendation	Not applicable

Adapted from Centers for Disease Control and Prevention. Exposure to blood: what healthcare personnel need to know. https://www.cdc.gov/HAI/pdfs/bbp/Exp_to_Blood.pdf. Updated July 2003. Accessed February 13, 2021.

Description

The following factors increase the risk of acquiring HIV after a needlestick injury:

- Deep injury
- Needle placed directly in a vessel (artery or vein)
- Visible contamination with source patient’s blood
- Terminal illness in the source patient

Universal, Standard, and Transmission-Based Precautions

Universal precautions are the isolation precautions taken when dealing with all patients regardless of disease status. At a minimum, they require using gloves to prevent direct contact between the provider and the patient. The use of gloves, mask, goggles, gown, and shoe covers when handling body fluids or tissues of a patient who is not suspected of having a transmissible disease is called

standard precautions. Think of a field childbirth: While the mother may be perfectly healthy, a health care provider would not think of assisting the delivery without wearing a gown, gloves, mask, goggles, and shoe covers.

More specific **transmission-based precautions** are used when the patient is suspected to have a specific illness. The type of PPE used is generally determined by the perceived means of spread of the pathogen—airborne, droplet, or contact. This logic actually is flawed, because few pathogens will fall neatly into these categories. Some pathogens spread by droplets may be small enough to travel via the airborne route in the right circumstances, whereas some pathogens spread by direct contact may be aerosolized into a droplet form.

Isolation Precautions

Two levels of **isolation precautions** are distinguished. The first level is designed for the care of all patients, regardless of their diagnoses, presumed infections, or immune status. The main goal of this level is to control nosocomial infection by facilitating the safe and proper handling of blood and other potentially infectious materials. The major features of these standard precautions are designed to reduce the risk of transmission of bloodborne pathogens from both known and unknown sources of infection. These precautions should be universally applied to all patients. They protect against contact with blood, body fluids, and secretions, regardless of the presence of visible blood, and contact with nonintact skin and mucous membranes.

The second level of isolation precautions comprises transmission-based precautions, which consist of isolation precautions designed to be employed during the transport of all patients with documented infections or those suspected to be infected with highly transmissible or epidemiologically significant infectious agents for which additional precautions above the first tier of standard precautions are warranted. The three means of providing transmission-based precautions are airborne, droplet, and contact precautions. These recommendations are intended to be used over and above the standard precautions and can be used singly or in conjunction, as the circumstances require.

It is likely that during the transport of critically ill patients from the scene to the tertiary facility, the etiology of any infectious disease will not be known. The risk of transmission is greatest before definitive diagnoses are made. Standard precautions should be implemented without fail on all transported patients. The use of transmission-based precautions should be implemented if the patient has any known risk factors or demonstrates suspicious symptoms or syndromes. It is much better to err on the side of prevention, until the definitive diagnosis can be determined, than to try to contain an infectious disease outbreak after the fact.

Certain clinical syndromes and conditions are red flags that indicate the empiric use of the second layer of precautions is warranted. Moreover, in the case of interfacility transfers, the infectious agent may have already been identified. If so, it is imperative that this information be known and contact precautions implemented accordingly.

Airborne Precautions

Airborne precautions include use of an N95 mask by CCTPs, a negative-pressure room (airborne infection isolation room) or transport vehicle, and an exhaust fan during transport. These precautions are designed to reduce the risk of transmitting infectious agents that are contained in airborne droplet nuclei or dust particles. Examples of agents carried in droplets (equal to or less than 5 μm) are tuberculosis (either pulmonary or laryngeal), measles, chickenpox, viruses that cause hemorrhagic fevers, and smallpox. Microbes found in droplet nuclei can remain viable when suspended in the air for long durations, and can be dispersed over a wide area, where they may be inhaled by susceptible hosts. Specialized air-handling equipment is required to provide airborne precautions.

Droplet Precautions

Droplet precautions include isolation of the patient and use of surgical masks by CCTPs. These precautions are designed to reduce the risk of transmitting infectious agents that are found in large-particle droplets (larger than 5 μm). Transmission via large-particle droplets requires close contact between the source of the infection and the susceptible recipient. Droplets are generated from infectious people during coughing or sneezing, and during invasive procedures such as suctioning of the airway, intubation, or bronchoscopy. Unlike airborne droplet nuclei, large-particle droplets travel only short distances and remain airborne for just a short time after being generated. Examples of infectious agents found in large-particle droplets include *S pneumoniae*, *C diphtheriae*, *Bordetella pertussis*, *N meningitidis*, *H influenzae*, and *Yersinia pestis* (pneumonic plague).

Droplet precautions should be implemented when caring for patients suspected or known to be infected with epidemiologically important pathogens that may be transmitted by infectious droplets. Eye protection (goggles, face shields, and safety eyeglasses) is recommended for use while transporting patients known to be infected with agents that can spread via the mucous membranes of the eye (conjunctiva), including *S aureus*, rhinovirus, adenovirus, herpes simplex virus, and any bloodborne agents (eg, HBV, HCV, HIV). These pathogens can be spread via respiratory droplets or by touching the patient and then touching the eyes with the contaminated hands or fingers. Eye protection prevents introduction of infectious agents into the conjunctiva. (Note: Full-face respirators also provide eye protection.)

Contact Precautions

Contact precautions for CCTPs include isolation of the patient, use of a gown (or uniform) and gloves, and, if warranted, face protection. These precautions are designed to decrease the risk of spread of infectious agents that can be transmitted by direct or indirect contact.

Direct contact transmission is defined as skin-to-skin contact and subsequent transfer of an infectious agent from an infected person to a susceptible host. It can occur during any patient care activity that requires physical contact between the CCTP and the infectious patient. Direct contact transmission can also occur between two patients, and between a patient and a family member.

Indirect transmission is the transfer of infectious agents from an infected patient through an intermediate (most often inanimate) object touched by or used during the care of the infected patient (ie, fomites). Examples of epidemiologically important infectious agents that can be transmitted via contact include MRSA, VRE, *Clostridioides difficile*, scabies, smallpox, and viruses that cause hemorrhagic fevers, and *Bacillus anthracis*.

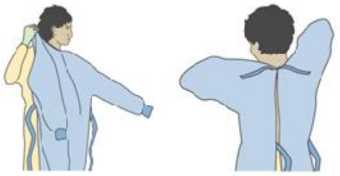
Contact precautions must be employed during the transfer of patients known or suspected to be infected with microorganisms that can be transmitted through direct or indirect contact. Any equipment used on these patients during the course of a transport must be discarded or disinfected to interrupt the cycle of indirect transmission.

In addition, CCTPs must follow the regimen for donning and removing PPE that has been established by their agency's infection control staff **FIGURE 20-13**. In general, you should never touch your eyes, nose, or mouth with contaminated gloves or hands. After handling contaminated equipment, always wash your hands. If handwashing is not possible, use a waterless hand sanitizer and then wash your hands as soon as it is practical.

SEQUENCE FOR DONNING PERSONAL PROTECTIVE EQUIPMENT (PPE)

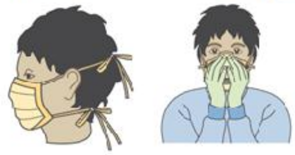
1. GOWN

- Fully cover torso from neck to knees, arms to end of wrists, and wrap around the back
- Fasten in back of neck and waist



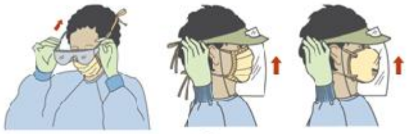
2. MASK OR RESPIRATOR

- Secure ties or elastic bands at middle of head and neck
- Fit flexible band to nose bridge
- Fit snug to face and below chin
- Fit-check respirator



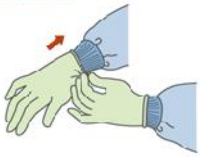
3. GOGGLES OR FACE SHIELD

- Place over face and eyes and adjust to fit



4. GLOVES

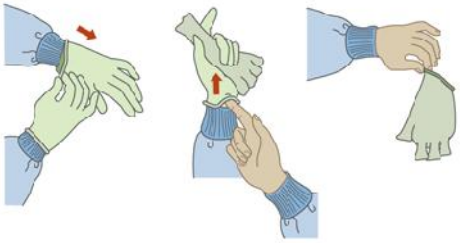
- Extend to cover wrist of isolation gown



SEQUENCE FOR REMOVING PERSONAL PROTECTIVE EQUIPMENT (PPE)

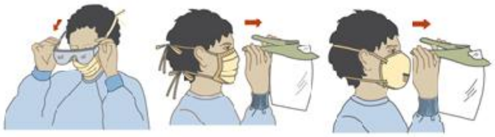
1. GLOVES

- *Outside of gloves is contaminated!*
- Grasp outside of glove with opposite gloved hand; peel off
- Hold removed glove in gloved hand
- Slide fingers of ungloved hand under remaining glove at wrist
- Peel glove off over first glove
- Discard gloves in waste container



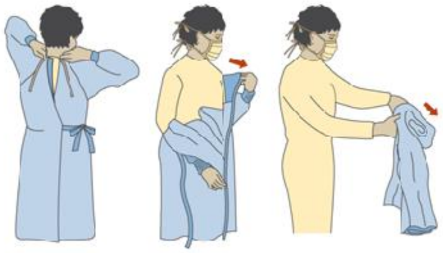
2. GOGGLES OR FACE SHIELD

- *Outside of goggles or face shield is contaminated!*
- To remove, handle by head band or ear pieces
- Place in designated receptacle for reprocessing or in waste container



3. GOWN

- *Gown front and sleeves are contaminated!*
- Unfasten ties
- Pull away from neck and shoulders, touching only inside of gown
- Turn gown inside out
- Fold or roll into a bundle and discard



4. MASK OR RESPIRATOR

- *Front of mask/respirator is contaminated—**do not touch!***
- Grasp bottom, then top ties or elastics and remove
- Discard in waste container

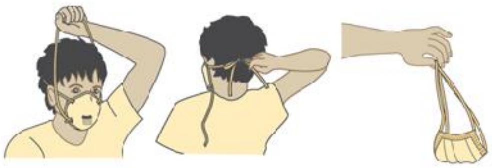


FIGURE 20-13 An example of a regimen for donning and removing personal protective equipment.

Description

Handwashing

As noted repeatedly throughout this chapter, handwashing is the single most important measure employed to reduce the person-to-person transmission of infectious agents **FIGURE 20-14**. For the CCTP, washing hands between patient transports is logistically difficult because sinks are not available on transport units. Therefore, the conscientious CCTP must make a concerted effort to wash between patients and after touching any body fluid. Waterless antiseptic agents can be used as a substitute for washing until soap and water are available. The use of alcohol-based waterless handwashing antiseptic has been shown to improve rates of handwashing among health care workers. Therefore, transport units should be equipped with easily accessible dispensers of hand antiseptic to facilitate compliance in handwashing.

FIGURE 20-14 Handwashing is crucial to preventing the spread of infection.

© Jones & Bartlett Learning.

Alcohol-based hand antiseptics are not effective against all infectious agents. *C difficile*, for example, is not killed by hand sanitizers. Consequently, handwashing with soap and water between transports is of paramount importance. Handwashing should take at least 1 minute and should incorporate the often-neglected areas under the fingernails, the sides of the fingers and hands, and the wrists.

Personal Protective Equipment

PPE is specialized clothing or equipment worn by an individual that provides protection from a potentially hazardous agent. The employer is required to provide PPE at no cost to the employee. Such equipment should be readily available and used consistently by the CCTP. However, it is important to understand that PPE itself is not enough; it must be accompanied by a culture of safety within the organization. Training and practice are essential to the safe donning and doffing of PPE.

Clean, nonsterile, disposable gloves are standard equipment on critical care transport units. They must be donned by all personnel prior to initiating patient care. Gloves are worn by CCTPs for three important reasons:

- Gloves provide a protective barrier that can prevent gross contamination of the hands when exposed to blood and body fluids, and while working on patients with open injuries or nonintact skin.
- Gloves protect patients from the microbial agents that exist on the hands of the CCTP while the health care provider is performing invasive procedures.
- Gloves decrease the likelihood of transmission of microorganisms between patients or from fomites to patient—albeit only if the gloves are changed for each new patient encounter.

Gloves should be removed if torn, punctured, or contaminated with gross blood. They should be promptly discarded after each use and before touching noncontaminated objects or surfaces. After removing their gloves, CCTPs should wash their hands or sanitize them with an alcohol-based waterless handwashing antiseptic.

Masks, face shields, and eye protection are worn to protect the mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, or excretions. Not all masks offer sufficient protection from airborne infectious agents. The N95 (or P100) mask must be worn when patients are known (or suspected) to be infected with agents that are transmitted by droplet nuclei. The N95 and P100 masks require proper fitting, so the CCTP should be fit tested before the need to use this equipment arises **FIGURE 20-15**. Studies have shown that the seals created by these masks, rather than the filters, are responsible for the protection created. A surgical mask alone is never sufficient in these situations.

Gowns are intended to protect the skin and prevent the soiling of clothing during procedures that are likely to generate splashes of blood or body fluids. They may not always be appropriate for the CCTP, however. Specifically, they may increase the risk of injury to the provider if that person tries to don the gown while in a moving vehicle. Also, when working in a small space, the gown may catch on equipment. If clothing or the gown becomes soiled, it should be removed as quickly as possible and disposed of properly, and the provider should then wash their hands promptly to avoid the transfer of contaminants to the patient or the environment.

PPE donning and doffing procedures should be detailed on workplace checklists that are consistent with CDC guidelines. These procedures should be practiced to prevent skill deterioration over time.

Other Exposure Prevention Practices

It is important to notify the accepting institution of the nature of the patient's illness or potential infectious disease so that the receiving facility can arrange for proper isolation. This information should be communicated by the transferring facility, but it is always a good policy for the CCTP to also notify the receiving facility. Patients with epidemiologically important infections should be sufficiently isolated from other patients.

Patients themselves should be enlisted in the effort to prevent transmission by educating them on methods to prevent the spread of infectious organisms to other vulnerable people. Patients can wear masks while being transported between or within medical facilities. They can cover their mouths while coughing, frequently wash their hands, and refrain from sharing drinking cups or utensils with family and friends.

During the Ebola outbreaks, it was learned that health care provider behaviors can either help limit the spread of disease or increase the chances of spread. For example, many nurses in West Africa felt great compassion for infants and children infected with Ebola and would often pick them up to console them. This practice led to transmission of the virus to health care workers. The lesson learned was that health care providers should remain more than 3 feet (1 m) away from the patient except when necessary. The interview, for example, can be conducted from this distance. Other lessons learned from this epidemic included the following points:

- Enter the patient area only when you have a specific task to perform.
- Do not sit on the bed of an infected patient.

- When working with infected people and infectious environments, keep your hands in front of you to prevent unintentional contact with contaminated surfaces.
- Avoid walking backward in a contaminated environment to minimize potential contact with contaminated surfaces.
- When cleaning grossly contaminated surfaces, avoid spraying cleaners to avoid secondary aerosolization of the infectious agent.

During the 2003 SARS outbreak in Toronto, Canada, more than 850 paramedics had 1,166 reported potential exposures to this virus. Of these personnel, 436 were quarantined at home, where they were required to wear an N95 mask and take their temperatures twice daily. To limit the spread of the disease throughout the EMS community, the following measures were implemented:

- Headquarters and offices were closed to field personnel during the outbreak.
- All personnel were required to screen themselves before reporting to work.
- Any EMS worker showing symptoms was told to stop working in an EMS capacity.

Additional advice includes EMS workers limiting physical contact between themselves and emergency department personnel. Affectionate behaviors such as handshakes, hugging, and pats on the back, for example, should stop.

Dr. Gavin Macgregor-Skinner, a biosafety and disease containment expert at Penn State University, offered several thoughts with regard to the rationale for such steps:

1. Disease spread, unlike storms or some other natural disasters, is unpredictable.
2. The most devastating impact is often financial.
3. A virus is more nimble than your disaster plan.

4. If hospitals are your only battleground, then you have lost.
5. The experts will be wrong (often).
6. Your advice will have to sound certain when the facts and science are not.
7. In the absence of advice, your community will react.

Work Practice Controls

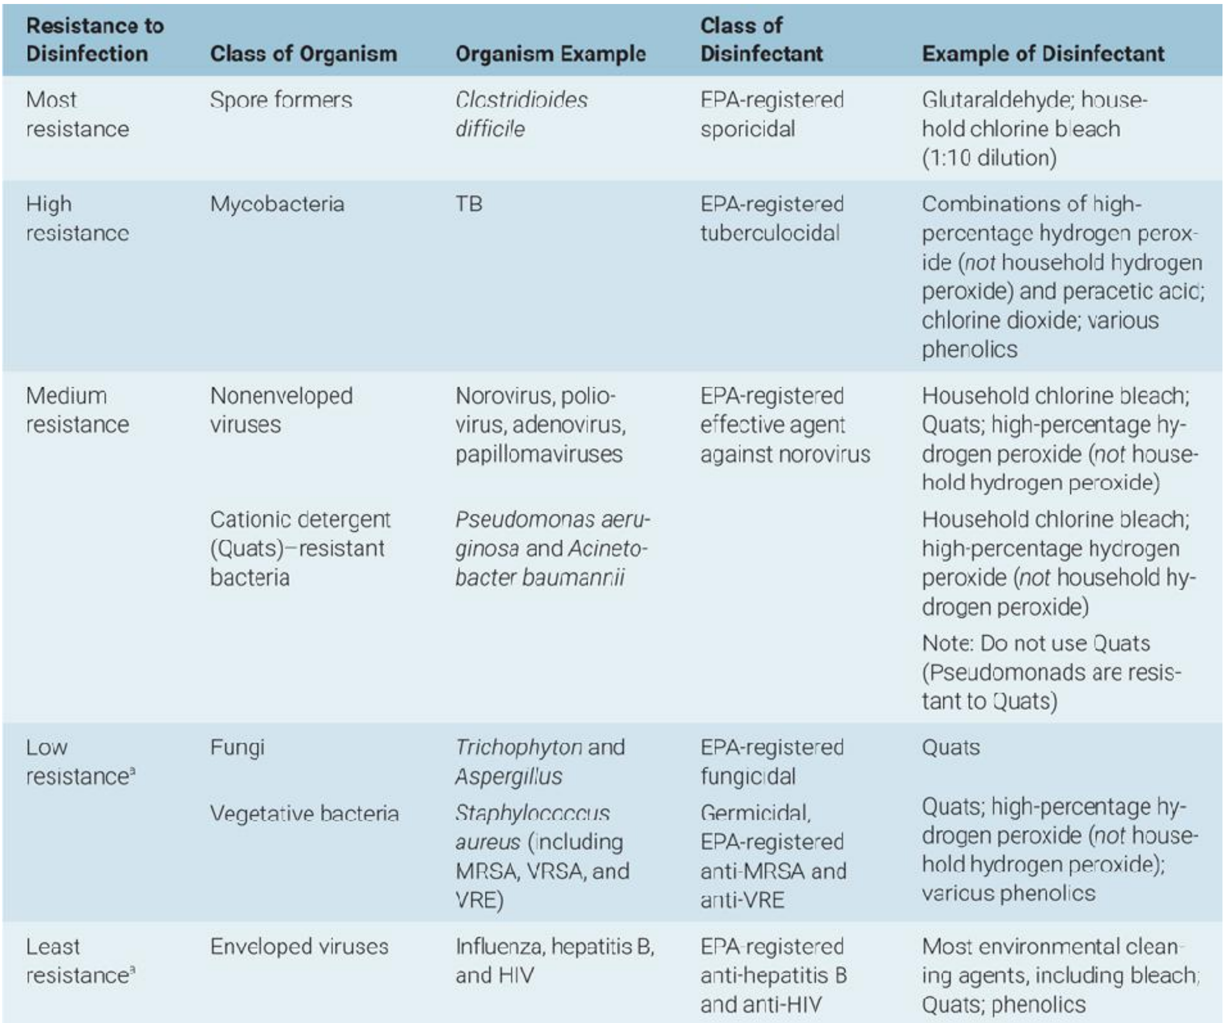
Control of the work environment and practices, when used consistently, can decrease the risk of contamination and subsequent transmission of infectious agents. Prohibitions against eating, drinking, smoking, applying cosmetics or lip balm, and handling contact lenses in the patient work areas, for example, help reduce the risks of uncontrolled exposures. Actions that cause splattering of fluids should be avoided. All single-use items should be disposed of immediately after they are used. Contaminated gloves must be removed before driving the ambulance and touching the steering wheel.

The proper handling of sharps is another method for controlling exposure risk in the work environment. Do not bend, remove, or recap needles. If you have no choice except to recap a needle (ie, no sharps receptacle is available, which in practice should never occur), use the one-handed “scoop” technique to do so. Shearing or breaking of needles should never occur. Dispose of sharps in an appropriate container as soon as possible after use. Sharps containers should be easily accessible, puncture-resistant, labeled or color-coded, and leakproof. They should not be filled beyond capacity and should be considered medical waste for disposal purposes.

Contaminated work surfaces must be decontaminated with an Environmental Protection Agency (EPA)–registered disinfectant on completion of the transport. All equipment used during the course of the transport must also be decontaminated. All bins, cans, and reusable receptacles must be decontaminated on a regular schedule and emptied after each use. Contaminated laundry should be placed into leakproof bags, labeled, and stored until proper disposal is possible. Regulated waste must be placed in closeable, leakproof containers designed for disposal. Regulated wastes include semiliquid blood or other potentially infectious materials, contaminated items that would release blood if compressed, and items that are caked with dried blood, contaminated sharps, and biological wastes. If droplet precautions are required, the transport vehicle should be equipped with a negative-pressure exhaust in the patient compartment. If this is not possible, the transport vehicle windows should remain open with the ventilation system set on "high" to move the air from within the vehicle to the outside.

TABLE 20-11 lists resistance of infectious organisms to disinfectants. Low resistance to disinfectant does not mean the organism is not dangerous; rather, it simply means some organisms can be killed more easily than other organisms. CCTPs should assume that *all* patients transported carry infectious pathogens, and take the necessary steps to decontaminate the equipment and vehicle prior to the next transport. There are three levels of disinfection:

TABLE 20-11 | **Resistance of Infectious Organisms to Disinfectants**



Resistance to Disinfection	Class of Organism	Organism Example	Class of Disinfectant	Example of Disinfectant
Most resistance	Spore formers	*Clostridioides difficile*	EPA-registered sporicidal	Glutaraldehyde; household chlorine bleach (1:10 dilution)
High resistance	Mycobacteria	TB	EPA-registered tuberculocidal	Combinations of high-percentage hydrogen peroxide (*not* household hydrogen peroxide) and peracetic acid; chlorine dioxide; various phenolics
Medium resistance	Nonenveloped viruses	Norovirus, poliovirus, adenovirus, papillomaviruses	EPA-registered effective agent against norovirus	Household chlorine bleach; Quats; high-percentage hydrogen peroxide (*not* household hydrogen peroxide)
	Cationic detergent (Quats)–resistant bacteria	*Pseudomonas aeruginosa* and *Acinetobacter baumannii*		Household chlorine bleach; high-percentage hydrogen peroxide (*not* household hydrogen peroxide) Note: Do not use Quats (Pseudomonads are resistant to Quats)
Low resistance[a]	Fungi	*Trichophyton* and *Aspergillus*	EPA-registered fungicidal	Quats
	Vegetative bacteria	*Staphylococcus aureus* (including MRSA, VRSA, and VRE)	Germicidal, EPA-registered anti-MRSA and anti-VRE	Quats; high-percentage hydrogen peroxide (*not* household hydrogen peroxide); various phenolics
Least resistance[a]	Enveloped viruses	Influenza, hepatitis B, and HIV	EPA-registered anti-hepatitis B and anti-HIV	Most environmental cleaning agents, including bleach; Quats; phenolics

Abbreviations: EPA, Environmental Protection Agency; HIV, human immunodeficiency virus; MRSA, methicillin-resistant *Staphylococcus aureus*; Quats, quaternary ammonium compounds; TB, tuberculosis; VRE, vancomycin-resistant enterococci; VRSA, vancomycin-resistant *Staphylococcus aureus*

[a] Low resistance to disinfectant does not mean the organism is not dangerous; it simply means some organisms can be killed more easily than other organisms. Assume all patients transported carry infectious pathogens and take necessary steps to decontaminate the equipment and vehicle prior to the next transport.

Description

- **High-level disinfection** is used on inanimate objects to kill all microorganisms. It does *not* kill bacterial spores.

- **Intermediate-level disinfection** is used on inanimate objects to kill *M tuberculosis*, vegetative bacteria, most viruses, and most fungi. It does *not* kill bacterial spores.
- **Low-level disinfection** is used on inanimate objects to kill most bacteria, some viruses, and some fungi. It does *not* kill *M tuberculosis* or bacterial spores.

CCTPs should strictly and properly decontaminate vehicles and equipment, change uniforms (including shoes/boots) or don new protective gowns over their uniforms and shoe covers, and perform handwashing between patient transports. Do not allow time constraints between transports to deter you from performing proper disinfection. Improper, cursory, or no **decontamination** of equipment and vehicles allows for transfer of organisms to susceptible hosts and spreads disease. Transport equipment, PPE, and personnel can all become reservoirs for disease organisms. To guard against this risk, ambulance and aircraft decontamination procedures in the presence of certain highly infectious agents should be included in organizational operations plans. The CDC has published specific guidelines for decontaminating EMS vehicles after exposure to a patient potentially infected with SARS-CoV-2 and similar guidelines for hospital facilities after potential exposure to the Ebola virus. The list of approved disinfectants differs for the two pathogens. Ebola virus is classified as a Category A infectious substance regulated by the US Department of Transportation’s Hazardous Materials Regulations (49 CFR, Parts 171–180). Any item transported offsite for disposal that is contaminated or suspected of being contaminated with a Category A infectious substance must be packaged and transported in accordance with these regulations.

Use barrier protection (eg, plastic wrap) for surfaces of equipment touched frequently with gloved hands or those that are difficult to clean with disinfectants (eg, computer keyboards) or more likely to be contaminated with blood or body fluids. Do not attempt to clean and reuse disposable materials. Instead, place contaminated disposable materials (eg, dressings, gloves, syringes, tubing, gowns, surgical masks, and disposable N95 respirators) into appropriately marked biohazard containers. Always place reusable contaminated PPE (eg, eye protection, uniforms, and shoes/boots) into appropriately marked storage containers until it can be decontaminated; do not reuse contaminated PPE until it has been disinfected. All biohazardous waste and uniforms should be handled with gloved hands. Uniforms should first be autoclaved and then laundered after transporting patients with highly virulent and communicable diseases, such as SARS or avian influenza (H5N1); alternatively, they may be disposed of along with biohazardous waste. CCTPs should decontaminate the transport vehicle, shower and scrub with antibacterial soaps, and don street clothes prior to leaving for home after they transport patients with highly virulent and communicable diseases.

It is important to consider treatment of footwear worn during transport or to cover shoes during transport. Shoes should be considered part of the uniform and treated with disinfectant. Uniforms and shoes or boots should not be worn home routinely after patient transport.

Postexposure Risks and Protocols

After a blood exposure, the appropriate actions differ depending on the type of exposure. Generally, the appropriate actions taken should be immediately employed: Wash the area with soap and water, flush mucous membranes with copious amounts of water, and irrigate the eyes with sterile solutions of saline or water. Exposure should be reported immediately to supervisory personnel and those charged with managing blood exposures. Prompt reporting is paramount to ensure that any applicable postexposure treatment begins as soon as possible.

Hepatitis B

CCTPs who have received the hepatitis B vaccine are protected against contracting HBV from a blood exposure. Those who have not been vaccinated or have not yet achieved full immunity have a 6% to

30% risk of contracting HBV from exposure to HBV-infected blood. The precise level of risk depends on the severity of exposure and the hepatitis B antigen status of the source. Blood that is positive for the antigen is more likely to transmit infection.

Postexposure prophylaxis (PEP) is available for the prevention of seroconversion after a known exposure to HBV. HBIG is effective against HBV infection after an exposure has occurred, but its use is not without risk; therefore, the risks and benefits of treatment should be considered. Treatment is appropriate for unvaccinated CCTPs who have been exposed to a source individual known to be positive for the hepatitis B antigen. If the exposed worker has not been immunized against hepatitis B, they should receive HBIG within 24 hours, followed by the hepatitis B vaccine within 7 days of the exposure. For this regimen to be effective, treatment should begin within 24 hours of exposure. HBV immunity should be confirmed by drawing an HB antibody titer (IgG). Any person whose antibody titer is negative and who has a blood exposure, regardless of the source person's HBV status, should receive the hepatitis B vaccine.

If the CCTP has been vaccinated against hepatitis B, but the anti-HB titer is unknown, an assay for anti-HB antibodies should be drawn to determine the person's immune status. This step should be followed by administration of HBIG and a booster dose of hepatitis B vaccine, if necessary.

Follow-up after PEP for HBV is not recommended because the treatment is highly effective. However, any symptoms associated with hepatitis should be reported to the CCTP's health care provider.

Hepatitis C

The risk of infection after direct nonintact skin exposure to blood infected with HCV is approximately 1.8%.

If the CCTP is exposed to HCV, no prophylactic treatment is available. Immune globulin is not recommended for exposures to HCV-tainted blood. As soon as possible after exposure, baseline laboratory studies should be performed, including liver function tests, and an HCV antibody titer should be drawn. These tests should be repeated at 4 to 6 months after exposure.

If and when signs of an acute infection develop, the HCV-exposed individual should receive interferon, unless the exposure involves a curable subtype of the virus. Acute infection is diagnosed based on increasing liver enzyme levels and detection of the viral RNA in the serum.

Human Immunodeficiency Virus

The average risk of contracting HIV after a percutaneous exposure to HIV-infected blood is 0.3%, or approximately 1 in 300. The risk after mucous membrane exposure is approximately 0.09%.

If the source patient is HIV negative, nothing needs to be done. If the patient's status is unknown, the risks and benefits of PEP should be discussed with the employer's health personnel, and the exposed CCTP should be informed of the options available.

An individual exposed to the blood of a patient known to be HIV positive should be tested immediately following the injury, and again at 6, 12, and 24 weeks after exposure. CCTPs should be aware of and report any febrile illnesses that occur during the 12 weeks following such an exposure. They should also refrain from blood donation and unprotected sexual encounters during that same postexposure 12-week period, until their negative HIV status can be confirmed.

Providers should begin PEP medication regimens as soon as possible if exposed to HIV. Treatment should be continued for 4 weeks. These medication regimens should contain at least three antiretroviral drugs. Exposed providers should receive expert medical consultation and close follow-up, including counseling, baseline and follow-up HIV testing, and monitoring for drug toxicity. Follow-up appointments should begin within 72 hours of an HIV exposure.

Recommended Vaccines for Health Care Workers

During the course of their routine activities, health care workers may be exposed to serious, and possibly even deadly, diseases. They should remain current on all appropriate vaccines to reduce their risk of contracting or spreading vaccine-preventable diseases. They must take whatever actions are under their control to protect themselves, their patients, and their family members; vaccination is a simple and effective action toward this goal.

The CDC recommends that health care workers remain up-to-date on the following vaccines:

- Hepatitis B
- Annual influenza (flu)
- Measles, mumps, rubella (MMR)
- Varicella (chickenpox)
- Tetanus, diphtheria, pertussis (TDaP)
- SARS-CoV-2 (COVID-19)

Flight Considerations

There are no special patient care considerations specific to air medical transport of patients with infectious diseases. Follow the same precautions and management strategies discussed in this chapter. One important air medical service consideration when receiving a transport request is the length of out-of-service time required to properly disinfect or decontaminate the aircraft after completing the transport.

Summary

CCTPs must be aware of their risk of exposure to a variety of infectious agents. Their job inherently puts them at risk of contact with both contagious agents and those transferred by needlesticks or body fluids. A solid knowledge of microorganisms and the diseases they cause is necessary to ensure CCTPs' protection. An understanding of the fundamental principles of the immune system and infectious disease is an essential tool for medical care professionals. This knowledge, when applied to the critical care arena, will enable the CCTP to assess risks, minimize exposures, and prevent transmission of infection.
